2. Antiquity. The science of chemistry is undoubtedly of very high antiquity; and, like most other sciences, its origin cannot be traced. In scripture, Tubal Cain, the 8th from Adam, is mentioned as the father or instructor of every artificer in brass or iron. This, however, does not constitute him a chemist, any more than a founder or blacksmith among us has a right to that title. The name of chemist could only belong to him, whoever he was, who first discovered the method of extracting metals from their ores; and this person must necessarily have lived before Tubal Cain, as every blacksmith or founder must have metals ready prepared to his hand. Nevertheless, as Tubal Cain lived before the flood, the science of chemistry must have existed before his time, some have conjectured, that the metallic part, on account of its extreme usefulness to mankind, was revealed to Adam by God himself.

Be this as it will, Siphos, an Egyptian, is considered as the chemist as the founder of their science. He was known by the Greeks under the name of Hermes, or Mercureius, or Triumfugius; and is supposed to have lived more than 1000 years before the Christian era. A numerous list of this philosopher’s works is given by Clemens Alexander; but none of them are now to be found, nor do any of them appear to have been written professedly on chemistry.

Two illustrious Egyptians, of the name of Hermes, are recorded by ancient authors. The elder supposed to be the same with Misraim, the grandson of Noah, the Hermes of the Greeks, and Mercury of the Romans. The younger Hermes lived a thousand years afterwards; and is supposed to have restored the sciences after they had fallen into oblivion, in consequence of an inundation of the Nile. No less than 36,000 books are said to have been written under the name of Hermes; but, according to Jamblichus, a custom prevailed of incribing all books of science with the name of Hermes. Some authors deny the existence of Hermes, and maintain that his history is allegorical.

As the science of chemistry is supposed to have been well known to the Egyptians, Moses, who was skilled in their wisdom, is thence ranked among the number of chemists; a proof of whose skill in this science is thought to be, his dissolving the golden calf made by the Israelites, so as to render it potable.

Of all the Greeks who travelled into Egypt in order to acquire knowledge, Democritus alone was admitted into their mysteries. The Egyptian priests are said to have taught him many chemical operations; among which were the art of softening ivory, of vitrifying flints, and of imitating precious stones. Dr Black, however, is of opinion, that Democritus knew nothing more of these arts than that of making a coarse kind of glass, as no mention is particularly made of precious stones. As no mention is particularly made of the making of glass, so as to render it potable.

After the time of Democritus, we may know that considerable improvements were made in chemistry, as physicians began to make use of metallic preparations, as cinnabar, verdigris, litharge, &c. Dioscorides describes the distillation of mercury from cinnabar by means of an embic, from which, by adding the Arabic A1, comes the term Alchemic. The art of distillation, how, of the word ever, at that time was in a very rude state; the operation being performed chiefly by separating the air, and more subtle part of tar, from the rest of the matter.

This was done by putting the matter to be distilled in a vessel, the mouth of which was covered with a wet cloth; and by this the steam of ascending vapour were condensed, which were afterwards procured by wringing out the cloth. No other distillation, besides this kind, is mentioned by Galen, Oribasius, Aldian, or Paulus Aegineta.

The precise time is not known when the three mineral acids were first discovered: though, as no mention is made of them by Geber, Avicenna, or Roger Bacon, it is probable that they were not known in the 12th century.
The Arabian alchemy, paring rose-water, the Argonauts, the making of glass, which he ascribes to the first Maternus.

"Some merchants in the Levant, who had niter on board their ship, having occasion to land, lighted a fire on the sand in order to prepare their food. To support their vessels they took some of the lumps of niter with which their ship was loaded: and the fire acting on these, melted part of them along with the sand, and thus formed the transparent substance called glass, to the great surprize of the beholders." It is probable, that the art of glass-making was known long before; and it is by no means likely that it took rise from such an accident.

The next traces we find of chemistry are to be extracted from the extravagant purports of the Alchemists, who imagined it possible to convert the bafer metals into gold or silver. The first mention we find of this study is by Julius Firmicus Maternus, who lived in the beginning of the fourth century, and first heft it as a well known pursuit in his time. Aeneas Blanius, who lived in the fifth century, likewise speaks of it; and Suidas explains the term by telling us, that it is the art of making gold and silver. He tells us, that Diocletian, when persecuting the Christians, forbade all chemical operations, lest they should discover the art of making gold, and thus be induced to rebel against him. He supposes also, that the Argonautic expedition was only an attempt to procure a skin or parchment, on which was written the receipt for making gold. It is a common practice, however, in some places where gold is washed down in small particles by brooks and rivulets from the mountains, to suspend in the water the skins of animals having wool or hair upon them, in order to detain the heavier particles which contain the gold; and this probably gave rise to the fable of the golden fleece. Suidas, however, who lived as late as the tenth century, deferves very little credit, especially as alchemy is not mentioned by any ancient author. The Arabian physicians afford the most clear and distinct evidence concerning alchemy. Avicenna, who lived in the tenth century, is said by a disciple of his to have written upon alchemy; he mentions also rofe-water, and some other chemical preparations; and in the 12th century we find physicians advised to cultivate an acquaintance with the chemists; and another of the Arabian writers says, that the method of preparing rofe-water, &c. was then well known. From this evidence of the existence of alchemy among the Arabians, with the prefatory article A/, to denote the greatnecf of the science, it has been conjectured, that the doctrine of the tranmutation of metals first took its rise among the Arabians, and was introduced into Europe by means of the Crusades, and by the rapid conquests of the Arabians themselves in Europe as well as in Asia and Africa. Europe at that time had been in a state of the greatest barbarity from the incursions of the northern nations; but the Arabians contributed to revive some of the sciences, and introduced alchemy among the rest, which continued till the middle of the 17th century; at which time the extravagance of its professors rose to the greatest height.

Though the pretensions of the alchemists are now no more universally refuted, yet from some of the discoveries which have been made in chemistry, we are far from being in danger of giving some credit to the possibility of the proceeds of transmutation. When we consider that the metals are bodies compounded of parts which we can take away and restore, and that they are closely allied to one another in their external appearance, we may be inclined to think favourably even of the projects of the alchemists. The very separation of the metals from their ores, the depriving them of their ductility and malleability, and the restoration of these properties to them at pleasure, will appear very surprising to those who are unacquainted with chemistry. There are also processes of the more difficult kind, by which quicksilver may be produced from metals that are commonly solid, as from lead. Some of these we find in Boerhave, Boyle, &c. authors of the greatest credit, who both speak of the operation and produce as realities of which they were convinced by their own experience. These processes have been urged, not without some plausibility, in favour of the tranmutation of the imperfect metals into gold; and hence the delusions of alchemy were not confined to the vain, the ignorant, and the ambitious part of mankind; but many ingenious and learned men, who took pleasure in the study of nature, have been seduced into this unhappy pursuit. This happened chiefly in Germany, where the variety of mines naturally turned the thoughts of chemists principally towards the metals, though the numerous failures of those who had attempted this art ought to have taught them better.

About the beginning of the 16th century, the pretenders to alchemy were very numerous, and a multitude of knaves, who had beggared themselves in the attempt, now went about to ensnare others, performing legendarie tricks, and causing people believe that they could actually make gold and silver. A number of the tricks they made use of are to be met with in Lernery. Many books, with the same design of imposing upon mankind, were written upon the subject of alchemy. They assumed fictitious names of the greatest antiquity, and contained rules for preparing the philosopher's stone; a small quantity of which thrown into a base metal should convert the whole into gold. They are wrote in a mysterious style, without any distinct meaning; and though sometimes processes are clearly enough described, they are found to be false and deceitful upon trial, the products not answering the pretensions of the authors. Their excuse was, that it was vain to expect plain accounts of these matters, or that the books on these subjects should be written distinctly and clearly; that the value of gold was in proportion to its scarcity, and that it might be employed to bad purposes: they wrote only for the laborious and judicious chemists, who would understand them provided they made themselves acquainted with the metals by study and experience. But in fact, no distinct meaning has ever been obtained, and the books have only served to delude and betray a great number of others into the loss of their lives. But though the alchemists failed in the execution of their

History.

Chemistry.

 mấy
their grand project, we must still own ourselves indebted to them for many discoveries brought to light during the time they vainly spent their labour in the expectation of making gold. Some of these are the methods of preparing spirit of wine, aquafortis, volatile alkali, vitriolic acid, and gun powder. Medicine too was indebted to them for several valuable remedies; whence also it appears that many, who had wasted their time in the vain pursuit of the philosopher's stone, thought of trying some of their most elaborate preparations in the cure of diseases; and meeting with some success, they presumed that diseases were only to be cured by the assistance of chemistry; and that the most elaborate of all its preparations, the philosophers' stone, would cure all diseases. Some cures they performed did indeed awaken the attention of physicians; and they introduced the use of opium, which had formerly been accounted poisonous. They succeeded also in the cure of the venereal disease, which had lately made its appearance, and baffled the regular physicians; but the chemists, by giving mercury, put a stop to its ravages, and, thus introduced this valuable article into the materia medica. This he used with great freedom and boldness. His successes in some cafes operated for upon the natural arrogance and self-sufficiency of his disposition, that he formed a design of overturning the whole system of medicine, and supplying a new one from chemistry: and indeed he found but very weak adversaries in the subtle theories of Galen with the refinements of the Alexandrian physicians, which only prevailed in his time; and he no doubt had some share in banishing that vaporation which had been so long entertained for their celebrated personages.

From the time of Paracelsus, chemistry began everywhere to assume a new face. In Great Britain, Lord Verulam amused himself at his leisure hours with forming plans for promoting the sciences in general, especially those which related to the study of nature. He soon found that chemistry might turn out one of the most useful and comprehensive branches of natural philosophy, and pointed out the means of its improvement. A number of experiments were proposed by him: but he observed, that the views of chemists were as yet only adapted to explain their particular operations on metals; and he observed, that, instead of the abstruse and barren philosophy of the times, it was necessary to make a very large collection of facts, and to compare them with each other very maturely and cautiously, in order to discover the common causes and circumstances of connection upon which they all depend. He did not, however, make any considerable discoveries, and his works are tedious and disagreeable to the reader.

A superior genius to Lord Verulam was Mr. Boyle, who was born the very day that the former died. His circumstances were opulent, his manners agreeable; he was endued by nature with a good heart; and his inclination led him entirely to the study of nature, which he was bent on cultivating in the way of experiment. He considered the weight, spring, and qualities of the air; and wrote on hydrostatics and other subjects; and was possessed of that happy penetration and ingenuity so well suited to the making of experiments in philosophy, which serves to deduce the most useful truths from the most simple and seemingly insignificant facts. As chemistry was his favourite science, he spared no pains to procure from chemists of great note the knowledge of curious experiments, and entertained a number of operators constantly about him. His discoveries are related in an easy style; and though rather copious, suited to the taste of the times in which he lived, and free from that abstruse and mysterious air which formerly prevailed in chemical writings: nor does he betray a design of concealing anything except several particulars which were communicated to him under the notion of secrecy, or the knowledge of which might do more harm than good. It is objected indeed, that he betrays a good deal of credulity with regard to facts which were given on the faith of others, and which may seem incredible; but this proceeded from his candour, and his being little disposed to suspect others. He showed the necessary connection between chemistry and the arts; and said, that by attending the stop of a workman, he learned more philosophy than he had done in the schools for a long time. Thus his writings showed an universal taste for the study of nature, which had now made some advances in the other parts of the world.

Agricola is one of the first and best authors on the subject of metallurgy. Being born in a village in Misnia, a country abounding in mines and metallurgical works, he described them exactly and copiously. He was a physician, and contemporary with Paracelsus, but of a character very different. His writings are clear and instructive, as those of Paracelsus are obscure and useless. Lazarus Ercker, Schinder, Schlotter, Henkel, &c. have also written on metallurgy, and described the art of assaying metals. Anthony Neri, Dr. Merret, and the famous Kinkel (who discovered the phaeanth of urine), have described very fully the arts of making glafs, enamels, imitations of precious stones, &c.; but their writings, as well as those of succeeding chemists, are not free from the illusions of alchemy: so true it is, that an obstinate and invertebrate malady never disappears at once, without leaving traces behind. In a short time, however, the alchemical phrenzy was attacked by many powerful antagonists, who contributed to rescue the science of chemistry from an evil which at once disgraced it and retarded its progress. Among these, the most distinguished are Kircher a Jesuit, and Conringius, a physician, who wrote with much success and reputation.

About the year 1650 the Royal Society was formed by a number of gentlemen who were unwilling to engage in the civil wars; and being struck with the extensive views of Lord Verulam and Mr. Boyle, contributed to the expense of costly experiments. This example appeared so noble, and the design so good, that it has been followed by all the civilized states of Europe, and has met with the protection of their respective sovereigns; and from these chemistry has received considerable improvements. In France, Groftruy, Lemery, Reaumur, &c. came to be distinguished;
The chemists who have made a considerable figure in that science. Kunc-
kel, Bega, Stahl, and Hoffman, &c. have done great
service to society, by introducing new arts, and the nu-
erous improvements they have made.

Of the improvements made by different
nations in chemistry.

The chemists who have made a figure in Germany
and France are more in number than those whom Bri-
tain has produced. In France, the society was en-
couraged by the sovereign; and in it they have de
cided themselves of that mysterious air which was affect-
ed in former ages. In Germany, the richmen of
the country, and the great variety of mines, by turning
the attention of chemists to the metals, have given that
alchemical air to their writings which we observe in
them. The number of those who have applied them-

elves to chemistry is very small in England, owing to
the great improvements made by Sir Isaac Newton in
the sciences of astronomy and optics; which, by turn-
ing the general attention that way, has occasioned what
may be called a neglect of chemistry. But if their
number be inconsiderable, they are by no means infe-
rior in merit and fame. The name of Boyle has always
been held in the highest esteem, as well as that of Hales,
for the analysis he has made of the air. Sir Isaac
Newton alone has done more to the establishing a ra-
tional chemical theory than ever was done before. Of
late, the taste for the study has become more general,
and many useful books have appeared; so that it is to
be hoped they will soon excel in this branch of science,
as they have done in all the rest.

**PART I. THEORY OF CHEMISTRY.**

According to the definition we have given of this
science, the theory of it ought to consist in a
thorough knowledge of all the phenomena which result
from every possible combination of its objects with one
another, or from exposing them in all possible ways to
those substances which chemists have found to be the
most active in producing a change. So various, how-
ever, and so widely extended are the objects of che-

mistry (comprehending all terrestrial bodies whatever),
that a knowledge of this kind is utterly unattainable by
man. The utmost that can be done in this case is, to
give some account of the phenomena which accompany
the mixtures of particular substances, or the appear-
cances they put out when exposed to heat; and these
have already been so well ascertained, that they may now be
laid down as rules, whereby we may, with a good
deal of certainty, judge of the event of our experi-
ments, even before they are made.

Here we must observe, that though the objects of
chemistry are as various as there are different substan-
ces in the whole system of nature, yet they cannot all
be examined with equal care. Some of these sub-
stances act upon others with great violence, and the
greater their activity, the more difficultly are they
themselves subjected to a chemical examination. Thus,
fire, which is the most active body in nature, is so
little the subject of examination, that it hath hi-

thero baffled the ingenuity of the greatest philos-

phers to understand its composition. This substance,
therefore, though it be the principal, if not the only
agent in chemistry, is not properly an object of it, be-

cause it cannot be made a subject of any chemical ope-

ration.

It hath been customary to consider all bodies as com-
posed of certain permanent and unchangeable parts
called elements; and that the end of chemistry was to
reduce bodies into these elements, and to recompose
them again by a proper mixture of the elements
when so separated. Upon this supposition the alche-

mists went; who, supposing that all bodies were com-
posed of salt, sulphur, and mercury, endeavoured to
find out the proportions in which these existed in gold,
and then to form that metal by combining them in a
similar manner. Had they taken care to ascertain the
real existence of their elements, and, by mixing them
together, composed any one metal whatever, though

but a grain of lead, the least valuable of them all;
their pretensions would have been very rational and
well founded; but as they never ascertained the exis-
tence of such elementary bodies, it is no wonder that
their labours were never attended with success.

Another set of elements which were as generally
reduced, and indeed continue to be so in some mea-
sure, to this day, are fire, air, earth, and water.—
This doctrine of elements was strenuously opposed by
Mr Boyle; who endeavoured to prove, that fire was
not an element per se, but generated merely from the
motion of the particles of terrestrial bodies among one
another; that air was generally produced from the sub-
stance of solid bodies; and that water, by a great
number of distillations, was converted into earth. His
arguments, however, concerning fire were not at all con-
clusive; nor does the expulsion of air from fixed bod-
ies prove that any of their solid parts were employ-
ed in the composition of that air; as later discoveries
have shown that air may be abstracted from the external
atmosphere, and fixed in a great number of solid sub-
stances. His offence concerning water deserves much
consideration, and the experiment is well worth re-
peating; but it does not appear that he, or any other
person, ought to have relied upon the experiment
which was intended to prove this transmutation. The
fact was this. Having designed to try the possibility
of reducing water to earth by repeated distillations,
he distilled an ounce of water three times over itself,
and found a small quantity of earth always remaining.
He then gave it to another, who distilled it 197 times.
The amount of earth from the whole distillations was
fix grains, or 1/4th of the quantity of water employed;
and this earth was fixed, white, and insoluble in wa-

ter.—Here it is evident, that great specious na-

tive against the fidelity of the unknown operator, who
no doubt would be wearied out with such a number of
distillations. The affair might appear trivial to
him; and as he would perhaps know to which side Mr
Boyle's opinion inclined, he might favour it, by mix-

ing some white earth with the water. Had the ex-
periment been tried by Mr Boyle's own hand, his
known character would have put the matter beyond a
doubt.

The decomposition of water, however, in another
way, by the combination of one part of it with the

CHEMISTRY.

Theory.

The opinions concerning the element of fire may be divided into two general classes; the one considering it as an effect, the other as a cause. The former is maintained by Lord Bacon, Mr Boyle, and Sir Isaac Newton; whose respectable names for a long time gave such a sanction to this theory, that it was generally looked upon as an establisht truth. Some learned men, however, among whom was the great Dr Berkeley, always disbelieved, and insisted that fire was a fluid universally diffused, and equally present in the frozen regions of Nova Zembia, as in a glass-house furnace, only that in the latter its motion made it conspicuous; and by setting it in motion in the coldest parts of the world, its previous existence there would be equally demonstrable as in the furnace abovementioned.

Lord Bacon defines heat, which he uses as a synonymous term with fire, to be an expansive undulatory motion in the particles of a body, whereby they tend with facility towards the circumference, and also a little upwards. Hence, if in any natural body you can excite a motion whereby it shall display the property of heat, and can reproduce and direct this motion upon itself, in such a manner that the motion shall proceed uniformly, but obtain in some parts and be checked in others, you will generate heat or fire.

The same opinion is supported by Mr Boyle in the following manner: "The production of heat discovers opinion nothing, either in the agent or patient, but motion, and its natural effects. When a smith briskly hammers a small piece of iron, the metal thereby becomes exceedingly hot; yet there is nothing to make it so, except the motion of the hammer impressing a vehement and universally determined agitation on the small parts of the iron; which, being a cold body before, grows hot by that superinduced motion of its small parts: first, in a more loose acceptance of the word, with regard to some other bodies, in comparison of which it was cold before; then feebly hot, because the motion in the parts of the iron is greater than that in the parts of our fingers; at the same time that the hammer and anvil, by which the percussion is communicated, may, on account of their magnitude, remain cold. It is not necessary, therefore, that a body should itself be hot in order to communicate heat to another."

The arguments made use of by Sir Isaac Newton are not intended positively to establish any kind of theory relating to fire, but are to be found in a conjecture, published at the end of his Treatise on Optics, concerning the nature of the sun and stars. "Large bodies (he observes) preserve their heat the longest, their parts heating one another; and why may not great, dense, and fixed bodies, when heated beyond a certain degree, emit light to copiously, as, by the evaporation and reaction of it, and the refractions and refractions within the pores, to grow continually hotter, till they arrive at such a period of heat as is that of the sun? Their parts
The hypothesis of these great men produced long and violent disputes, which were never decisively settled: The discoveries in electricity, however furnished such additional strength to the followers of Dr Boerhaave, that fire is now believed to be an element and fluid distinct from all others, by at least as many as espoused the contrary system; but the question is not decided, Whether the fire itself is to be considered as the agent! or, Whether its action is to be derived from the principles of attraction and repulsion, the natural agents supposed to influence other material substances. This has produced two other systems of a kind of mixed nature, in which heat or fire is considered as a substance distinct from all others, but which acts in other bodies according to its quantity. These systems have been promulgated by Dr Black of Edinburgh and Dr Irvine of Glasgow. They differ from the opinions of Mr Boyle, Lord Bacon, and Sir Isaac Newton, in supposing heat to be a fluid distinct from all other material substances; and they also differ from the hypothesis of Dr Boerhaave, Lemery, and others, in supposing different terrestrial substances to be hot according to the quantity of fluid contained, and not according to the force with which it moves in them.

Dr Black is of opinion that heat, which he seems to make synonymous with fire, exists in two different states; in one of which it affects our senses and the thermometer, in the other it does not. The former therefore he calls sensible heat, the later latent heat. On these principles he gives the only satisfactory explanation of the phenomena of evaporation and fluidity that has yet appeared, as shall afterwards be more fully explained. At present we shall only observe, that, according to the theory of Dr Black, heat or fire itself seems to be the agent; but, according to that of Dr Irvine, as far as we can gather it from the treatises of Dr Crawford and others, the principles of attraction and repulsion are the agents by which heat, as well as other bodies, is influenced. Thus, on the principles of Dr Black, we say, that water is converted into vapour by a quantity of heat entering into it in a latent state, and thereby rendering it specifically lighter than the atmosphere; according to the principles of Dr Irvine, we say, that water is converted into vapour by having its capacity for attracting heat from the atmosphere increased. So that, according to the former, of the abstraction of heat is the cause; according to the latter, the effect of its conversion into vapour.

Dr Crawford, in his Treatise on Heat, published in 1788, informs us, that heat, in the philosophical sense of the word, has been used to explain what is frequently called the element of fire, in the abstract, without regard to the peculiar effects which it may produce in relation to other bodies. This, with Dr Irvine, he calls absolute heat; and the external cause, as having a relation to the effects it heat produces, he calls relative heat. "From this view of the matter (says he), it appears, that absolute heat expresses, in the abstract, that power or element which, when it is present to a certain degree, excites in all animals the sensation of heat; and relative heat expresses the same power, considered as having a relation to heat, the effects by which it is known and measured. The effects by which heat is known and measured are three; and therefore relative heat may admit of three subdivisions. 1. This principle is known by the peculiar sensations which it excites in animals. Conceived as exciting these sensations, it is called sensible heat. 2. It is known by the effect which it produces upon an instrument that has been employed to measure it, termed a thermometer. This is called the temperature of heat in bodies. 3. It has been found by experiment, that in bodies of different kinds the quantities of absolute heat may be unequal, though the temperatures and weights be the same. When the principle of heat is considered relatively to the whole quantity of it contained in bodies of different kinds, but which have equal weights and temperatures, I shall term it comparative heat. If, for example, the temperatures and tive weights being the same, the whole quantity of heat in defined water be four times as great as that of Antony, the comparative heats of these substances are said to be as four to one."

In order to have a proper conception of what is Experimented by a difference in absolute heat, when the temperatures by peratures are the same, it will be necessary to relate which Dr Black was of the experiments, by which Dr Black was first led to the discovery of latent heat. He observes, that when he discovered two equal masses of the same matter, heated to different degrees, are mixed together, the heat of the mixture ought to be an arithmetical mean between the two extremes. This, however, only takes place on mixing hot and cold water together; but if instead of cold water we take ice, the difference is remarkably different. Here the temperature of the mixture is much below the arithmetical mean, and a quantity of heat is apparently lost. Now we know that the temperature of ice newly frozen is generally 32 degrees of Fahrenheit; supposing therefore the temperature of the water which dilutes it to be 120, the arithmetical mean is 71; but if the mixture indicates a temperature only of 60°, then we must suppose that the ice contained 11° of heat left than was indicated by the thermometer; and consequently, that water at 32° contains 11° more of absolute heat than ice at 32°.

The same thing is made still more evident from the condensation of vapour. The fluid of water is not capable of sustaining a great degree of heat; and 212° of Fahrenheit is the utmost it can be made to bear, by the contraction of heat, without an extraordinary degree of pressure, as in Pa-

Difference of absolute heat in different fluids.

Difference of absolute heat in different fluids.

Thinnest fluids contain the greatest quantity of heat.

Great difference betwixt the calculations of Drs. Cleghorn and Crawford.

Crawford's account of sensible heat.

The temperature, the capacity for containing heat, and the absolute heat contained, may be distinguished from each other in the following manner.

"The capacity for containing heat, and the absolute heat contained, are distinguished as a force distinct from the subject upon which it operates. When we speak of the capacity, we mean a power inherent in the heated body; when we speak of the absolute heat, we mean an unknown principle which is retained in the body by the operation of this power; and when we speak of the temperature, we consider the unknown principle as producing certain effects upon the thermometer.

"The capacity for containing heat may continue unchanged, while the absolute heat is varied without end. If a pound of ice, for example, be supposed to retain its solid form, the quantity of its absolute heat will be altered by every increase or diminution of its sensible heat: but as long as its form continues the same, its capacity for receiving heat is not affected by

pin's digester, or the admixture of saline substances: the temperature of the steam emitted by it therefore never can exceed 212°, except in the cafes just mentioned; and it is often capable of bearing a great degree of cold without being condensed. When the conden-

94

densation takes place at last, however, a very con-

iderable degree of heat is always produced; and Dr Black has shown, that in the condensation of steam by the refrigeratory of a common still, as much heat is communicated to the water in the refrigeratory as would be sufficient to make the water which comes over as hot as red hot-iron, were it all to exist in a sensible state. His method of making the calculation is very easy. For, supposing the refrigeratory to contain 100 pounds of water, and that one pound has been distilled; if the water in the refrigeratory has received 10 degrees of heat, we know that the distilled pound has parted with 1000. If in passing through the worm of the refrigeratory, it has been reduced to the temperature of 50° of Fahrenheit, having been at 321° when it entered it, then it has lost only 162° of sensible heat; all the rest communicated to the water of the refrigeratory amounting to more than 800°, having been contained in a latent state, and such as could not then afford a degree of sensible heat as in the common method of distilling. It came over therefore with a very gentle warmth, scarce more than what the hand could bear; nevertheless it had absorbed as much heat as though the distillation had been performed in the common way; for the refrigeratory had 1000 degrees of heat communicated to it.

The difference of absolute heat is likewise perceptible betwixt any two bodies of different density, water and mercury for instance: and in comparing these, it will always be found that the thinnest fluids contain the greatest quantity of absolute heat; as water more than mercury, spirit of wine, more than water, ether more than spirit of wine, and air more than any of them. Dr Black having brought equal bulks of water and water, the former to a temperature of 50 degrees higher than the latter, found that, on mixture, there was a gain of only 20 degrees above the original; but on reverting the experiment, and heating the water 50 degrees above the mercury, there was a gain of 50 degrees on the whole. "Hence (says Dr Cleghorn in his thesis de Iqce) it appears, that the quantity of heat in water is to that in mercury, when both are of equal temperatures, as 3 to 2." Dr Crawford, however, tells us, that "the same quantity of heat which raises a pound of water one degree, will raise a pound of mercury 29 degrees; whence it follows, that the comparative heat of water is to that of mercury as 28 to 1: and consequently, the alterations which are produced in the temperatures of bodies by given quantities of absolute heat, may properly be applied as a measure of their comparative heats; the alterations of temperature and the comparative heats being reciprocally proportional to one another.

"Sensible heat (continues Dr Crawford) depends partly on the state of the temperature, and partly on that of the organ of feeling; and therefore if a variation be produced in the latter, the sensible heat will be different, though the temperature continue the same. Thus water at the temperature of 62° of Fahrenheit appears cold to a warm hand immersed in it; but on the contrary, that fluid will appear warm if a hand be applied to it which has a lower degree of heat than 62°. For this reason, the thermometer is a much more accurate measure of heat than the senses of animals. As long, however, as the organs remain unchanged, the sensible heat is in proportion to the temperature; and therefore those terms have generally been considered as synonymous. On this subject Dr Reid observes, that until the ratio between one temperature and another be ascertained by experiment and induction, we ought to consider temperature as a measure which admits of degrees, but not of ratios; and consequently ought not to conclude, that the temperature of one body is double or triple to that of another, unless the ratio of different temperatures were determined. Nor ought we to use the expressions of a double or triple temperature, those being expressions which convey no distinct meaning until the ratio of different temperatures be determined."

In making experiments on the comparative quantities of heat in different bodies, our author chooseth rather to use equal weights than equal bulks of the substances to be compared. Thus he found the comparative heat of water to be to that of mercury as 28 to 1 by weight, and 2 to 1 by bulk; which differs very considerably from the conclusion of Dr Black, who makes it only as 3 to 2, as has been already mentioned.

From the differences observed in the quantities of absolute heat contained in different bodies, our author concludes, that "there must be certain essential differences in the nature of bodies; in consequence of explained which, some have the power of collecting and retaining that element in greater quantity than others. These different powers he calls the capacities for containing heat. Thus, if we find by experiment that a pound of water contains four times as much absolute heat as diaphoretic antismony, when at the same temperature, the capacity of water for containing heat is said to be to that of antismony as 4 to 1.

"The temperature, the capacity for containing heat, and the absolute heat contained, may be distinguished from each other in the following manner."

"The capacity for containing heat, and the absolute heat contained, are distinguished as a force distinct from the subject upon which it operates. When we speak of the capacity, we mean a power inherent in the heated body; when we speak of the absolute heat, we mean an unknown principle which is retained in the body by the operation of this power; and when we speak of the temperature, we consider the unknown principle as producing certain effects upon the thermometer.

"The capacity for containing heat may continue unchanged, while the absolute heat is varied without end. If a pound of ice, for example, be supposed to retain its solid form, the quantity of its absolute heat will be altered by every increase or diminution of its sensible heat: but as long as its form continues the same, its capacity for receiving heat is not affected by
Theory.

Of the Element of Fire

An alteration of temperature, and would remain unchanged though the body were wholly deprived of its heat.

In the course of his work, Dr Crawford observes, that "he has not entered into the inquiry which has been so much agitated among the English, the French, and the German philosophers: Whether heat be a substance or a quality? In some places indeed he has used expressions which seem to favour the former opinion; but his whole motive for adopting this was, because the language seemed to be more simple and natural, and more consonant to the facts which had been established by experiment. At the same time, he is persuaded that it would be a very difficult matter to reconcile the following facts. Thus for instance, heat is preserved in the course of his work, Dr Crawford observes, that heat is a quality.

It is not easy to conceive, upon this hypothesis, how heat can be absorbed in the processes of fusion, evaporation, combustion; how the quantity of heat in the air can be diminished, and that in the blood increased, by respiration, though no sensible heat or cold be produced.

Whereas, if we adopt the opinion that heat is a distinct substance, or an element sui generis, the phenomena will be found to admit of a simple and obvious interpretation.

Fire will be considered as a principle; which is distributed in various proportions throughout the different kingdoms of nature. The mode of its union with bodies will resemble that particular species of union, wherein the elements are combined by the joint forces of pressure and attraction. Of this kind is the combination of fixed air and water; for fixed air is retained in water partly by its attraction for that fluid, and partly by the pressure of the external air; and if either of these forces be diminished, a portion of the fixed air escapes. In like manner, it may be conceived that elementary fire is retained in bodies, partly by its attraction to these bodies, and partly by the action of the surrounding heat; and in that case a portion of it will be disengaged, either by diminishing the attractive force, or by lessening the temperature of the surrounding medium. If, however, fire be a substance which is subject to the laws of attraction, the mode of its union with bodies seems to be different from that which takes place in chemical combination; for, in chemical combination, the elements acquire new properties, and either wholly or in part lose those by which they were formerly characterized. But we have no sufficient evidence for believing that fire, in consequence of its union with bodies, does, in any instance, lose its distinct properties.

Dr Berkenhout, in his first Lines of the Theory and Practice of Philosophical Chemistry, informs us, that "heat, or the matter of heat, is by Scheele and Bergman substituted for fire, which they believe to be the action of heat when increased to a certain degree.

The first of these celebrated chemists believed this matter of heat to be a compound of phlogiston and pure air. He was certainly mistaken. It seems more philosophical to consider heat as an effect, of which fire is the sole cause.

Heat I consider not as a distinct substance, but as an effect of fire, fixed or volatile; in both which states fire seems to exist in all bodies, solid and fluid. Fixed fire I believe to be a conjoint part of all bodies, and their specific heat to depend on the quantity of the fixed fire in each. This fixed, this latent fire, cannot be separated from the other constituent parts of bodies but by their decomposition: it then becomes volatile and incorrigible. If this hypothesis be true, fire exists, in all natural bodies that contain phlogiston, in three different states: 1. In that volatile state in which it perpetually fluctuates between one body and another. 2. Combined with an acid, probably in the form of fixed inflammable air or phlogiston. 3. Uncombined and fixed, as a constituent principle, determining the specific heat of bodies.

Pure (or volatile) fire is distinguished by the following properties. 1. It is essentially fluid, invisible, light, and without weight. 2. It is the immediate cause of all fluidity. 3. It penetrates and pervades all bodies on the surface of the earth, and as far beneath the surface as hath hitherto been explored. Water hath never been found in a congealed state in the deepest mines. 4. It has a constant tendency to diffuse itself equally through all bodies, howsoever different in point of density. A marble slab, a plate of iron, a decanter of water, and a lady's muff, at the same distance from the fire, and other external circumstances, being equal, possesses an equal degree of heat, which is precisely that of the atmosphere in which they stand. 5. It is perpetually in motion from one body to another, and from different parts of the same body, because external circumstances are continually varying. 6. In fluctuating from one body to another, it produces a constant vibration of their constituent parts; for all bodies expand and contract in proportion to the quantity of fire they contain. 7. Accumulated beyond a certain quantity, it affects the diffillation of bodies, by forcing their constituent parts beyond the sphere of mutual attraction, called the attraction of cohesion, which is the cause of solidity. Hence the sovereign agency of fire in chemical operations.

Dr Crawford, besides the opinions already quoted, tells us, that fire, in the vulgar acceptation of the word, expresses a certain degree of heat accompanied with light. In this sense, heat and light which are produced by the decomposition of combustible bodies. But as heat, when accumulated in a sufficient quantity, is constantly accompanied with light; or, in other words, as fire is always produced by the increase of heat, philosophers have generally considered these phenomena as proceeding from the same cause: and have therefore used the word fire to express that unknown principle, which, when it is present to a certain degree, excites the sensation of heat alone; but, when accumulated to a greater degree, renders itself obvious both to the sight and touch, or produces heat accompanied with light. In this sense, the element of fire signifies the same thing with ab ab light heat.

Having premised these general definitions and remarks, he gives the properties of heat in the following words:

I. Heat has a constant tendency to diffuse itself over all bodies: with the aid of heat alone: but, when accumulated to a greater degree, renders itself obvious both to the sight and touch, or produces heat accompanied with light. In this sense, the element of fire signifies the same thing with ab light heat.

Having premised these general definitions and remarks, he gives the properties of heat in the following words:

II. Heat has a constant tendency to diffuse itself over all bodies: with the aid of heat alone: but, when accumulated to a greater degree, renders itself obvious both to the sight and touch, or produces heat accompanied with light. In this sense, the element of fire signifies the same thing with ab light heat.
and that all inanimate bodies, when heated and placed in a cold medium, continually lose heat, till in process of time they are brought to the state of the surrounding medium.

If, from this property of heat it follows, that the various classes of bodies throughout the earth, if they were not acted upon by external causes, would at length, arrive at a common temperature when the heat would become quiescent; in like manner as the waters of the ocean, if not prevented by the winds and by the attractions of the sun and moon, would come to an equilibrium, and would remain in a state of rest. But as causes continually occur in nature to disturb the balance of heat as well as that of the waters of the ocean, those elements are kept in a constant fluctuation.

II. Heat is contained in considerable quantities in all bodies when at the common temperature of the atmosphere.

From the interesting experiments which were made on cold by Mr Wilson, we learn, that at Glasgow, in the winter of the year 1780, the thermometer on the surface of snow sunk 25 degrees below the beginning of Fahrenheit’s scale.

We are told by Dr Pallas, that in the deserts of Siberia, during a very intense frost, the mercury was found congealed in thermometers exposed to the atmosphere, and a quantity of that fluid in an open bowl placed in a similar situation, at the same time became solid. The decisive experiments of Mr Hutchins at Hudson’s Bay prove, that the freezing point of mercury is very nearly 40° below the zero (or 0°) of Fahrenheit. From which it follows, that at the time of Dr Pallas’s observation, the atmosphere in Siberia must have been cooled to minus 40°. By a paper lately transmitted to the Royal Society we are informed, that the spirit-of-wine thermometer in the open air at Hudson’s Bay fell to — 42 in the winter of 1785; and from the same communication we learn, that by a mixture of snow and vitriolic acid, the heat was so much diminished, that the spirit of wine sunk to — 80, which is 112 below the freezing point of water.

Hence it is manifest, that heat is contained in considerable quantities in all bodies when at the common temperature of the atmosphere. It is plain, however, that the quantity inherent in each individual body is limited. This, I think, must be admitted, whatever be the hypothesis which we adopt concerning the nature of heat; whether we conceive it to be a force or power belonging to bodies, or an elementary principle contained in them. For those who consider heat as an element, will not suppose that an unlimited quantity of it can be contained in a finite body; and if heat be considered as a force or power, the supposition that finite bodies are actuated by forces or powers which are infinite is equally inadmissible.

To place this in another light, we know that bodies are universally expanded by heat, excepting in a very few instances, which do not afford a just objection to the general fact; because, in those instances, by the action of heat a fluid is extricated that previously separated the particles from each other. Since, therefore, heat is found to expand bodies in the temperatures which fall within the reach of our observation, we may conclude that the finite thing takes place in all temperatures.

Our author, by a fact of very accurate and laborious experiments, determines that the expansions in mercury and some other fluids are proportional to the quantities of heat applied; from which (says he) it is manifest, that the quantities of heat in bodies are limited, because an infinite heat would produce an infinite expansion.

It is manifest, that the number of degrees of sensible heat, as measured by the thermometer, and estimated from the beginning of the scale, must be the same in all bodies which have a common temperature; for by the first general fact it is proved, that heat has a constant tendency to diffuse itself uniformly over bodies till their temperatures become equal. From which it may be inferred, that if a quantity of heat were added to bodies absolutely cold, the same uniform diffusion would take place; and that if a thermometer, altogether deprived of its heat, were applied to such bodies, it would be equally expanded by them, the whole of the sensible heat which they had acquired being indicated by that expansion.

III. If the parts of the same homogeneous substance have a common temperature, the quantity of absolute heat will be proportional to the bulk or quantity of matter. Thus the quantity of absolute heat in two pounds of water is double that which is contained in one pound when at the same temperature.

IV. The dilatations and contractions of the fluid in the mercurial thermometer are nearly proportional to the quantities of absolute heat which are communicat ed to the same homogeneous bodies, or separated from them, as long as they retain the same form. Thus the quantity of heat required to raise a body four degrees in temperature by the mercurial thermometer, is nearly double that which is required to raise it two degrees, four times that required to raise it one degree, and so in proportion.

Thus we find, that Dr Black, Dr Irvine, Dr Crawford, and Dr Berkenhout, agree in speaking of fire or heat as a fluid substance distinct from all other bodies.

Mr Kirwan, in his Treatise of Phlogiston, agrees in the same sentiment. Some (says he) have thought, that wasn’t opinion; I should have included the matter of heat, or elementary fire, in the definition of inflammable air; but as fire is contained in all corporeal substances, to mention it is perfectly needless, except where bodies differ from each other in the quantity of it they contain.

Mr Cavendish, on the other hand, Mr Cavendish, Phil. Trans. xxvii. on the subject of fire, gives no reason for this opinion, it seems probable that the greater part of philosophers either positively believe that heat is an elementary fluid distinct from all others, or find themselves obliged to adopt a language which necessarily implies it. The only difficulty which now remains therefore is, to affix a proper idea to the phrase quantity of heat, which we find universally made use of, without any thing to determine our opinions concerning it.

That we cannot speak of a quantity of fire or heat in the same sense as we speak of a quantity of water or any other fluid is evident, because we can take away the quantity of water which any substance contains, but cannot do so with heat. Nay, in many cases we are sure, that a substance very cold to the touch does not lose the word "degree of heat."
The quantity of heat contained in any substance depends, in the first place, on the attracting power of that substance, which is altogether unknown; and, in the second place, on the repulsive powers of the particles of heat themselves, which are equally unknown. To determine the quantity, therefore, must be impossible. Neither will the mixture of two different fluids, as in Dr Black's experiments, affift us in the least; for though water, heated more than mercury, communicates a greater heat to that fluid than the latter does to water; this only shows that water more readily parts with some part of the heat it contains than mercury does, but has not the least tendency to discover the quantity contained in either.

Dr Crawford, as we have already seen, calls the degree, or, if we may vary the phrase, the quantity of power or element (fluid, if we may substitute a synonymous word) existing or present in any body, its absolute heat; and lays down a rule for determining the proportional quantities of heat in different bodies. "It will appear (says he) from the experiments afterwards recited, that if a pound of water and a pound of diaphoretic antimony have a common temperature, the quantity of absolute heat contained in the former is nearly four times that contained in the latter." The manner in which he illustrates this is as follows.

"If four pounds of diaphoretic antimony at 20 be mixed with one pound of ice at 32, the temperature will be nearly 26: the ice will be cooled six degrees, and the antimony heated six. If we reverse the experiment, the effect will be the same. That is, if we take six degrees of heat from four pounds of antimony, and add to it a pound of ice, the latter will be heated six degrees. The same quantity of heat, therefore, which raises a pound of ice six degrees, will raise four pounds of antimony six degrees.

"If this experiment be made at different temperatures, we shall have a similar result. If, for example, the antimony at 15, or at any given degree below the freezing point, be mixed with the ice at 32, the heat of the mixture will be the arithmetical mean between that of the warmer and colder substance. And since the capacities of bodies are permanent as long as they retain the same form, we infer, that the result would be the same if the antimony were deprived of all its heat, and were mixed with the ice at 32. But it is evident, that in this case the ice would communicate to the antimony the half of its absolute heat. For if 200 below frost be conceived to be the point of total privation, the antimony will be wholly deprived of its heat when cooled to 200 degrees below 32, and the heat contained in the ice when at 32 will be 200 degrees. If we now suppute these to be mixed together, the temperature of the mixture will be half the excess of the hotter above the colder, or the ice will be
be cooled 100 degrees and the antimony heated 100.
The one half of the heat, therefore, which was con-
tained in the ice previous to the mixture will be com-
municated to the antimony; from which it is manifest,
that after the mixture the ice and antimony must con-
tain equal quantities of absolute heat.

"To place this in another light, it has been proved,
that the same quantity of heat which raises a pound of
ice 100 degrees will raise four pounds of antimony 25
degrees. And as the capacities of bodies, while they
retain the same form, are not altered by a change of
temperature; it follows, that the same quantity of heat
which raises the ice 100 degrees, or any given number
of degrees, will raise the antimony an equal number of
degrees.

A pound of ice, therefore, and four pounds of
antimony, when at the same temperature, contain
equal quantities of absolute heat. But it appears from
the third general fact (n° 6), that four pounds of
antimony contain four times as much absolute heat as
one pound of antimony; and hence the quantity of
absolute heat in a pound of ice is to that in a pound of
antimony as four to one."

From this quotation it is evident, that notwithstanding
all the distinctions which Dr Crawford has
laid down betwixt absolute heat and temperature, it is
only the quantity of the latter that can be measured;
and it is only from a consideration of this latter, that
we can say concerning the matter is, that
when certain bodies are mixed together, some of them
part with a greater quantity of heat than others; but
how much they contain must remain for ever
unknown, unless we can fall on some method of measur­
ing the quantity of heat as we do that of any other
fluid.

Mr Nicholson, who has collected the principal opini­
sions on the subject of heat, seems determined not to
accept the doctrine of Boyle or of Boerhave on the
subject. "There are two opinions (says he) concern­ing heat. According to one opinion, heat
consists in a vibratory motion of the parts of bodies
among each other, whose greater or lesser intensity oc­
casions the increase or diminution of temperature. Ac­
cording to the other opinion, heat is a fluid which
cannot pervade the pores of all bodies, causing them
to expand by its influence, and which, unless they
are endowed with some property of vibratory motion,
will not be communicated to the particles of bodies.
Each of these opinions is attended with its peculiar diffi­
culties. The phenomena of heat may be accounted for
by either of them; provided certain suppositions be
allowed to each respectively; but the want of proof of
the truth of such suppositions renders it very difficult,
if not impossible, to decide as yet whether heat consists
merely in motion or in some peculiar matter. The
word quantity, applied to heat, will therefore denote
either motion or matter, according to the opinion
made use of, and may be used indefinitely without de­
determining which."

"The chief advantage which the opinion that heat
is caused by mere vibration possesses, is its great sim­
pli city. It is highly probable, that all heated bodies
have an intrinsic motion, or vibration of their parts;
and it is certain that percution, friction, and other
methods of agitating the minute parts of bodies, will
likewise increase their temperature. Why, then, it is
demanded, should we multiply causes, by supposing the
existence of an unknown fluid, when the mere vi­

bration of parts which is known to obtain may be ap­
plied to explain the phenomena?"

To this the reply is obvious, that the vibration of parts is an effect; for matter will not begin to move of
itself: and if it is an effect, we must suppose a cause for
it; which, though we should not call it a fluid, would
be equally unknown and inexplicable with that whole
existance is asserted by those who maintain that fire is
a fluid per se. Dr Cleghorn, however, in the discussion
already quoted, affirms, that "heat is occasioned
by a certain fluid, and not by motion alone, as some
 eminent writers have imagined: because 1. Those
who have adopted the hypothesis of motion could
never even prove the existence of that motion for
which they contended; and though it should be
granted, the phenomena could not be explained by it.
2. If heat depended on motion, it would instantaneously pass through an elastic body; but we see
that heat passes through bodies slowly like a fluid.
3. If heat depended on vibration, it ought to be com­
municated from a given vibration in proportion to the
quantity of matter; which is found not to hold true
in fact. On the other hand, there are numberless arguments in favour of the opinion that heat proceeds from
elementary fire. 1. Mr Locke hath observed, that
when we perceive a number of qualities always existing
 together, we may gather from thence that there really
is some substance which produces these qualities. 2. The
hypothesis of elementary fire is simple and agreeable
to the phenomena. 3. From some experiments made
by Sir Isaac Newton, it appears, that bodies acquire heat
and cold as metals, until they become of the same tem­
perature with the atmosphere; so that heat exists in the
absence of all other matter, and is therefore a sub­
stance by itself."

But though these and other arguments seem clearly
difficulties concerning the nature and properties. If it be supposed a fluid, it is impossible to assign any limits to its extent;
and we must of necessity like­wise suppose that it per­
vades the whole creation, and consequently constitutes
an absolute plenum, contrary to a fundamental princi­
ples of the received system of natural philosophy. But
if this be the case, it is vain to talk of its being absorb­
ed, accumulated, collected, or attracted by different
bodies, since it is already pre­sent in all points of space;
and we can conceive of terrestrial bodies no other­wise
than as sponges thrown into the ocean, each of which
will be as full of fluid as it can hold. The different capac­
ities will then be similar to the differences between bits
of wood, sponge, porous stones, &c. for containing
water; all of which depend entirely on the structure of
the bodies themselves, and which, unless we could se­
parate the water by pre­sure, or by evaporation, would
be for ever unknown. Supposing it were impossible to
collect this water in the manner we speak of, we
could only judge of the quantity they contained by the
degree to which they swelled by being immersed in it.
It is easy to see, however, that such a method of
judging would be very inadequate to the purpose, as
substances might contain internal cavities or pores in
which water could lodge without augmenting the ex­
ternal bulk. This would suggest another method of
judging of the quantity, namely, the specific gra­
vity; and we might reasonably suppose, that substance of the greatest specific gravity would contain the smallest quantity of water, though still we could by no means determine what quantity they did contain, unless we could lay hold of the element itself.

This seems to be very much the case with elementary fire, if we suppose it to be a fluid per se. We judge of its presence by the degree of expansion which one heated body communicates to another: but this is only similar to the calculation of the quantity of moisture a sponge or any other body contains, by what it communicates to wood when it comes into contact with it; which never could be supposed to carry the least precautions to accuracy, though we should ascertain it with all imaginable exactness. It is likewise probable, that the most dense bodies contain the smallest quantity of fire, as they generally communicate least when heated to an equal temperature than those which are more rare, though we are far from having any perfect knowledge in this respect.

But the greatest difficulty of all will be, on the supposition that heat is a fluid, and an omnipresent one (which it must be, or there would be some places where bodies could not be heated), to answer the question: Why are not all bodies of an equal temperature, excepting only the differences arising from their specific densities, which render some capable of containing a greater quantity than others?—The difficulty will not be lessened, though the omnipresence of the fluid should be given up, if we suppose, as is generally done, that heat has a tendency to diffuse itself equally every way. If it has this tendency, what hinders it from doing so? Why doth not the heat from the burning regions of the torrid zone diffuse itself equally all over the globe, and reduce the earth to one common temperature? This indeed might require time; but the experience of all ages has shown that there is not the least advance towards an equality of temperature. The middle regions of the earth continue as hot, and the polar ones as cold, as we have any reason to believe that they were at the creation of the world, or as we have any reason to believe they will be while the world remains. This indeed is one of the many instances of the impropriety of establishing general laws from the trifling experiments we are capable of making, and which hold good only on the narrow scales on which we can make them, but are utterly insufficient to solve the phenomena of the great system of nature, and which can be solved only by observing other phenomena of the same system undisturbed by any manoeuvres of our own.

Again, supposing the objection already made could be got over, and satisfactory reasons should be given why an equilibrium of temperature in the earth and its atmosphere should never be obtained, it will by no means be easy to tell what becomes of the heat which is communicated to the earth at certain times of the year. This difficulty, or something similar, Dr Crawford seems to have had in view when treating of the effects of the evolution and absorption of heat. Thus, says he, "the Deity has guarded against sudden vicissitudes of heat and cold upon the surface of the earth.

"For if heat were not evolved by the process of congelation, all the waters which were exposed to the influence of the external air, when its temperature was reduced below 32°, would immediately become solid; and, at the moment of congelation, the progress of cooling would be as rapid as it was before the air had arrived at its freezing point.

"This is manifest from what was formerly observed respecting the congelation of different fluids. It was shown, that if the velocities of the separation of heat were equal, the times of the congelation would be in proportion to the quantities of heat which the fluids gave off from an internal source in the freezing process. Whence it follows, that if no heat were evolved, the congelation should be instantaneous.

"In the present state of things, as soon as the atmosphere is cooled below 32°, the waters begin to freeze, and at the same time to evolve heat; in consequence of which, whatever may be the degree of cold in the external air, the freezing maifs remains at 32°, until the whole is congealed; and as the quantity of heat extricated in the freezing of water is considerable, the progress of congelation in large masses is very slow.—That the absorption and extraction of heat in the melting and freezing of bodies has a tendency to retard the progress of these processes, is remarked by Mr Wilkie in his essay on latent heat. The same doctrine is likewise taught by Dr Black in his lectures.

"In the northern and southern regions, therefore, as the quantity of the cooling fluid in the ice is extricated from the waters, proportional to the degree of cold that prevails in the atmosphere. Thus it is that the severity of the frost is mitigated, and its progress retarded; and it would seem, that during this retardation of the cooling process, the various tribes of animals and vegetables which inhabit the circumpolar regions become gradually acquire power of resifting its influence.

"On the contrary, if, in the melting of ice, a quantity of heat were not absorbed, and rendered insensible, that substance, when it was exposed to a medium by which it was rendered warmer than 32°, would speedily become fluid, and the process of elevation would be as rapid as if no alteration in its form had taken place. If things were thus constituted, the vast maifs of ice and snow which are collected in the frigid zones would, upon the approach of summer, suddenly disolve, and great inundations would annually overflow the regions near to the poles.

"But by the operation of the law of the absorption of heat, when the ice and snow upon the return of spring have arrived at 32°, they begin to melt, and at the same time to imbibe heat: during this process, a large quantity of elementary fire becomes insensible; in consequence of which the earth is slowly heated, and those gradual changes are produced which are essential to the preservation of the animal and vegetable kingdoms.

"We may remark, in the last place, that this law equalizes not only refults sudden changes of temperature, but prevents them from being repeated in different climates, and that it likewise contributes to a more equal distribution of heat proportionate to the principle of heat throughout the various parts of the earth, in different seasons and climates. Thus the diurnal heats are moderated by the evaporation of the waters on the earth's surface, a portion of the fire derived from the sun being absorbed and extinguished by the vapours at the moment of their ascent. On the approach of night the vapours are again condensed, and falling in the form of dew, communicate

CHEMISTRY.

Theory.

...to the air and to the earth the fire which they had immersed during the day.

"It was before shown, that, in the regions near to the poles, when the vernal and summer heats prevail, provision is made for tempering the severity of the winter cold, a quantity of elementary fire, upon the dissipation of the ice and snow, being absorbed by the waters, and deposited, as it were, in a great magazine for the purpose of mitigating the intensity of the cold when the frost returns.

"From the experiments of Hales, Halley, and Watson, it appears, that vast quantities of water are continually converted into vapour by the action of the solar rays upon the portion of the earth's surface which is exposed to the light; and by the celebrated discovery of Dr Black, it is proved, that, in the process of evaporation, much elementary fire is absorbed. It is manifest, that this cause will have a powerful influence in mitigating the intensity of the heat in the torrid zone, and in promoting a more equal diffusion of it through the earth. For a considerable portion of the heat, which is excited by the action of the solar rays upon the earth's surface within the tropics, is absorbed by the aqueous vapours, which being collected in the form of clouds, are spread like a canopy over the horizon, to defend the subjacent regions from the direct rays of the sun. A great quantity of elementary fire is thus rendered intenable in the torrid zone, and is carried by the dispersion of the vapours to the north and to the south, where it is gradually communicated to the earth when the vapours are condensed."

"That all this takes place, as the Doctor has advanced, cannot be denied; but, by allowing it, the difficulty is not removed in the smallest degree, as will appear from a due consideration of the phenomena which he himself has mentioned. He owns that the sun communicates fire to the earth; the question is, What becomes of it, seeing the emission is continual? In summer, the air, the earth, and the water, are heated to a certain degree. On the sun's declining southward, the air first loses its heat. Whether does it go? It does not ascend into the higher regions of the atmosphere, of which we are constantly found colder than the parts below. It does not descend to the earth and water; for these give out the quantity they had absorbed, as Dr Crawford observes. Neither does it go laterally to the southern regions; for they are constantly very hot, and ought to impart their heat to those farther north, instead of receiving any from them. How comes it, then, that the atmosphere seems perpetually to receive heat without ever being fattated? or if the heat cannot be found going off either upwards, downwards, or sidewise, how are we to account for its disappearance?

This question seems to be altogether unsatisfactory on the supposition that heat is occasioned by the mere presence of a fluid; but if we suppose it to be only a particular mode of action of an omnipresent fluid, the whole difficulty vanishes at once. On this supposition indeed the question will naturally arise, Whence does this motion proceed, or by what is its action in general determined? Dr Berkenhout, in enumerating the properties of matter, exempts fire from two of those usually ascribed to other material substances, viz. gravitation and the vis inertiae. "According to the philosophers (says he), matter cannot move without being either impelled or attracted. I doubt much whether this is true of fire, and whether, when combined, motion be not one of its essential properties.—Gravitation seems also to be no property of fire, which moves with equal facility in all directions, and may be accumulated in hard bodies to any degree without increasing their weight. Fire, being the cause of volatility, seems rather to be in confant contradiction to gravity."

"But however essential we may suppose the motion of fire to be to it, there cannot be any self-existent mobility in its parts, otherwise it would soon be diffused equally throughout the universe, and the temperature of the whole reduced to an equilibrium. According to the present constitution of nature, we see that the distribution of heat is principally owing to the sun; and owing to what we call its quantity, depends on the position of the sun with regard to terrestrial objects and the length of time they are exposed to his rays. Heat is not produced while the rays have a direct passage; and therefore fluids through which they pass easily, as air, are not heated by the rays of the sun. But when the rays are impeded in their course, and reflected in considerable quantity, a degree of heat takes place, which is always greater or less in proportion to the intensity of the rays. In the reflecting substance, the heat will be comparatively greater in proportion to the quantity of rays which are absorbed or stopped in their course by it: but in any substance interposed between the sun and the reflecting body, the heat is proportional to the quantity of rays reflected. Now it is plain, that when the particles of light fall upon any opaque substance, and enter its pores, which by their extreme fubtility they are well calculated to do, they must make an attempt to pass directly through it in their natural course; but as this cannot be done, they will pass laterally, and in all directions, in consequence of being perpetually urged by the impulse of the light coming from the sun; and thus an action will be propagated in all directions as radii from a centre towards a circumference, which when it takes place in that fubtile fluid always produces what we call electricity."

"In completing the system of nature, we perceive three kinds of fluids of extreme fubtility, and very the identity much resembling one another, viz. fire, light, and electricity. That it should be agreeable to vulgar conception to suppose these all to be ultimately the same, is not surprising; and on examining the evidence of their identity, it will certainly be found exceedingly strong. They all agree in the property of exciting the fentation of heat in certain circumstances, and in not doing so in others. Fire, we know, in the common acceptance of the word, always does so; but when it affumes the latent and invisible state, as in the formation of vapour, it lays aside this seemingly essential property, and the vapour in which it is is devitalised. Light, when collected in a focus by a burning glass, i.e. when its rays converge towards a centre, and diverge or attempt to diverge from one, produces heat also: and so does the electric fluid; for it has been found that the aura converging from a very large conductor to the point of a needle, is capable of setting fire to a small cartridge of gunpowder, or a quantity of tinder surrounding it *. There seems also to be a connexion between..."
fire and electricity in another way; for in proportion as heat is diminished, or the bodies are cooled, electricity succeeds in its place. Thus all electric bodies by heat become condensers of electricity, and cannot be excited or made to show any signs of containing that fluid; but as soon as the heat is removed, their electric property returns. Water is naturally a conducting substance: by being frozen its conducting power is lessened, which shows an approach to electricity; and, by being cooled down to 20° below 0 of Fahrenheit, the ice actually becomes electric, and will emit sparks by friction like glass#. The atmosphere is a natural electric: but by a certain degree of heat it loses this property, and becomes a conductor; nor is there any doubt that its electric properties are increased in proportion to the degree of cold imparted to it. In the winter time, therefore, we must consider the frozen surface of the earth, the water, and the atmosphere of the polar regions, as forming one electrical machine of enormous magnitude; for the natural cold of those countries is often sufficient to cool the water to more than not below 0, and consequently to render it an electric. That this is really the case, appears from the exceedingly bright aurora borealis and other electric appearances, far exceeding any thing observed in this country. In the summer time, however, no such appearances are to be seen, nor anything remarkable except an excessive heat from the long continuance of the fun above the horizon. This quantity of heat then being succeeded by a proportionable quantity of electricity in winter, it is impossible to avoid concluding that the heat in summer becomes electric fluid in winter, which, going off through the celestial expanse, returns again to the grand source of light and heat from which it originally came; thus making room for the succeeding quantities which are to enliven the earth during the following summer.

Thus the disappearance of heat in winter, and of electricity in summer, in these countries, will be very naturally and easily accounted for. It is true, that the phenomena of thunder and lightning show the existence of this fluid in vast quantities during the summer season; but these phenomena are only partial, and therefore formidable to us, arisirring in comparison with the vast quantities of electric matter discharged by the continual flashing of the aurora borealis, not to mention the fire-balls and meteors called falling stars, which are very often to be seen in the northern countries. In the summer-time, the air which is an electric, heated by the rays of the sun, is excited or made to part with the fluid to the vapours contained in it; and it is the unequal or opposite electricity of the clouds to one another, or to the earth, which produces the lightning. But in winter, when the air, earth, and vapours, all become electric, they cannot discharge sparks from one to another as before; but the whole, as one connected and vaft electrified apparatus, discharges the matter almost in a continued stream for many months.

From a consideration of these and other phenomena of nature, as well as of the beet experiments which have hitherto been made, we must consider fire in the abstract as an omnipresent fluid, of such fubtility as to pervade all terrestrial substances. When by any means it is made to diverge every way as from a centre, there it operates as heat; expands, rarefies, or burns, according to the intensity of its action. Proceeding in straight lines and parallel lines, or such as diverge but little, it acts as light, and shows none of that power discoverable in the former case, though this is easily discoverable by making it converge into a focus. In a quiescent state, or where the motion is but little, it prolixes on the surfaces of bodies, contracts and diminishes them every way in bulk, forces out the expanding fluid within their pores, and then acts as cold. In this case also, being obliged to sustain the vehement action of that part of the fluid which is in motion, it flies with violence to every place where the pressure is lessened, and produces all the phenomena of Electricity.

§ 1. Of the Nature of Heat.

The manner in which the phenomena of heat may be solved, and its nature understood, will appear from the following propositions.

1. It is in all cases observed, that when light proceeds in considerable quantity from a point, diverging as the radii of a circle from its centre, there a considerable degree of heat is found to exist, if an opaque body, having no great reflective power, is brought near that point.

2. This action of the light, therefore, may be accounted the ultimate cause of heat, without having recourse to any further suppositions; because nothing else besides this action is evident to our senses.

3. If the point from which the rays are emitted is placed in a transparent medium, such as air or water, that medium, without the presence of an opaque body, will not be heated.

4. Another cause of heat, therefore, is the resistance of the parts of that body on which the light falls, to the action mentioned in Prop. 1. Where this resistance is weak, as in the cases just mentioned, the heat is either nothing, or very little.

5. If a body capable of reflecting light very copiously is brought near the lucid point, it will not be heated#.

6. A penetration of the light, therefore, into the substance of the body, and likewise a considerable degree of resistance on the part of that body to the action of the light, are the requisites to produce heat.

7. Those bodies ought to conceive the greatest degrees of heat into whole substance the light can best penetrate, i.e. which have the least reflective power, and which most strongly resist its action; which is evidently the case with black and solid substances.

8. By heat all bodies are expanded in their dimensions every way, and that in proportion to their bulk and the quantity of heat communicated to them.

9. This expansion takes place not only by an addition of sensible heat, but likewise of that which is latent. Of this last we have a remarkable instance in the case of snow mixed with spirit of nitre. The spirit of nitre contains a certain quantity of latent heat, which cannot be separated from it without effecting a change on the spirit itself; so that, if deprived of this heat, it would no longer be spirit of nitre.—Besides this, it contains a quantity of sensible heat, of a great part of which it may be deprived, and yet retain its characteristic properties as nitrous acid. When it is poured upon snow, the latter is immediately melted by the action of the latent heat in the acid. The snow cannot
be melted or converted into water, without imbuing a quantity of latent heat, which it receives immediately from the acid which melts it. But the acid cannot part with the heat without decomposition; to prevent which, its sensible heat occupies the place of that which has entered the snow and liquefied it. The mixture then becomes exceedingly cold, and the heat forces into it from all the bodies in the neighbourhood; so that, by the time it has recovered that quantity of sensible heat which was lost, or arrived at the temperature of the atmosphere around it, it will contain a considerably larger quantity of heat than it originally did, and is therefore observed to be expanded in bulk. Another instance of this expansive power of latent heat is in the case of steam, which always occupies a much larger space than the substance from which it was produced; and this whether its temperature is greater or less than the surrounding atmosphere.

10. The difference between latent and sensible heat, then, as far as we can conceive, is, that the expansive power of the former is directed only against the particles of which the body is composed; but that of the latter is directed also against other bodies. Neither doth there seem to be any difference at all between them farther than in quantity. If water, for instance, hath but a small quantity of heat, its parts are brought near each other, it contracts in bulk, and feels cold. Still, however, some part of the heat is detained among the aqueous particles, which prevents the fluid from condensing into a solid mass. But, by a continuation of the contracting power of the cold, the particles of water are at last brought so near each other that the internal or latent heat is forced out. By this discharge a quantity of air is also produced, the water is congealed, and the ice occupies a greater space than the water did; but then it is full of air-bubbles, which are evidently the cause of its expansion. The heat then becomes sensible, or, as it were, lies on the outside of the matter; and consequent is coldly diffipated into the air, or communicated to other bodies. Another way in which the latent heat may be extracted is by a continuous addition of sensible heat. In this case the body is first raised into vapour, which for some time carries off the redundant quantity of heat. But as the quantity of this heat is continually increased, the texture of the vapour itself is at last totally destroyed. It becomes too much expanded to contain the heat, which is therefore violently thrown out all on sides into the atmosphere, and the body is said to burn, or be on fire. See Combustion, Flame, and Ignition.

11. Hence it follows, that those bodies which have the least share of latent heat, appear to have the greatest quantity of sensible heat; but this is only in appearance, for the great quantity they seem to contain is owing really to their inability to contain it. Thus, a body composed of a fluid is capable of emitting heat through it as fast as it received it; if such a substance was set over a fire, it would be as hot as the fire itself, and yet the moment it was taken off, it would be perfectly cool, on account of its incapacity to detain the heat among the particles of which it was composed.

12. The heat, therefore, in all bodies consists in a certain violent action of the elementary fire within them tending from a centre to a circumference, and making an effort to separate the particles of the body from each other, and thereby to change its form or mode of existence. When this change is effected, bodies are said to be diffipated in vapour, calcined, vitrified, or burnt, according to their different natures.

13. Inflammable bodies are such as are easily raised in vapours; that is, the fire easily penetrates their parts, and combines with them in such quantity, that, becoming exceedingly light, they are carried up by the atmosphere. Every succeeding addition of heat to the body increases also the quantity of latent heat in the vapour, till at last, being unable to retain its action, the heat breaks out all at once, the vapour is converted into flame, and is totally decomposed. See the article Flame, and Prop. 10.

14. Uninflammable bodies are those which have their parts more firmly connected, or otherwise disposed in such a manner, that the particles of heat cannot easily combine with them or raise them into vapour.

15. Heat therefore being only a certain mode of the action of elementary fire, it follows, that the capacity of a body for containing it, is only a certain constitution of the body itself, or a disposition of its parts, which can allow the elementary fire contained in it to exert its expansive power upon them without being diffipated on other bodies. Those substances which allow the expansive power of the fire to operate on their own particles are said to contain a great deal of heat; but those which throw it away from themselves upon other bodies, though they feel very hot, yet philosophically speaking they contain very little heat.

16. What is called the quantity of heat contained in any substance, if we would speak with the strictest propriety, is only the apparent force of its action, either upon the parts of the body itself, or upon other bodies in its neighbourhood. The expansive force of the elementary fire contained in any body upon the parts of that body, is the quantity of latent heat contained in it; and the expansive force of the fire exerted upon other bodies which touch or come near it, is the quantity of sensible heat it contains.

17. If what we call heat consists only in a certain action of that fluid called elementary fire, namely, its expansion, or acting from a centre to a circumference, it follows, that if the same fluid acted in a manner directly opposite to the former, or pres by upon the particles of a body as from a circumference to a centre, it will then produce effects directly opposite to those of heat, i.e. it will then be absolute cold, and produce all the effects already attributed to cold. See that article.

18. If heat and cold then are only two different modifications of the same fluid, it follows, that if a hot body and a cold one are suddenly brought near each other, the heat of the one ought to drive before it a part of the cold contained in the other, i.e. the two portions of elementary fire acting in two opposite ways, ought in some measure to operate upon one another, as any two different bodies would when driven against each other. When a hot and a cold body therefore are brought near each other, that part of the cold body farthest from the hot one ought to become colder than before, and that part of the hot body farthest from the cold one ought to become hotter than before.

19.
19. For the same reason, the greatest degree of cold in any body ought to be no obstacle, or at least very little, to its conceiving heat, when put in a proper situation. Cold air, cold fuel, &c. ought to become as intensely heated, and nearly as soon, as that which is hotter.

The two last propositions are of great importance. When the first of them is thoroughly established, it will confirm beyond a doubt, that cold is a positive, as well as heat; and that each of them has a separate and distinct power, of which the action of its antagonist is the only proper limit; i.e. that heat can only limit the power of cold, and vice versa. A strong confirmation of this proposition is the experiment related by M. Geoffroy; an account of which is given under the article Cold. Another, but not so well authenticated, is related under the article Congelation.

—De Luc’s observation also, mentioned by Dr Clegborne, affords a pretty strong proof of it; for if the lower parts of the atmosphere are cooled by the passage of the sun’s rays at some distance above, and it has been already shewn, they do not attract the heat from the lower parts, it follows, that they must expel part of the cold from the upper regions.

The other proposition, when fully established, will prove, that heat and cold are really convertible into one another; which indeed seems not improbable, as we see that fires will burn with the greatest fierceness during the time of intense frosts, when the coldest air is admitted to them; and even in those diffused regions of Siberia, when the intense cold of the atmosphere is sufficient to congeal quicksilver, it cannot be doubted that fires will burn as well as in this country; which could not happen if heat was a fluid, and capable of being carried off, or absolutely diminished in quantity, either in any part of the atmosphere itself, or in such terrestrial bodies as are used for fuel.

§ 2. Of the general Effects of Heat.

Having said thus much concerning the nature of heat in general, we come now to a particular explanation of its several effects, which indeed constitute the whole of the active part of chemistry. These are,

1. Expansion, or increase of bulk in every direction. This is a necessitous consequence of the endeavour which the fluid makes to escape in all directions, when made to converge into a focus. The degree of expansion is unequal in different bodies, but in the same body is always proportionable to the degree of heat applied. There are two different instruments in use for ascertaining the degrees of expansion; and as we have already shewn, that the degree of heat can only be known by the expansion, these effects of heat upon the instrument are usually taken for the degrees of heat themselves. These instruments are called the Thermometer and Pyrometer. The former is composed of a glass tube, with a globe or rather oval tube at one end, and exactly closed at the other: it is most usually filled with mercury or spirit of wine; but mercury is generally preferred on account of its expansions being more equal than those of any other fluid. It has the disadvantage, however, of being subject to congelation; which is not the case with spirit of wine, when very highly rectified. Spirit-of-wine thermometers, therefore ought not to be entirely disused, but seem rather a necessary part of the chemical apparatus, as well as those made of mercury.

2. As no thermometer can be used with any fluid that can measure either the degrees of heat about the point at which it boils, or the degree of cold below which it congeals, instruments have been contrived by which the expansion of solid bodies, though much less than what is occasioned by an equal degree of heat in a fluid, may become visible. These were usually called Pyrometers; but Mr Wedgwood has lately contrived a method of connecting the two together, in which the highest degree of heat, exceeding even that of a glafs-house furnace, may be measured as accurately as the more moderate degrees by the common mercurial thermometer. See Thermometer.

Expansion in some cases does not appear to be the influence of the body, which has two remarkable instances. The first is the expansion of bodies by heat, when a piece of a fluid body is changed into a solid, and then heated to its conceiving heat, when very highly rectified. The ball, being made very strong, resisted the expanding force of the water twice, even though a considerable part of its thickness had been pared off when it was perceived to be strong at first. At the third time it burst; and by a calculation founded on the thickness of the globe and the tenacity of the metal, it was found that the expansive power of a sphere of water only one inch in diameter, was sufficient to overcome a resistance of more than 27,000 pounds, or 13 tons and a half.

A power of expansion so prodigious, little less than that of the most powerful steam-engines, and more than twice as strong as that of the best cannon, would have been sufficient to burst the body, or to make it expand to such an extent as to fill a room. Dr Black, however, has demonstrated, that these are only air extricated during the congelation; and to the extrication of this air he very justly attributes the prodigious expansive force exerted by freezing water. The only
only question, therefore, which now remains is, By what means this air comes to be extricated, and to take up more room than it naturally does in the fluid? To this we can scarce give any other answer, than that part of the heat which is discharged from the freezing water combines with the air in its undissipable state, and, by restoring its elasticity, gives it that extraordinary force, as we see also in the air suddenly extricated in the explosion of gunpowder. Thus expansion, even in the cafe of freezing, is properly an effect of heat; and must therefore be considered as a phenomenon uniformly and certainly attending the action of heat, and in all cafes to be ascribed to it.

The only way in which the element or fluid of fire can be supposed to act, and the way in which we have a rational idea of its being able to produce both heat and cold according to the diversity of its actions, has been already explained so fully, that it is needless at present to enter into any further discussion of the subject. It will easily appear, that the capacity for containing heat is nothing different from the action of heat upon that body in expanding, and at last altering its form in such a manner, as either to be able to intiminate itself among the particles in much greater quantity than before; still retaining its internal action, though the external one becomes imperceptible; or, if actuating them in such a manner, that it breaks forth in great quantity in its peculiar appearances of fire and light: in the former case producing vapour or smoke, and in the latter flame, as shall afterwards be more fully explained. It must likewise appear, that to determine the quantity of heat in any body is altogether impossible; and with regard to the lowest degree of heat, or total expulsion of that fluid, so far from being able to determine what it is, the probability must be, that nature does not admit of any such thing; for if heat confits in the expansive action of a certain fluid, and cold in its opposite or contraactive action, there is very little reason to suppose that the constitution of nature will allow any one of these actions entirely to cease, as it does not appear by what means it could again be renewed. Cold, as we have already seen, always tends to conjugate electricity; and the connexion between that and fire is so strong, that we cannot suppose the former to be carried to any great extreme without producing the latter. Whatever we may therefore suppose concerning the capacities of different bodies for containing heat, or concerning the point of total privation of heat, must be altogether void of foundation. A rule, however, has been given by Mr. Kirwan for finding the point of total privation, which, together with its demonstration, we shall subjoin; and as it is necessary for the better understanding of this, to call to remembrance what has been said concerning the difference between the temperatures and specific heats of different bodies, we shall infer an epitome of the doctrine from Mr. Nicholson.

If two equal bodies of different kinds and temperatures be brought into contact, the common temperature, will seldom, if ever, be the mean betwixt the two original temperatures; that is to say, the surplus of heat in the hotter body will be unequally divided between them, and the proportions of this surplus retained by each body will express their respective dispositions, affinities, or capacities for heat. If, therefore, a given substance, as for example fluid water, be taken as the standard of comparison, and its capacity for heat be called one, or unity, the respective capacities of their bodies may be determined by experiment, and expressed in numbers in the same manner as specific gravities usually are. And because it is established as well from reason as experiment, that the same capacity for heat obtains in all temperatures of a given body, so long as its state of fluidity, fluidity, or vapour is not changed, it will follow, that the whole quantities of heat in equal bodies of a given temperature will be as those capacities. And as the respective quantities of heat in bodies of equal weight and temperature give the proportions of their specific heats.

A greater capacity for heat, or greater specific heat, in a given body, answers the same purpose with respect to temperature as an increase of the mass; or the quantity of heat required to be added or subducted, in order to bring a body to a given temperature, will be as its capacity or specific heat.

The capacities not only differ in various bodies, but also in the same body, according as it is either in a solid, fluid, or vaporous state. All the experiments hitherto made confpire to show, that the capacity, and consequently the specific heat, is greatef in the vaporous, least in the fluid, and least in the solid state.

The quantity of heat that constitutes the difference between the several states, may be found in degrees of the thermometer. Thus if equal quantities of water at 162° and ice at 32° of temperature be mixed, the ice melts, and the common temperature becomes 32°; or otherwise, if equal quantities of frozen or fluid water, both at 32°, be placed in a like situation to acquire heat from a fire, the water will become heated to 162°, while the ice melts without acquiring any increase of temperature. In either case the ice acquires 130° of heat, which produces no other effect than rendering it fluid. Fluid water, therefore, contains not only as much more heat than ice, as is indicated by the thermometer, but also 130°, that is in some manner or other employed in giving it fluidity. As fluid water cannot become ice without partaking with 130° of heat besides what it had above 32° in its temperature, so also steam cannot become condensed into water without imparting much more heat to the matters it is cooled by, than water at the same temperature would have done.

The heat employed in maintaining the fluid or vaporous form of a body, has been called latent heat, because it does not affect the thermometer.

From the consideration of the specific heats of Mr. Kirwan's body in the two states of fluidity and solidity, and the difference between those specific heats, is rem for a deduced method of finding the number of degrees, which denote the temperature of any body immediately after congelation, reckoned from the natural zero, or absolute privation of heat. The rule is; multiply the degrees of heat required to reduce any solid to a fluid state, by the number expressing the specific heat of the fluid: divide this product by the difference between the numbers expressing the specific heat of the body in each state: the quotient will be the number of
The quantity of heat required to produce a given change of temperature in a body is as its capacity; and consequently the changes of temperature, when the quantity of heat is given, will be inversely as the capacities: therefore, \( n : m = \frac{\ln t}{\ln i} \),

which is the rule abovementioned.

"If the data \( i, m, \text{ and } n \) be accurately obtained by experiment, in any one instance, and the difference between the zero of Fahrenheit's scale and the natural zero be there found in degrees of that scale, this difference will serve to reduce all temperatures to the denomination which commences at the natural zero. So that \( s \) being known in all cases, if any two of the quantities \( i, m, \text{ or } n \) be given in any body, the other may be likewise had. For \( i = \frac{m - s}{n - i} \), and \( n = \frac{m - i}{s - i} \),

"To give an example of this curious rule, let it be required to determine how many degrees of refrigeration would absolutely deprive ice of all its heat? The degrees of heat necessary to melt ice are 130; and the specific heats of ice and water are as 9 to 10. The number 130 multiplied by 10, produces 1300, and divided by the difference between 9 and 10 gives 1300: therefore if ice were cooled 1300 degrees below 32°, or to \(-108\) of Fahrenheit's scale, it would retain no more sensible heat.

II. Fluidity is another effect of heat, and is capable of taking place in all bodies hitherto known, when the fire is carried to a certain pitch. Theories have been invented, by which fluidity was ascribed to the malleable and round figures of the particle whereof bodies were composed, and solidity to an angular or irregular figure. It has also been ascribed to a stronger degree of attraction between the parts of solids than of fluids. Dr Black, however, has shown, that in the case of melting ice, we are certainly to ascribe the acquired fluidity of the water to the absorption of heat. This was determined by a decisive experiment, in which he exposed a Florence-bottle full of water to the atmosphere in a warm room, when he found that the heat in the air evidently left it, to flow into the ice in the bottle, and reduced it to fluidity. The air thus deprived of its heat, he felt sensibly descending like a cold blast from the bottle, and continuing to do so as long as any of the ice remained unthawed; yet after it was all melted, the temperature of the fluid was no more than 32°. Different degrees of heat are requisite for converting different solids into fluids, for which see the Table of Degrees of Heat.

This theory receives an additional confirmation from General Theory.

The quantity of heat which is always known to be produced by the conversion of a fluid into a solid. And that this is really the case appears, 1. From what happens in the congelation of waters, it appears that ice is formed very slowly, and with several circumstances which support the theory. — Thus, if we suppose equal quantities of water to the air, which is perhaps 10 below frost, and add to one of these a small quantity of salt or spirit of wine, and observe the cooling of each, we shall find them both grow gradually colder, until they arrive at the temperature of frost; after which the water containing the salt will continue to grow colder, until it has arrived at the temperature of the air, at the same time that only a small quantity of the other water is converted into ice. Yet were the common opinion just, it ought all to have been congealed by this time; instead of which, it is scarce grown a degree colder during the whole time. Its remaining at the same temperature for so long a time, shows that it has been communicating heat to the atmosphere; for it is impossible that any body can remain in contact with another that is colder, without communicating heat to it. Whence then comes this heat? There must be some source adding to the sensible heat of the water, so as to keep its temperature to the freezing point: and this source of heat must be very considerable; for it will continue to act for a very long time before the water is changed into ice; during all which time, even to the last drop, the water is not a degree colder than 32° of Fahrenheit's thermometer. This, therefore, is the latent heat of the water, which had formerly entered into it during its transition from ice to a fluid state.

A still stronger argument is derived from the following experiment; which evinces that the fluidity of water really depends upon its latent heat, and that the sensible heat is only a mean or condition to its containing the latent heat. This experiment consists in exposing water contained in a covered beer-glasses to the air of a cold frosty night; and when the atmosphere is at the temperature of perhaps 16° or 12° below 32° of frost, the water will continue at that temperature without freezing; so that the fluidity of the water, which does not altogether depend on the quantity of sensible heat contained in it. The congelation, however, may be brought on by touching it with a bit of ice, with the extremity of a wire, by a shock upon the board, or otherwise disturbing it; and we then find the temperature suddenly raised up to 32°. This shows plainly, that the water has a disposition to retain the quantity of latent heat, upon which its fluidity must immediately and necessarily depend; and it retains it with a certain degree of force, so as to keep the water fluid in a temperature below that in which it usually parts with the latent heat and congeals. By disturbing it, however, we instantly bring on the congelation, which cannot take place without an excitation of the latent heat; which then, being changed into the ordinary or moveable heat, raises the thermometer as usual. The quantity of heat discharged from the first small portion of ice formed in the water is sufficient to prevent any more latent heat from separating, and consequently from any more ice being produced till more of the sensible heat is abstracted.

This doctrine extends not only to such bodies as are actually converted from a solid to a fluid, or from
CHEMISTRY.

General Theory.

118 Heat the atmosphere, and enabled to rise in it. To account for the certain degree of heat below which every body is solid, the experiment being to show how far the evaporation of a fluid may be rendered specifically lighter than the surrounding fluid, the boiling point, but after the fluid gradually receives a sensible form, and keeps up the temperature, proving a source of specific heat, which is communicated to the neighbouring bodies as well as the surrounding air. The fixness and ductility of bodies depend on this also.

III. Evaporation. A third effect of the action of heat is that of converting bodies into vapour, by which they are rendered specifically lighter than the surrounding atmosphere, and enabled to rise in it. To account for this, many theories have been invented; but that of Dr Black, who accounts for it, as well as fluidity from the abstraction of latent heat, is now universally received. The circumstances by which he proves and illustrates his doctrine are the following:

1. When we attend to the phenomena of boiling water, in a tea kettle for instance, it may, when first put upon the fire, be at the temperature of 48° or 50°. In a quarter of an hour it will become heated to 212°. It then begins to boil, and has gained 162° of vapour in that time. Now, if the conversion of it into vapour depended on the quantity of sensible heat introduced, we might ask how long it will be necessary to raise it all in vapour? Surely another quarter of an hour should be sufficient; but this is far from being the case.

Dr Black made some experiments upon this subject in conjunction with another gentleman. Having the opportunity of what is called a kitchen-table or a thick plate of cast iron, one end of which was made sufficiently red-hot, they set upon this some iron vessels with circular flat bottoms, of about four inches diameter, and which contained a quantity of water. The temperature of the water was noted, as also when it began to boil; and when the whole of it was boiled away, it was found, that when set on the table its temperature had heat diminished very fast till it became opaque and almost in a latent state, for the iron plate contained equally hot, the whole time. The vessels were of different shapes, some of them cylindrical, some conical, others widening upwards; one of the designs of the experiment being to show how far the evaporation was retarded by the particular form of the vessels.

By suspending a thermometer in the mouth of one of the evaporating vessels, the heat of the steam was found to be exactly 212°; so that as the great quantity of heat absorbed was found neither to have remained in the water, nor to have been carried away by the steam in a sensible manner, we have nothing left to suppose, but that it flew off as one of the component parts of the steam in a latent state.

2. In an experiment to show the fixness of the boiling point of water, Dr Black inclosed some of that fluid in a strong vessel having a thermometer in it, and stopped close with a cork. By the application of heat to the cork he hoped now to be able to raise the thermometer some degrees above the boiling point, which would be the natural consequence of the confinement of the steam. When this was done, he pulled out the cork, and supposed that the water would now all fly out in vapour; but in this he was totally disappointed; a sudden and very tumultuous boiling ensued, which threw out some of the water; but though some quantity of steam like-wise flew, the quantity of water was not considerably diminished. The vessel had been heated to 20° above the boiling point, but almost instantly cooled down to 212°, when the cork was taken out.

3. Mr Watt, in making some experiments on the force of steam, had occasion to use Papin's digester, with a pipe proceeding from its side; the orifice of which was shut with a valve pressed down by one end of a lever. Thus he heated steam to 400° of Fahrenheit, and therefore had 5. Thus he heated steam to 420° above the boiling point, but almost instantly cooled down to 212°, when the cork was taken out.

4. The change of sensible into latent heat in the boiling water in vacuo, Mr Boyle took a quantity of water in vacuo determined by Mr Boyle's air-pump. In consequence of this it began again to boil, and continued boiling till it was only lukewarm, and it soon arrived at this temperature; so that in this case also the heat had disappeared during the conversion of the fluid into vapour. Others have repeated the experiment, as Boerhaave, Mufchenbroek, and Robison, Mr Robins, who lectures on chemistry in Glasgow, says that the heat diminishes very fast till it comes to 90° or 95°. Glen, which seems to be the boiling point of water in vacuo.

5. Thus also we may understand some curious experiments made by Dr Cullen upon ether and other volatile...
Theory.

General Effects of Heat.

Dr Cullen's experiments on cold produced by evaporation.

Mr Watt's experiments on the condensation of fluids in vacuo.

Heat expelled in great quantity by the condensation of vapour.

On this principle we may explain some curious experiments made by Mr Watt with regard to the evaporation of fluids in vacuo. That gentleman had formed a design of converting water into steam with less expense of fuel, which he imagined might be done by removing the preasure of the air from the water, which he thought would thus require a much smaller quantity of fuel to convert it into vapour. Dr Black, however, perceiving that only the small quantity ofensible heat the steam polysed could thus be carried off, informed him beforehand that his project would not be found attended with the advantages he imagined. The experiment, however, was made in the following manner: A still was procured of tinned iron, the body of which resembled that of a retort, with a vessel serving as a condenser; the whole apparatus being close, excepting a little hole in the extremity of the condensing vessel. He first exhausted this vessel of air by holding the condenser over the retort, in which some boiling water was contained, until it was entirely converted into steam. He then suddenly stopped the little hole, and removed the vessels from the fire; when, after they were cooled, there was a pretty perfect vacuum formed by the condensation of the steam. The retort was then put on the fire, and turned so that the pipe and condensing vessel should hang downward; and plunging them into cold water, he employed some persons to make experiments upon the cold produced by evaporation; and willing to repeat them himself in vacuo, he put some of the most volatile liquids under the receiver of an air-pump. One of these was ether. It was contained in a glass, in which there was also placed some water. When the air was extracted, the ether began to boil, and to be converted into vapour, till it became so very cold that it froze the water contained in the vessel, though the temperature of the room was about 50°. Here therefore there was a quantity of heat which disappeared all of a sudden; which it is plain could not be owing to its having any communication with that of the atmosphere or other cold bodies, as they could not render it colder than they were themselves. Either therefore is to be considered as a fluid so volatile, that were it not for the preasure of the atmosphere it would be perpetually in the state of vapour.

6. That this heat which enters into the vapour is not destroyed, but remains in a latent state, is easily proved; for we find that a great quantity of heat is expelled from vapour when it is condensed again to form the body it composed originally. This is easily ascertained by observing the quantity of heat communicated to the water in the refrigeratory of a still by any given quantity of liquid which comes over. Thus, if the refrigeratory contain 100 pounds of water, and the distillation be continued till only one pound has come over, suppose the water in the refrigeratory to have received 8° of heat; it is plain, that if the whole of the quantity thus received could be thrown into one pound of water, the latter would be heated to 800°; which is sufficient to make an equal space of iron red-hot. But that this quantity of heat is received by the water in the refrigeratory has appeared from several experiments, which show that water, by being converted into vapour, absorbs between 800° and 900° of heat.

Mr Watt's experiments on the evaporation of fluids in vacuo.

On this principle we may explain some curious experiments made by Mr Watt with regard to the evaporation of fluids in vacuo. That gentleman had formed a design of converting water into steam with less expense of fuel, which he imagined might be done by removing the preasure of the air from the water, which he thought would thus require a much smaller quantity of fuel to convert it into vapour. Dr Black, however, perceiving that only the small quantity ofensible heat the steam polysed could thus be carried off, informed him beforehand that his project would not be found attended with the advantages he imagined. The experiment, however, was made in the following manner: A still was procured of tinned iron, the body of which resembled that of a retort, with a vessel serving as a condenser; the whole apparatus being close, excepting a little hole in the extremity of the condensing vessel. He first exhausted this vessel of air by holding the condenser over the retort, in which some boiling water was contained, until it was entirely converted into steam. He then suddenly stopped the little hole, and removed the vessels from the fire; when, after they were cooled, there was a pretty perfect vacuum formed by the condensation of the steam. The retort was then put on the fire, and turned so that the pipe and condensing vessel should...
not mis of being made red hot. Dr Black has also frequently seen the vapour of water heated by throwing it into the alu- pit of a furnace, so as to produce a very large and transparent flame in rising up through the vent. There is reason therefore to conclude, that ignition is one of the more general effects of heat, only that some bodies are incapable of it until they be reduced to a state of vapour.

V. The last of the effects of heat here to be taken notice of is inflammation. It differs from ignition in this, that the bodies subject to the latter gradually grow cooler as soon as they are taken out of the fire, without undergoing any considerable change; while those subject to inflammation become continually hotter and hotter, communicating a vast quantity of heat to others, and undergoing a kind of decomposition themselves, infomuch, that by this means they have been thought to be reduced to their constituent principles or elements. Some substances indeed seem to be an exception to this, as in the open air they burn totally away, without leaving any residuum or producing any foot. These are spirit of wine, sulphur, and especially inflammable air; which last, by a proper mixture with dephlogificated air, may be totally consumed, that scarce a fifth part of the two will remain. On a careful examination of these substances, however, we find that there is by no means a total combination, or indeed, properly speaking, any combustion at all, at least if we measure the quantity of matter by the weight of the substance employed. Thus, if we are at pains to collect the vapour of burning spirit of wine, we will find, that an aqueous dew is collected, which sometimes equals the spirit of wine itself in weight. With regard to sulphur, the cace is still more evident; for the vapour of this, when collected, not only equals but greatly exceeds the weight of the sulphur employed; and on burning dephlogificated and inflammable air together, as much water is found to be produced as nearly equals the weight of both airs. In like manner, when we collect the ashes, water, foot, and oil, procured by burning any of the common inflammable substances, we will find, that they in general exceed the weight of the matter employed. The great waste of bodies by fire, therefore, is owing to the dissipation of the volatile principles they contain, which are carried off and rendered invisible by being mixed with the atmosphere.

The processes of inflammation have long been explained from the presence of a substance called phlogiston in those bodies which are subject to it, and which is supposed to be the same in all bodies belonging to this class; the differences between them arising from the principles with which it is combined. This doctrine, which was first introduced by Stahl, has given occasion to such various and discordant theories, that the existence of phlogiston has been lately denied altogether by M. Lavoisier, who brought in a new method of solving the phenomena of fire, heat, and ignition, without any allusion from this principle.

The foundation of M. Lavoisier’s doctrine is the increase of weight in metals by calcination. This increase he finds to be precisely, or very nearly so, proportional to the decrease of weight in the air in which they are calcined. His theory, therefore, is, that in the act of calcination, the pure part of the air, which he calls the acidifying or oxygenous principle, unites with the metal, and converts it into a calx. In effects of like manner, in substances truly inflammable, the heat and flame are supposed to proceed from the union of the pure air, or the oxygenous principle, with the substance, and converting it into those principles which are found to remain after inflammation. Thus the increased weight of the substance is easily accounted for; while the inflammation, in his opinion, is nothing more than a combination of the inflammable body itself with pure air, which has an attraction for it: and in confirmation of that it is urged, that when combustion is performed in empyreal or dephlogificated air, the whole of the latter is absorbed; but in common atmospheric air only one-fourth, being the quantity of pure air contained in it.

Other arguments in favour of this opinion are, that the calxes of the perfect metals may be reduced without addition by the mere emission of the oxygenous principle, (dephlogificated air); by an union with which it affumes the form of a calx. Thus he evades a very strong argument used by the opposite party; who adduced, as a proof of the existence of phlogiston, the calxes of perfect metals without addition. A dispute between M. Lavoisier and Dr Priestley concerning the reduction of the whole of a chemic calx, formed by an union with the nitrous acid without addition; the Doctor be- lieved that the whole could not be reduced by mere heat, but that a very perceptible quantity was always lost: but on a thorough examination of the subject, the truth seemed rather to lie on M. Lavoisier’s side. See AEREOLOGY.

Another theory, somewhat similar to that of Lavoisier’s, has been published by Dr Lubbock, in an Inaugural Dissertation in 1784. In this he supposes two kinds of matter to exist in the universe; one he calls the principle properum, the other the principle for- bile; and it is this latter, which, according to our author, is the principle of mutability, or which by being united in various proportions with the other, forms bodies of all the different kinds we see in nature. It is this principle, therefore, which he supposes to be ab- sorbed in the calcination of metals, and not empyreal air, as M. Lavoisier supposes; and he contends, that this same principle extends throughout the whole sy- stem of nature, even to the utmost celestial bounds.

It would exceed the limits of this treatise to give an account of the various theories which have been invent- ed, and the arguments used for and against them; nor is it in any measure do any of the preceding disqui-sites have reduced the dispute into a much narrower compass than before, and furnished the most decisive arguments in favour of the existence of phlogiston.

The greatest objection to the belief of this prin- ciple was, that it could neither be seen nor felt by our senses directly, nor discover itself indirectly by the weight it communicated to the bodies with which it was united; on the contrary, the latter always became lighter in proportion to the quantity they contained: so that it was imagined, instead of being pofterious of itself, any specific gravity of its own, to be a principle of po- gravity. This idea, such as that of heat or light may be rea- sonably supposed. This objection, however, is now entirely removed; and phlogiston in the abstract is found.
Theory of the effect of Heat.

Common charcoal and phlogiston the same.

Gwu:d man, certain its quantity with the union of spirit of wine with the metal), and which like produced by the charcoal, is enabled to been discovered by Dr PRIESTLEY. Still, it was inferred by the French philosophers and others, that no facts had been adduced against M. Lavoisier, nor any decisive proofs of this identity given by Mr Kirwan. It was sufficient at present to mention, that he has been able to convert the purest spirit of wine, and one of the hardest metals, viz. copper, as well as several others, into a substance entirely resembling charcoal; that by means of the heat of a burning glaas in vacuo, he has distilled this metallic charcoal, as well as the common kind, entirely into inflammable gas, which is the subject of water, and the aid of the charcoal, is enabled to resist conflagration in the common way. This inflammable air, when absorbed by metallic calces, again reduces them to their metallic form, and perhaps is the true solvent of it; and by a combination with the element of heat, with the aid of the charcoal, is enabled to resist conflagration in the common way.* This inflammable air, when absorbed by metallic calces, again reduces them to their metallic form: so that here is one fact by which the phlogiston not only appears to our senses, but we are able to ascertain its quantity with the utmost precision. Nor can it here be any objection, that the reduced metal is lighter than the calx; for this only proves that the metallic earth, which a calx is united to a heavy ingredient (the basis of dephlogisticated air), and in the latter to a light one, viz. charcoal, the basis of inflammable air.

Another case in which the existence of phlogiston is made equally evident to our senses, and where no such objection can occur, is related under the article AEREOLOGY, n° 112. It is there shown, that "by the loss of one grain of charcoal of copper (formed by the union of spirit of wine with the metal), and which like charcoal was consumed without having any residue, he reduced four ounce-measures of dephlogisticated air till only one-ninth remained unabsorbed by water; and, again, with the loss of one grain and a half of charcoal, and an half measures of dephlogisticated air were reduced till five and an half measures were pure fixed air."—Here, then, is an absolute and undeniable evidence, that fixed air is composed of dephlogisticated air, and charcoal or phlogiston, and elementary fire. There were no other ingredients present, and the charcoal must either have been annihilated or dissolved in the manner just mentioned: but the superior weight of the fixed air evidently shows that some ingredient had been added to the dephlogisticated air; and which increased was more than we can

Suppose to arise from the condensation of the dephlogisticated air during the operation, for this sometimes amounted to no more than one-thirtieth part.

The strongest objection which can be made against the doctrine of phlogiston may be drawn from the total consumption of pure air in certain cases of combustion, for instance, in the case of phosphorus, inflammable air, and iron. It must be observed, however, that in no case whatever is the air totally consumed; and in that of inflammable air water is produced by the union of the basis of the latter, that is charcoal, with the basis of dephlogisticated air, the oxygeneous principle of M. Lavoisier, and which appears to be one of the component parts of Water. In the case of phosphorus, the latter is converted into an acid; and in all probability a quantity of water is also produced, by which part of it is converted into crystalline flowers. The case of the iron, therefore, alone remains to be considered. Dr Priestley's experiments on this subject are related at length under the article AEREOLOGY, n° 67 et seq. In them the iron burnt briskly in dephlogisticated air, which, according to the common theory, should have indicated the expulsion of a great quantity of phlogiston; yet the whole residuum, of which the fixed air, produced by the supposed union of the phlogiston or principle of inflammability, was only a part, scarce amounted sometimes to one-fourteenth of the air originally employed.

The argument, however, instead of contradicting the existence of phlogiston, only shows, that in some cases the diffipation of a very small quantity of phlogiston is necessary to inflammation; or that the aerial principle may combine with the iron in its metallic state. In this case only a very little quantity of the phlogiston of the iron was diffipated; for it was not reduced to a calx, but to that kind of Scor!:e iron is not reduced to a calx by burning in red-hot with an hammer. A decisive proof of this was had by uniting iron thus combined with the basis of dephlogisticated air with inflammable air. By this the metal was indeed reduced to perfect iron again, but water was produced at the same time. Water produced from the union of the bases of the two airs, that is one of inflammable air being capable of furnishing a superfusum quantity, which united with the other into the form of a fluid.

The existence of phlogiston being thus proved, and its nature ascertained, we may now proceed to deter- heat produce the question, Whether the great quantity of heat produced by the combustion of inflammable bodies...
Heat may enflame and each other. Too great the same air has not only the rational idea of the manner in which inflammation is generally accomplished, but see why a fire may be put out both by too great a quantity of fuel, and by too great a quantity of air, which, by furnishing a greater quantity of phlogisticated bodies, affords an opportunity for the evolution of a greater quantity of heat. On the other hand, when the quantity of air is too great, the phlogisticated air is too much dispersed, the flame is higher and the fire goes out. From this theory, which is farther illustrated under the articles Fire, Flame, Heat, Phlogiston, &c, we may not only have a rational idea of the manner in which inflammation is generally accomplished, but see why a fire may be put out both by too great a quantity of fuel, and by too great a quantity of air. We may also see why the solar beams and electric fluid, which contain no phlogisticated matter, excite a much more powerful heat than any we can raise in our hot- telt furnaces. The difference between ignition and inflammation will now likewise appear; such bodies as are capable only of ignition containing little or no phlogiston, but inflammable bodies a great deal. The following table shows the most remarkable destinations of heat from the conglomeration of mercury to that of Wedgewood's hottest furnace.

| Mercury freezes at | 40 |
| Weak spirit of wine | 32 |
| Brandy at | 10 |
| Cold produced by snow and salt mixed | 0 |
| Strong wine freezes at | 20 |
| Vinegar freezes at | 27 |
| Water freezes at | 32 |
| Temperature of spring and autumn | 50 |
| Ordinary summer heat | 65 |
| Sultry heat | 75 |
| Heat of human blood | 97 to 100 |
| Feverish heat | 188 |
| Bees wax melts | 142 |
| Serum coagulates | 156 |
| Spirit of wine boils | 174 |
| Water boils | 212 |
| Tin melts | 408 |
| Bismuth melts | 460 |
| Oil of vitriol boils | 550 |
| Oil of turpentine boils | 561 |
| Lead melts | 585 |
| Quicksilver and linseed-oil boil | 600 |
| Iron begins to shine in the dark | 635 |
| Iron shies briskly in the dark | 750 |
| Iron shies in the twilight | 884 |

Greatest heat of Wedgewood's small air-furnace 21877
Extremity of the scale of his thermometer 32277

**SECT. II. Of the Doctrine of Elective Attraction, and of the different Objects of Chemistry.**

Before we proceed to give a general theory of the Chemical changes which happen upon the mixtures of different attraction, bodies together, or expelling them singly to heat, we must observe, that all depend on certain qualities in bodies, by which some of them are apt to join together, and to remain united while they have an opportunity. The cause of these qualities is totally unknown; and therefore philosophers, after the example of Sir Isaac Newton, have expressed the apparent effect of this unknown cause by the word attraction. From them the word has been adopted by the chemists, and is now generally used in speaking of the phenomena which are observed in the mixture of different substances; but to distinguish it from other kinds, it is usually called Elective.

This attraction is not equally strong between all substances; in consequence of which, if any body is composed of two others, and another is preferred to it which has a greater attraction for one of the component parts than they have for one another, the substance will be compounded. A new compound is then formed by the union of that third substance with one of the component parts or elements (if we please to call them so) of the first. If the attraction between the body supersedes and either of the component parts of the other is not so strong as that between themselves, no decomposition will ensue; or if the third substance is attracted by both the others, a new composition will take place by the union of all the three.

The objects of chemistry, as we have already observed, are so various, that an enumeration of them all is impossible. To save the mind, therefore, when speaking of them, and render more useful any thing that is said or written on chemistry, it is necessary to divide them into different classes, comprehending in each class those bodies which have the greatest resemblance to one another, and to which one common rule applies pretty generally. — The division formerly used, was that of vegetables, animals, and minerals, but this has been thought improper, as there are many substances in each of those kingdoms which differ very widely from one another, and which are by no means subject to the same laws. The most approved method,
ChE M I S T R Y.

SECT. III. Salts.

SALTS are either fusible, that is, capable of abiding the fire, and melting in a strong heat, without being dis sipated; or volatile, that is, being dispersed in vapour with a small heat. Their other properties are, that they are soluble in water: not inflammable, unless by certain additions; and give a sensation of taste when applied to the tongue.

The most general characteristic of salts is, that they are all soluble in water, though some of them with much more difficulty than others. Most of them have likewise the property of forming themselves, in certain circumstances, into solid transparent maelies of regular figures, different according to the different salt made up of, and which are termed cRYSTALS of that salt. In this state they always contain a quantity of water; and therefore the utmost degree of purity in which a salt can be procured, is when it has been well crystallized, and the crystals are freed of their superfluous moisture by a gentle heat. They generally appear then in the form of a white powder.

In the solution of salts in water, the first thing observable is, that the water parts with the air contained in it; which immediately rises to the top in the form of bubbles. This, however, is most remarkable when the salt is in the dry form we have just now mentioned, because there is always a quantity of air entangled among the interfaces of the powder, which rises along with the rest; and this discharge of air is sometimes so great, as to be mistaken for an effervescence. From this, however, it is essentially different. See EFFERVESCENCE.

Another thing observable in the solution of salts is, that a considerable change happens in the temperature of the water in which they are dissolved; the mixture becoming either a good deal warmer or colder than either the salt or the water were before. In general, however, there is an increase of cold, and scarce any salt produces heat, except when it has been made very dry, and deprived of that moisture which it naturally requires; and thus the heating of salts by being mixed with water may be explained on the same principle with the heat produced by quicklime. See QUICKLIME.

After salt has been dissolved in a certain quantity by water, no more of that salt will be taken up unless the water is heated; and as long as the heat continues to increase, the salt will be dissolved. When the water boils, at which time it has attained its greatest heat, and will take up no more salt, it is then said to be SATURATED with that salt. This, however, does not prevent it from taking up a certain quantity of another salt, and after that perhaps of a third, or fourth, without letting go any of the first which it had dissolved. How far this property of water extends, has not yet been ascertained by experiments.

To the above rule there is only one exception known as yet; namely, common sea-salt: for water dissolves it in the very same quantity when cold as when boiling hot. It has been said by some, that all deliquescent salts, or those which grow moist on being exposed to the air, had the same property: but this is found to be a mistake.

This property of solubility, which all the salts possess in common, renders them easily miscible together; and the property by which most of them shoot into crystals, renders those easily separable again which have no particular attraction for one another. This is likewise rendered still more easy by their requiring different proportions of water, and different degrees of heat, to suspend them; for by this they crystallize at different times, and we have not the trouble of picking the crystals of one out among those of the other.

The manner in which the solution of salts in water is effected, is equally unaccountable with most of the other operations of nature. Sir Isaac Newton supposed that the particles of water got between those of the salt, and arranged them all at an equal distance from one another; and from this he also accounts for the regular figures they assume on passing into a crystalline form; because, having been once arranged in an orderly manner, they could not come together in disorder, unless something was to disturb the water in which they were suspended; and if any such disturbance is given, we find the crystals are by no means so regular as otherwise they would have proved. Others have thought that these figures depend on a certain PARITY in the very small particles into which the salt is resolved when in a state of solution. Those things, however, are merely conjectural; neither is it a matter of any consequence to a chemist whether they are right or wrong.

Though solution is that operation which salts undergo the most easily, and which should seem to affect them the least of any, a repetition of it proves never less injurious to them, especially if it is followed by quick evaporation; and the salt, instead of being crystallized, is dried with a pretty strong heat. Newman relates, that a pound of sea-salt was reduced, by 13 solutions and evaporation, to half an ounce; and even that was mostly earth. Where solution is required, therefore, it ought always to be done in close vessels, in which also the subsequent evaporation should be performed, (see Evaporation); and in all cases where crystallization is practicable, it ought to be preferred to violent evaporation.

The two great divisions of salts are into acids and alkalies. The former of these are known by their peculiar taste, which is called acid or sour. They are not found in a solid form; neither are any of them, except the acids of vitriol, of tartar, of phosphorus, and of borax, capable of being reduced to solidity. The others, when highly concentrated, that is, brought to the utmost degree of strength of which they are capable, always become an invisible vapour, permanently elastic, until it comes in contact with water, or some other sub stance with which they are capable of uniting. For such acids the name of salts seems less proper, as we can scarcely say that a vapour, which is already much more fluid than water, can be dissolved in that element.

The acids are divided into the mineral, the vegetable, and the animal; expressing their different origin, or where they are most commonly to be found. The mineral acids are commonly reckoned three: the vi-
In the vegetable kingdom affords only two distinct species of acids, at least without the assistance of some chemical operation. The one appears fluid, and when concentrated to the utmost degree becomes an invisible vapour. This is produced from fermented liquors, under the name of vinegar. An acid similar to this, and which is thought not to be essentially different from it, is extracted from mossy vegetables by distillation with a strong fire. The other is likewise a consequence of fermentation; and crusts on the bottom and sides of caffins in which wine is put to separate itself. In its crude state it is called tartar; and when afterwards purified, is called the cream, or crystals, of tartar. As for the various acids produced in the different chemical processes to be afterwards related, we forbear to mention them at present, it being justly suspected that some of them are artificial.

The animal acids, which have hitherto been discovered, are only two; the acid of ants and that of urine, which is also the acid of phosphorus. The first of these is volatile; and consequently must be supposed a vapour when in its strongest state; the other is exceedingly fixed; and will rather melt into glafs than rise in vapours. Besides these, it is said an acid is contained in blood, in wafps, bees, &c.; but no experiments have as yet been made on these to determine this matter with any degree of precision.

The alkalies are of two kinds; fixed and volatile. The fixed kind are subdivided into two; the vegetable, and mineral or fotal alkali. The vegetable is so called, because it is procured from the ashes of burnt vegetables; the fotal, because it is found native in some places of the earth, and is the basis of sea-falt, which in some places is dug out of mines in vast quantity. They are called fixed, because they endure a very intense degree of heat without being disipated in vapour, so as even to form a part of the composition of glafs. The volatile alkali is generally obtained by distillation from animal substances. In its pure state this alkali is perfectly invisible; but affects the sense of smelling to such a degree, as not to be approached with safety.

The acids and alkalies are generally thought to be entirely opposite in their natures to one another. Some, however, imagine them to be extremely similar, and to be as it were parts of one substance violently taken from each other. Certain it is, that when separated, they appear as opposite to one another as heat and cold. Their opposite action indeed very much resembles that of heat and cold, even when applied to the tongue; for the alkali has a hot, bitter, burning taste, while the acid, if not considerably concentrated, always gives a sensation of coldness. In their action too upon animal substances, the alkali dissolves, and reduces the part to a mucilage; while the acid, if not very much concentrated, tends to preserve it incorruptible.

If an alkaline salt, and moderately strong acid in a liquid state, be mixed together, they will immediately unite; and, provided the alkali has not been deprived of its fixed air, their union will be attended with a very considerable effervescence: (see Aerology.) If the alkali has been deprived of air, no effervescence will ensue, but they will quietly mix together; but if a due proportion of each has been added, the liquor will neither have the properties of an acid nor an alkali, but will be what is called neutral. The bringing the liquor into this state, is called saturating the acid or alkali, or combining them to the point of saturation.

If the liquor after such a saturation be gently evaporated, a saline mass will be left, which is neither an acid nor an alkali, but a new compound formed by the union of the two, and which is called a perfect neutral salt. The epithet perfect is given it, to make a distinction between the salts formed by the union of an acid and an alkali, and those formed by the union of acids, with earthy or metallic substances; for these will likewise unite with acids, and some of the compounds will crystallize into regular figures; but, because of their weaker union with these substances, the salts resulting from combinations of this kind are called imperfect.

All acids, the volatile sulphurous one excepted, change the blue infusions of vegetables, such as violet, to a red; and alkalies, as well as some of the mineral or fotal acids, as to as like aCts are changed by acids and alkalies.

Though between every acid and alkali there is a very strong attraction, yet this is far from being the same in all; neither is it the same between the same acid and alkali in different circumstances of the acid.

When the acids are in a liquid state, and as free as possible of inflammable matter, between which and the nitrous and vitriolic acids there is a very strong attraction, the vitriolic will expel any of the rest from an alkaline basis, and take its place. Thus, if you combine the acid of sea-falt, or marine acid, to the point of saturation, with the fotal alkali, a neutral salt will be formed, which has every property of common salt: but, if you pour on a certain proportion of the vitriolic acid, the acid of sea-falt will immediately be expelled; and the liquor, upon being evaporated, will contain not the neutral salt formed by an union of the marine acid with the alkali, but another consisting of the vitriolic acid joined with that alkali, and which has quite different properties from the former.

When the acids and alkalies are applied to one another in a liquid state, the vitriolic acid always shows itself to be the most powerful; but when applied in a solid form, and urged with a violent heat, the case is very much altered. Thus, the acid of horax, commonly called sal fationum, is so weak as to be disregarded from its basis by every acid applied in a liquid form, of that tartar alone excepted; but if even the vitriolic acid combined with an alkali be mixed with this weak acid, then exsiccated, and at last urged with a vehement fire, the vitriolic acid will be diffugaged from its basis, and rise in vapours, leaving the weaker acid in precision of the alkali. The same thing happens on adding the phosphoric or ursine acid,
Theory.

Chemistry.

SALTS.

Acids unite with phlogiston.

With metals and earth.

Elective attractions.

The acids have the property of uniting themselves to many other substances besides fixed alkalies, and forming neutral compounds with them. Of these the chief is the principle of inflammability or phlogiston. In the vitriolic, nitrous, and phosphoric acids, the attraction for this principle is very strong; so great, that the two former will even leave a fixed alkali to unite with it. In the marine acid it is less perceptible; in the liquid vegetable or animal acid still less; and in the acid of tartar, and salted evaporia, not at all.

Besides this, all acids will dissolve metallic and earthy substances: with these, however, they do not in general unite so firmly with alkaline salts; nor do they unite so strongly with metals as with earths. In general, therefore, we may expect, that after having dissolved a metal in any acid whatever, if we add an earthy substance to that solution, the acid will quit the metal, which it had before dissolved, to unite with the earth. In this case the solution will not be clear as before, but will remain muddy, and a quantity of powder will fall to the bottom. This powder is the metallic substance itself, but deprived of one of its component parts; and in this case it is said to precipitate in the form of a calx.

If to this new solution of the earthy substance in an acid liquor, a volatile alkaline salt, not deprived of its fixed air, is added, the acid will quit the earth, and unite with the alkaline salt. The earth thus disengaged will again precipitate, and lie at the bottom in fine powder, while the volatile alkali and acid remain combined together, and the liquor again becomes clear.

The attraction between volatile alkalies and acids is considerably less than between fixed alkalies and the same acids. If, therefore, a fixed alkali be now added to the liquor, the volatile alkali will be separated, and the acid will unite with the fixed alkali. The volatile alkali indeed, being perfectly soluble in water, cannot precipitate, but will discover its separation by the pungent smell of the mixture; and upon evaporating the liquor, the volatile alkali will be disdiluted, and a saline mafs, consisting of the acid and fixed alkali, will remain.

Lastly, if the acid employed was the nitrous, which has a strong attraction for the principle of inflammability, if the saline mafs be mixed with a proper quantity of inflammable matter, and exposed to a strong heat, the acid will leave the alkali with vast rapidity, combine with the inflammable matter, and be destroyed in flame in a moment, leaving the alkali quite pure.

Though the above-mentioned effects generally happen, yet we are not to expect that they will invariably prove the same whatever acid is made use of; or even that they will be the same in all possible circumstances in which the same acid can be used. The acid of tartar is one exception, where the general rule is in a manner reversed; for this acid will quit a fixed alkali for an earth, especially if calcined, and even for iron. If lead, mercury or silver, are dissolved in the nitrous acid, and a small quantity of the marine acid is added, it will separate the stronger nitrous acid, and fall to the bottom with the metals in form of a white powder. The vitriolic acid, by itself, has a greater attraction for earthy substances than for metals; and greater still for fixed alkaline salts than for either of these: but if quicksilver is dissolved in the nitrous acid, and this solution is poured into a combination of vitriolic acid with fixed alkali, the vitriolic acid will quit the alkali to unite with the quicksilver. Yet quicksilver by itself cannot easily be united with this acid. The reason of all these anomalies, however, is fully explained in the following section.

§ 1. Of the Operations of Solution and Precipitation.

The chemical solution of solid bodies in acid or other menstrua, is a phenomenon which, though our familiarity with it has now taken off our surprise, must undoubtedly have occasioned the greatest admiration and astonishment in those who first observed it. It would far exceed the limits of this treatise to speak particularly of all the various circumstances attending the solution of different substances in every possible menstrum. The following are the most remarkable, collected from Mr Bergman's Differtation on Metallic Precipitates.

1. On putting a small piece of metal into any acid, it is dissolved sometimes with violence, sometimes gently, according to the nature of the menstrum and of the metal to be dissolved.

2. The nitrous acid is the most powerful in its action.
Solution and Precipitation.

Nitrous acid, the most violent in its operation, has no solution by the nitrous acid, either by dilution or cold, or both. In other cases, however, as when put to gold or platina, the nitrous acid has no effect until it be united with the marine, when the mixture acts upon those metals, which neither of the acids singly would touch.

3. The action of the vitriolic acid, though in the highest degree of concentration, is more weak. It does not readily attack silver or mercury unless assiduously boiled, nor will even that be sufficient to make it act upon gold or platina.

4. The action of marine acid, unless on particular substances, is still more weak; but when depholotificated, or deprived of part of the phlogiston essential to its constitution as an acid, it acts much more powerfully, and diffuses all the metals completely.

5. The other acids, as those of flour, borax, with such as are obtained from the animal and vegetable kingdoms, are much inferior in their powers as solvents, unless in very few instances.

6. Metals vary very much in their degrees of solubility; some yielding to almost every menstruum, and others, as has been already observed, being scarce acted upon by the most powerful.

7. Zinc and iron are of the former kind, and gold and silver of the latter, eluding the marine; and gold, unless in one particular case, viz. when assiduously boiled in a close vessel, the action of the nitrous acid also.

These metals, however, which in their perfect state resist the action of the most powerful menstrua, may be diffolved much more readily when deprived of a certain quantity of their inflammable principle. But though the separation of this principle in some degree renders metals more soluble, the abstraction of too much of it, particularly in the case of iron and tin, renders these metals almost entirely insoluble. Manganese is the most remarkable instance of this power of the phlogitic principle, in depriving metals of their inflammability by its absence, or restoring it to them by its presence; for this substance, when reduced to blackness, cannot be dissolved by any acid without the addition of some inflammable matter; but when by the addition of phlogiston it has become white, may be dissolved in any acid.

8. The dissolution of metals by acids, even to their very last particle, is attended with a visible effervescence; this is more perceptible according to the quickness of the solution; but more obscure, and fearfully to be seen at all, when the solution proceeds slowly.

9. The elastic fluids extracted by these solutions are various, according to the nature of the acid and of the metal employed. With the nitrous, the fluid produced is commonly that called nitrous air; with vitriolic and marine acids the produce is sometimes inflammable, sometimes otherwise, according to the nature of the metal acted upon.

10. Heat in a greater or smaller degree is always produced during the dissolution of metals; and the degree of it is in proportion to the quantity of the matter and the quickness of the solution; hence, in small quantities of metal, and when the solution proceeds very slowly, the temperature of the metal is scarcely altered.

11. The calxes of metals either yield no air at all, or only the aerial acid, unles when urged by a violent heat almost to ignition; when, by means of vitriolic or nitrous acid, they yield a quantity of pure air, after other elastic fluids, such as vitriolic, nitrous, or phlogotitic air. None of the depholotificated air is usually produced by the marine acid in conjunction with metallic calxes.

12. The solutions of some metals are coloured, others are not. The colour of the former is only that which is proper to the calx, but rendered more vivid by the moisture. Thus solutions of gold and platina are yellow; those of copper, blue or green; solutions of nickel of a bright green; but those of cobalt are red, although the calx is black. We may observe that even this red colour may be heightened to blackness. Iron moderately calcined is green, but this rarely continues upon further depholotification. The white calxes of silver, lead, tin, bismuth, arsine, antimony, and manganese, are diffolved without colour; but solutions of lead, tin, and antimony, are somewhat yellow, unless sufficiently diluted. Mercury, however, forms a singular exception to this rule; for the orange-coloured calx of this metal forms a colourless solution. The metals yielding coloured solutions are gold, platina, copper, iron, tin, nickel, and cobalt; the reft, if properly depurated, give no tinge. A solution of silver is sometimes of a blue or green colour at first; although there be no copper present; the vitriolic acid becomes blue with copper; the nitrous may be made either blue or green at pleasure; the marine varies according to the quantity of water with which it is diluted. Manganese, when too much depholotificated, renders both the vitriolic and marine acids purple.

With regard to the cause of chemical solutions, our author observes, that though attraction must be looked upon as the fundamental cause, yet we may also lay it down as a maxim, that no metal can be taken up by an acid, and at the same time preserve the whole quantity of phlogiston which was necessary to it in its metallic state. A certain proportion of the principle of inflammability therefore may be considered as an obstacle which must be removed before a solution can be taken place. Thus, of all the acids, the nitrous attracts phlogiston the most powerfully, and separates it even from the vitriolic. A proof of this may be had by boiling sulphur slowly in concentrated nitrous acid.

At length all its phlogiston may be separated, and the vitriolic acid will remain, deprived of its principle of inflammability. The extraordinary solvency powers of this acid, therefore, is conformed to the peculiarity of its nature in this respect. For this menstruum dissolves metals for solution with the greatest ease, most commonly without any assistance from external heat; which in some instances would be hurtful, by separating too much of phlogiston, as appears in the case of iron, tin, and antimony; all of which may be far depholotificated by the nitrous acid, as to be rendered extremely soluble. The difficulty of solution for this reason it is very often soluble or necessary, as has already been observed, to temper the activity with heat.

Theory.

Solution and Precipitation.

190 Heat produces the most violent in its operation, has no solution by the nitrous acid, either by dilution or cold, or both. In other cases, however, as when put to gold or platina, the nitrous acid has no effect until it be united with the marine, when the mixture acts upon those metals, which neither of the acids singly would touch.

191. The calxes of metals either yield no air at all, or only the aerial acid, unless when urged by a violent heat almost to ignition; when, by means of vitriolic or nitrous acid, they yield a quantity of pure air, after other elastic fluids, such as vitriolic, nitrous, or phlogotitic air. None of the depholotificated air is usually produced by the marine acid in conjunction with metallic calxes.

192. The solutions of some metals are coloured, others are not. The colour of the former is only that which is proper to the calx, but rendered more vivid by the moisture. Thus solutions of gold and platina are yellow; those of copper, blue or green; solutions of nickel of a bright green; but those of cobalt are red, although the calx is black. We may observe that even this red colour may be heightened to blackness. Iron moderately calcined is green, but this rarely continues upon further depholotification. The white calxes of silver, lead, tin, bismuth, arsine, antimony, and manganese, are diffolved without colour; but solutions of lead, tin, and antimony, are somewhat yellow, unless sufficiently diluted. Mercury, however, forms a singular exception to this rule; for the orange-coloured calx of this metal forms a colourless solution. The metals yielding coloured solutions are gold, platina, copper, iron, tin, nickel, and cobalt; the reft, if properly depurated, give no tinge. A solution of silver is sometimes of a blue or green colour at first; although there be no copper present; the vitriolic acid becomes blue with copper; the nitrous may be made either blue or green at pleasure; the marine varies according to the quantity of water with which it is diluted. Manganese, when too much depholotificated, renders both the vitriolic and marine acids purple.

With regard to the cause of chemical solutions, our author observes, that though attraction must be looked upon as the fundamental cause, yet we may also lay it down as a maxim, that no metal can be taken up by an acid, and at the same time preserve the whole quantity of phlogiston which was necessary to it in its metallic state. A certain proportion of the principle of inflammability therefore may be considered as an obstacle which must be removed before a solution can be taken place. Thus, of all the acids, the nitrous attracts phlogiston the most powerfully, and separates it even from the vitriolic. A proof of this may be had by boiling sulphur slowly in concentrated nitrous acid.

At length all its phlogiston may be separated, and the vitriolic acid will remain, deprived of its principle of inflammability. The extraordinary solvency powers of this acid, therefore, is conformed to the peculiarity of its nature in this respect. For this menstruum dissolves metals for solution with the greatest ease, most commonly without any assistance from external heat; which in some instances would be hurtful, by separating too much of phlogiston, as appears in the case of iron, tin, and antimony; all of which may be far depholotificated by the nitrous acid, as to be rendered extremely soluble. The difficulty of solution for this reason it is very often soluble or necessary, as has already been observed, to temper the activity with heat.
Theory.

CHEMISTRY.

Solution and precipitation.

197 Why the vitriolic acid cannot act on lead, silver, &c., without a boiling heat.

198 Why marine acid acts on some metals and not on others.

199 Why some metals are more fusible than others.

200 Why nitrous acid precipitates a solution of tin or antimony.

201 Different kinds of air produced during the diffusion of metals.

202 Pure vitriolic acid cannot be reduced into an aerial form but by a combination with phlogiston.

Activity of this menstruum by water. The vitriolic acid requires a boiling heat before it can act upon silver or mercury. The reason of this, that by means of the heat, the watery part of the menstruum is diminished, its power is thereby increased, and the connection of the metallic earths with the inflammable principle diminished. Marine acid, which contains phlogiston as one of its constituent principles, must necessarily have little or no effect on these metals which retain their principle of inflammability very obtrusively. But its watery part being diminished by boiling, it assumes an aerial form, and powerfully affects a larger quantity of phlogiston than before; so that in a vaporous state it will dissolve metals, particularly silver and mercury, which in its liquid form it would scarce be brought to touch. When dephlogisticated as much as possible, it attracts phlogiston with prodigious avidity, disolving all metals by its attraction for their phlogiston, and, uniting the inflammable principle to itself, resumes the ordinary form of marine acid. When dephlogisticated by means of nitrous acid in aqua regia, it dissolves gold and platina. On the same principle we account for its inferiority in power to the other acids.

It has already been observed that the metals differ much in their degrees of solubility, which is owing to the various degrees of force with which they retain their phlogiston. Those called perfect metals effectually react calcination in the dry way. In this operation, the fire on the one hand, the great cause of the volatility of bodies, and continually endeavours to expel the phlogiston; on the other hand, the bases of the dephlogisticated part of the atmosphere (the acidifying principle of M. Lavoisier, and the primum foraneum of Dr Lübbeck) attracts the calx strongly. Experience, however, shows, that these two forces united, cannot decompose gold, silver, or platina to any considerable degree. All the other metals yield to these forces when united, but not singly. Iron and zinc retain their inflammable principle so highly, that any acid immediately acts upon them; but if the other metals be properly prepared for solution by being calcined to a certain degree, the acid will immediately take them up. Any further privation, however, would be injurious, and precipitate what was before dissolved. Thus the nitrous acid, when added to a solution of tin or antimony in marine acid, by its extraordinary attraction for phlogiston carries off such a quantity of it, that the calxes of the metals are immediately precipitated.

The various elatic fluids which resemble air, and which are produced in plenty during the dissolution of metals, may be reduced to the following: the first extracted by the vitriolic, nitrous, and marine acids, fluoric acid, vinegar, alkaline salts, and hepatic sulphur. Pure vitriolic acid exposed to a violent heat, is indeed resolved into vapours, but of such a nature, that when the heat is gone, they condense again into an acid liquor of the same nature as before. But if any substance be added which contains phlogiston in a separable state, an elatic fluid is produced by means of fire, which is scarcely condensible by the most extreme cold, unless it comes in contact with water. This is called the volatile sulphurous acid, or vitriolic acid air, which may be totally absorbed by water. In this cafe the bond of union betwixt it and the phlogiston is so weak, that the latter soon flies off totally, and solution common vitriolic acid is regenerated.

The nitrous acid undergoes a similar change in a more obvious manner. Let a piece of silver, for instance be put into a dilute nitrous acid, and the surface face of the metal will instantly be covered with innumerable bubbles, which arling to the top of the liquor, there burst; and if collected, are found to be nitrous air. The nitrous acid faturates itself with phlogiston more completely than the vitriolic; therefore the elatic fluid produced, or nitrous air, does not unite with water, and scarce retains any vestige of an acid nite with nature. The vitriolic acid, however, differs from the nitrous in this respect, that the phlogiston is absorbed by the latter even beyond the point necessary to oblige its acid nature. In proof of this, this author adduces the decomposition of hepatic by means of nitrous air.

The marine acid exhibits different phenomena. Phlogiston, as it naturally contains phlogiston, and therefore can be exhibited by its means be resolved into a kind of air resembling similar to that produced by the vitriolic acid when artificially united to the same principle, and which has the same property, viz. that of remaining permanently elastic as long as it is kept from the contact of water. But as the acid we speak of naturally contains phlogiston, there is no necessity of adding more to produce this effect. In the mean time, the marine as well as nitrous air, when in its expanded state, attracts phlogiston, and with wonderful avidity.

When the marine acid is dephlogisticated, it yields of the another elatic fluid of a reddish brown colour, having phlogisticated an odour like that of warm aqua regia. This does not unite with water, or only in very small quantity; and by the addition of a proper proportion of phlogiston may be reduced again to common marine acid. It is said that the marine acid may be dephlogisticated by lead as well as by manganece, the nitrous acid, and arsenic.

The fluoric acid abounds with phlogiston, and therefore may, without any adventitious matter, be reduced to an elatic fluid. This air is easily distinguished from all others by its corroboration of glafs whilfht hot.

Vinegar also contains phlogiston; and for that reason, when well dephlegmated, may be reduced without gas or air being put into a permanently elatic fluid, called acetous air.

All these fluids seem to be nothing else, according to Mr Bergman, than the acids themselves expanded by phlogiston. "Perhaps (says he) the matter of Heat and heat also enters their composition." The experiments made on these subjects, however, have put beyond all doubt, that the expansive principle is phlogiston but heat; nevertheless, it seems highly probable, that these elatic fluids do really consist of the acid united to phlogiston, and expanded by heat. This is also the case with the caustic volatile alkali, now called alkaline air.

In the hepatic air, it has been shown by Mr Bergman, that sulphur exists which contains phlogiston; and there is little reason to doubt that the expansive power here is the same as in other cafes. See Hepatic Air.

The heat generated during the solution of metals is by Mr Bergman supposed to be owing to the matter.
of heat which had been fixed in the metals; but it may with much more reason be opposed to proceed from the acid. Dr Black has demonstrated, that heat universally the principle of fluidity, and all fluids, whether acid or not, are found to contain a great quantity of it. It is not probable that solids, even the most inflammable, contain an equal quantity; for it is always observed, that bodies in becoming fluid absorb heat, and throw it out again on becoming solid. Acids in all probability contain a much greater quantity than what is necessary to their fluidity; for we see that the nitrous acid, when poured upon snow, parts with as much heat as is necessary to dissolve the snow, at the same time that it still retains its fluidity. The caie is not so with common salt, which is a solid: for though, in a mixture of salt and snow, the latter absorbs as much heat from the salt as is necessary for its own liquefaction; yet the salt could not be held in solution by a liquid of this temperature, were it not that an additional quantity is perpetually absorbed from the adjacent bodies, particularly the atmosphere. But were it possible to prevent this adventitious increase of heat, there is not the least reason to believe that the salt would be dissolved; for the strongest brine, when reduced to the temperature of 0 of Fahrenheit, is decomposed, the salt falling to the bottom in powder, and the water being converted into ice. Add to this also, that the cold produced by spirit of nitre and snow is much more intense than that produced by common salt and snow; which undoubtedly shows, that a solid does not readily part with as much heat as a fluid, and consequently cannot be supposed to contain as much.

The solution of metals in acids also demonstrates, that the solid substance has not parted with heat, but absorbed it; for as soon as the solution becomes solid again, i.e., when it crystallizes, the temperature becomes higher than before.

The calxes of metals have not that quantity of phlogiston that is necessary for their metallic state, but yet are not entirely destitute of it; therefore, in their solution, scarce any elastic fluid is generated, unless the fire be continued after evaporation. Such as contain acetic acid, discharge it immediately in the same form as they had received it. It is remarkable, that Dr Prieftley mentions a calx of lead, which, with the acid of phosphorous, produced an inflammable air. By means of the nitrous acid and evaporation to dryness, a pure air is produced. Sometimes a small portion of vitriolic acid air is obtained by means of a proper degree of fire from vitriolic acid, but a far greater quantity of pure air.

The solutions made by the menruna abovementioned, contain a metallic calx intimately united with the acid, the quantity of phlogiston left being various according to the difference of the menruna and of the temperature: but the performance of the operation either with or without intense heat, frequently occasions a remarkable difference. That metals are less calcined by the marine than by the nitrous acid, appears from pouring concentrated nitrous acid on tin or antimony; but the difference, if actually does take place, is less visible in other metals.

Some modern chemists have denied this calculation of metals by solution. They have insisted, that the perfect metals ought to be excepted, as they do not yield to the most intense fire. On this subject, however, it may be observed, 1. That during their solution the nitrous air is always generated, and that of a very perfect kind, which cannot happen without phlogiston; but in this case there is nothing present which can yield phlogiston except the metals. Therefore 2. The metals, when precipitated from their menruna by fixed alkalis, both with respect to their external appearance and internal properties, appear to be calcined. Thus the precipitate of gold refuses to unite with mercury, and may be dissolved by marine acid and other simple menruna, and that without the production of any elastic fluid. 3. Glass may be stained by these calxes; but no metal in its perfect state can be taken up by glasses.

The common objection is, that the calxes of the perfect metals may be reduced by heat alone without the addition of charcoal. Many theories have been invented to solve this phenomenon. Some have suppos'd, that the matter of heat and light are the same with the phlogiston, and that thus the calxes are reduced in the same manner as by charcoal or other substances usually termed phlogistic. But in this case we ought to find the calxes of the imperfect metals also reduced by a long continuance of heat, as well as the more perfect; which, however, has never yet been known to take place. Some, among whose number is Dr Lewis, have imagined, that the porosity of the vessel, particularly that made of earthen ware, may be such as to admit the passage of phlogistic vapours through them; and he instances the revival of globules of lead in the middle of pieces of glass upwards of an inch in thickness, and that there was not the least appearance of a crack. But from an experiment of Mr Kirwan's to be afterwards related, it is much more probable that the reduction is effected by means of the phlogiston contained in one part of the calx attracted by another; by which means the latter is reduced to a perfect metal, while the former becomes somewhat more dephlogisticated. In consequence of this it appears, that the calxes of the perfect metals are never totally reduced: for if the operation be performed in a glass retort, the bottom of it is always stained; which indicates the existence of a calx, in however little quantity.

The following fact, Mr Bergman says, has been proposed to him as an inextricable dilemma. Silver cannot amalgamate with mercury except when in its metallic state; yet both calked and nitrated silver are taken up by mercury; it is therefore not calcined by the acids, but adheres to them in its metallic form. This, however, may be easily solved in the following manner.

It is well known that the calx of copper, dissolved in the vitriolic acid, is precipitated in its metallic form on the addition of iron, and that by means of a double elective attraction; for the iron, dissolving in the acid, would form an inflammable air by its phlogiston, were not the copper present which takes it up, and thereby becomes insoluble as long as it retains it; but mercury has a stronger attraction for acids than silver; if therefore calked or nitrated silver be triturated with mercury, the silver must be precipitated in a metallic state, and the mercury be calcined by being dissolved. This also takes place, provided there be moisture sufficient to suffer the elective attraction.

Some modern chemists have denied this calculation of metals by solution. They have insisted, that the perfect metals ought to be excepted, as they do not
Solution and Precipitation.

All metals may be precipitated by alkaline faults; vitriol; occasional of phlogiston, and why.

Thus nitrate or salted mercury, boiled in water together with the crude metal, can take up a certain proportion of it without dephlogitisation; and the latter of these facts, even in the oxa fissa, becomes a mercurius dulcis, which contains at the same time a crude and a calcined mercury.

Perfect solutions should in general be transparent; but some, as has been already mentioned, are distinguished by a peculiar colour. That phlogiston is the chief cause of colour appears from hence, that the black clax of manganetic tinges vitriolic acid of a red colour; but on the addition of sugar the tinge is entirely destroyed. Nitrous acid is rendered blue by copper; but when the metal is added in considerable quantity, it becomes of a very deep green. The marine acid, which dephlogitises the copper leaf, is yet more green; but by dephlogitisation, it may be so condensed as to become brown. Mr Bergman has sometimes seen a solution of silver green, without the presence of the smallest particle of copper. This depends on the absorption of nitrous air: for let smocking nitrous acid be diluted, on the addition of a certain quantity of water it will be of a deep green; by a greater, blue; and upon a still greater, becomes limpid. By means of water, the nitrous air is extended to a greater space: and this attenuation gradually increased varies the colours. Hence we see why nitrous acid is made green by a large quantity of copper.

Metals dephlogitised by acid solvents powerfully attract phlogiston; nay, nitrate silver and mercury, and salted antimony, corrode animal substances, in order, as our author supposed, to extract it. “This metallic causticity (says he), which is only to be moderated by phlogiston, ought to be carefully distinguished from the acid causticity, which is repulsed by alkali, and the alkaline, which is mitigated by acids. Colours vary according to the quantity of phlogiston present; and some experiments shew, that by a sufficient quantity all colour is entirely destroyed.

All metals may be precipitated by alkaline faults; which, by their superior power of attraction, separate them from their menstruum; but their difference with regard to their nature and preparation alters the nature of the precipitate. With the caustic fixed alkalii, the calces fall almost entirely pure, but loaded with water. The weight is found to be increased by the matter of water, but yet less than by the aerial acid. With the aerated fixed alkalii, by means of a double decomposition, the aerial acid unites to most calces. The volatile alkalii, which naturally contains phlogiston, sometimes phlogitises the precipitate. It throws down a black or white precipitate of mercury; nay, it makes the orange-coloured precipitate white. Gold receives its fulminating quality from this precipitant, as is afterwards to be explained. The alkalii, which is commonly called phlogistificated, generally precipitates metals with an increase of weight.
CHEMISTRY.

Neither the caustic nor aerated mineral alkali precipitate one half of platina dissolved in aqua regia; the precipitate is of an orange colour, which on dying becomes brown. An over-proportion of alkali dissolves the precipitate, and the liquor becomes more dark; nay, the precipitation is so imperfect, that the alkali matter seems to be dissolved even by neutral salts. The phlogisticated alkali does not precipitate the undepurated solution, nor even make it turbid, but heightens the colour in the same manner as an excess of alkali.

Solution of silver in nitrous acid lets fall a white precipitate by the aerated alkali; brown by the caustic, and of an obscure yellow. By the nitrous and of silver, marine acids it lets fall a white precipitate, which with the former consists of more distinct particles, which grow black more slowly with the light of the sun.

Salted mercury lets fall a red precipitate, or rather one of a ferruginous colour, by aerated alkali; cury, but of a more yellowish or orange colour by the caustic. Nitrated mercury prepared without heat, yields a ferruginous precipitate with mineral alkali; a black with caustic; and when prepared with heat, it yields to caustic alkali an orange or reddish yellow precipitate.

By phlogisticated alkali it is precipitated from all acids of a white colour; but turns of a brownish yellow when dry. Salted mercury is very sparingly precipitated by this alkali. The precipitate by phlogisticated alkali is again dissolved, if too much of the precipitant be made use of. Corroive sublimate must be very cautiously precipitated by caustic, as well as aerated fixed alkali; for the part separated may again be dissolved by a large quantity of water. When too much alkali is used, a new compound arises of a peculiar nature.

Solution of lead in spirit of nitre is precipitated down by aerated, caustic, or phlogisticated alkali. By using too much alkali, the precipitate by the phlogisticated kind is dissolved with a brownish yellow colour. Vitriol of lead and solution of lead in marine acid are precipitated white.

Blue solution of copper in spirit of nitre is precipitated of a bright green by aerated fixed alkali; by the caustic of a greyish brown, which grows reddish by age. By phlogisticated alkali copper is precipitated of a greenish colour, which grows afterwards of a brownish red, and upon exsiccation almost black. The aerial acid takes up a small quantity of copper during the precipitation, which is again deposited by the heat of boiling.

Aerated fixed alkali precipitates iron of a green colour from vitriolic and marine acid; but the precipitate becomes of a brownish yellow, especially on exsiccation; with the caustic alkali it approaches more to black. In the precipitation some part is held in solution by the aerial acid, when the mild alkali is used. With phlogisticated alkali a Prussian blue is formed.

Tin is precipitated of a white colour by every alkaline salt, even by the phlogisticated kind; but at length some blue particles appear in the mixture: so that the whole, when collected and dried, appears of a light blue colour. That these blue particles are occasioned by iron appears by calculation; for they become ferrous.

**Chemistry.**

**Theory.**

Solution and Precipitation.

Ferruginous, and obey the magnet. Our author has always found a proportion of iron in tin.

Bismuth is thrown down of a fine white by water and alkalies, particularly the former; phlogificated alkali throws down a yellow powder, which being mixed with blue particles occasioned by iron, at length appears green. This yellow sediment easily dissolves in nitrous acid.

Of nickel:

Nickel is precipitated of a whitish green by fixed alkalies; by the phlogificated alkali of a yellow; and by exsiccation it is condensed into a dark brown mass.

Of arsenic:

Arsenic dissolved in acids, which prevent too great phlogification, may, to a certain degree, be precipitated white by the fixed alkali, even when phlogificated, but the sediment is found soluble in water; yet nitrous acid, either alone, or joined with the marine, generally phlogifies the arsenical acid, which thereby becomes unfit for separation. Arsenic dissolved in marine acid, with the assistance of a little nitrous acid, deposited a white sediment on the addition of a large quantity of phlogificated alkali. The sediment was mixed with Prussian blue. This was dissolved in water, and freed by frequent filtration from the blue particles; and at length, on evaporating to dryness, yielded a semipellucid mass.

Of cobalt:

Cobalt dissolved in acids is thrown down by fixed alkali, whether aerated or caustic, of a reddish blue, which grows darker on exsiccation, especially when the former alkali has been used. Phlogificated alkali throws down a powder of almost the same colour, which, upon exsiccation, becomes of a reddish brown.

Zinc is precipitated white by aerated and caustic fixed alkalies, as also by the phlogificated alkali; but this last becomes of a citron colour on exsiccation: a small portion of aerial acid may easily escape during the precipitation.

Of antimony:

Antimony is precipitated white by alkalies. When the phlogificated alkali is used, some blue particles are always precipitated at the same time, though the regulus had been prepared without any iron. This operation should be cautiously conducted, lest some part be taken up by the alkaline salt.

Of manganese:

Manganese procured by reduction from common magnesia nigra, generally renders menstrua brown, and with aerated alkali yields a yellowish brown sediment; with the caustic, one still darker; with the phlogificated, first a blue, then a white, powder is separated, the mixture of which renders the masts a black green. To obtain a pure and white calx of manganese, we must dissolve in pure vinegar the precipitate thrown down by caustic alkali; for there still remains a quantity of iron which is taken up by the aerial acid. This acetous solution contains little or nothing of iron. That metal may also at first be separated by a small quantity of volatile alkali.

The common solution of the regulus is not perfectly precipitated by the aerated alkali; and upon evaporating the remaining liquor spontaneously to dryness, grains of a metallic splendor, and not unlike copper, are deposited on the glass. The nitrous acid attracts these readily, though they are only partially dissolved by it; but on the addition of zinc, nothing but the manganese, though at first it is a little reddish. With phlogificated alkali, we obtain a yellow precipitate like pure manganese, provided the solution has deposited the iron when too much phlogificated by age. But the new solution yields a precipitate almost like that which is obtained from common regulus. The yellow sediment may be dissolved in water.

The following is Mr. Bergman’s table of the quantities of precipitate of different metals, thrown down from various menstrua by the different alkalies. On comparing the weights (says he), a question occurs concerning the ease of such enormous differences; weight of and it is plain, that this ease must be sought for in precipitates themselves. The fixed alkali saturated with aerial acid, when added to the solution, is taken up by the more powerful menstrua; and the weaker is of course expelled, and is absorbed by the calx as it falls, in greater or lesser quantity according to circumstances. That this is actually the case is easily demonstrated:—Let a bottle containing a quantity of nitrous acid be accurately weighed. Let there be put into it, for instance, 132 parts of lead precipitated by aerated alkali; and not only an effervescence will be observed, which continues until the very last particle is dissolved, but when the solution is finished, a deficiency of weight is discovered, which amounts nearly to 21, and is undoubtedly owing to the extraction of aerial acid. But 132—21=111; a weight which still considerably exceeds that of the metal. Upon distillation nearly eight of water are discovered. There yet remain therefore three, which by violent heat are increased by seven; for 132 of the calx well calcined yield 110. The whole increment of weight then does not depend on the water and aerial acid. The same thing is evinced by considering the precipitate of lead by the caustic alkali; in which case there can be no aerial acid, nor does any effervescence accompany the solution. If we suppose the quantity of water equal in both cases, yet even on this supposition the whole excess of weight is not accounted for; for 116—8=108. It is therefore probable, that the matter of heat is attached to the calx (a).—In proof of this opinion, and that caustic alkalies contain the matter of heat, our author adduces several arguments, of which the following is the strongest. Let Argument the heat occasioned by the mixture of any acid and favours of calcium alkali be determined by a thermometer; let the weight of then an equal portion of the same menstruum be suffi- ptecites being rated with a metal; afterwards, on the addition of an equal quantity of caustic alkali, it will be found, clue to the heated that no heat is generated, or a degree very much by the mat- ter of heat. Some of the matter of heat there- fore is taken up and fixed, which also generally makes the colours of the precipitates more obscure; and in distillation with sal-ammoniac, communicates to the vol- lutate alkali the quantity that had been taken away.”

In this instance also, however, our author seems to be insufficient have been deceived. It has already been observed, that in all solutions generating heat, it most probably comes from the fluid. Acids contain a quantity suf-
CHEMISTRY.

Theory.

When the latter is dissolved in aqua regia, it ought to solution yield a Prussian blue on the addition of phlogiilicated alkali; which indeed is the case when common platina is employed, but not with that which is well depurated.

In the same manner, if iron, adhering very obstinately to platina is nickel, forms a great part of the latter, the precipitates obtained from it by alkali could not differ from metallic precipitates so much as they do in colour, weight, and other properties. The same holds true of cobalt and manganese. The regular obtained from the latter contains about 0.008 of iron, which affects the mixture in the following manner. An hundred pounds dissolved in an acid menstruum, yields, by treatment with phlogiilicated alkali, a powder consisting partly of blue, partly of brownish yellow particles, equal in weight to 150 pounds; but eight pounds of precipitate yield 48 of Prussian blue, nearly 1 of the whole mass of precipitate; whence it follows, that 100 parts of pure manganese yield to phlogiilicated alkali scarcely 3:1, i.e., nearly six times less than an equal weight of iron.

Lastly, by this method of examining precipitates, it may be possible to determine the unequal quantities of phlogiilicated in different metals; for a given weight of precipitating metal does not yield an equal quantity of precipitate: thus, for instance, copper is able to precipitate from nitric acid four times its weight of silver.

Mr Kirwan has made a great number of experiments on the attractive powers of the mineral acids to various substances, and greatly illustrated the operations of both solution and precipitation. Chemical attraction, he observes, is that power by which the volatile particles of different bodies intermix and unite with each other so intimately, as to be inseparable by mere mechanical means. Thus it differs from the attraction of cohesion, as well as from that of magnetism and electricity, as not acting with the indifference observed to take place in these powers, but causing a body already united to another to quit that and unite with a third; whence it is called elective attraction. Hence attraction of cohesion often takes place between bodies that have no chemical attraction for each other; as for instance, blinthus and regulars of cobalt, which cannot be made to unite together by fusion, though they cohere with each other so strongly, that they cannot be separated but by the blow of a hammer.

To determine the degrees of attraction between different substances, M. Geoffroy laid it down as a general rule, that when two substances are united, and either of them is to unite with a third, which thus unites to the third must be paid to have a greater affinity to it than to the substance it has quitted in many cases, however, the seemingly single decomposition is in truth a double one. Thus, when the vitriolic acid expels the air from a fixed alkali, it does not necessarily follow, that the acid is more attracted by the alkali than the fixed air; for here though the latter resigns its place to the acid, yet the acid gives out its fire to the air; whence a decomposition might take place, even though the attractive powers of both the vitriolic and aerial acid to the alkali were equal. To attain to any certainty in this matter, therefore, it is necessary to determine the quantity and force of each of the attractive powers, and denote it by numbers. The necessity of this has been observed by Mr Morveau and Mr Wenkel, who have both proposed methods for answering the purpose; but Mr Kirwan has showed that both are defective; and he tells us, that the discovery of the quantity of real acid in each of the mineral acid liquors, with the proportion of real acid taken up by a given quantity of each basis at the point of saturation, led him unexpectedly to what seems the true method of investigating the quantity of attraction which each acid bears to the several bases to which it is capable of uniting: "for it was impossible

(fays he) not to perceive, 1. That the quantity of real Solution acid necessary to saturate a given weight of each basis is inversely as the affinity of each basis to such acid.

2. That the quantity of each basis requisite to saturate a given quantity of each acid is directly as the affinity of such acid to each basis. Thus 100 grains of each of the acids require for their saturation a greater quantity of fixed alkali than of calcareous earths, more of this earth than of volatile alkali, more of this alkali than of magnetia, and more of magnetia than of earth of alum.

"If an acid be united to less of any basis than is requisite for its saturation, its affinity to the deficient part of its basis is as the ratio which that deficient part bears to the whole of what the acid can saturate. Thus, if 100 grains of vitriolic acid, which can saturate 110 of calcareous earth, be united only to 55, its affinity to the deficient 55 parts should be estimated one half of its whole affinity; but its affinity to the retained part is as its whole affinity."

To explain the decompositions in which these acids Method of are concerned, we must consider, first, the powers explaining which result any decomposition, and tend to keep the decompositions bodies in their present state; and, secondly, the powers affected Method of by which tend to effect a decomposition and new union; acids alone. Quiescent Our author calls quiescent affinities, the last decomposition. A decomposition will therefore always take place when the sum of the divalent affinities is greater and divalent than the quiescent; and, on the contrary, no decomposition will happen when the sum of the quiescent affinities is greater than that of the divalent. All we have to do therefore is to compare the sums of each of these powers. The method our author takes to compare the affinities together is by the following table, in which the quantity of calcareous earth, &c. saturated by 100 grains of each of the mineral acids, is stated.

<table>

</tbody>
</table>

These numbers he considers as adequate expressions of the quantity of each of the affinities. Thus the affinity of the vitriolic acid to fixed vegetable alkali is to the affinity with which it adheres to calcareous earth as 215 to 110; and to that which the nitrous acid bears to calcareous earth as 215 to 96, &c. Hence Expressive we sum up the powers of affinity betwixt any number of the quantity of different substances, and account for their decompositions, as in the following example of the double decomposition, which takes place when a solution of vitriolated tarrat and solution of lime or chalk in nitric acid are mixed together.

**Quiescent Affinities.**

| Vitriolic acid to vegetable fixed alkali, 215 | 110 |
| Nitrous acid to calcareous earth, 96 | 110 |

**Divalent Affinities.**

| Vitriolic acid to calcareous earth, 215 | 110 |
| Nitrous acid to vegetable alkali, 215 | 110 |

**Sum of quiescent affinities**

| 711 |

**Sum of divalent affinities**

| 725 |

Hence we see that a double decomposition must ensue. The same will be produced, if instead of vitriolated tarrat we make use of Glauber's salt; for the sum of the
the quiescent affinities is 261., of the divellent 275.; with vitriolic ammonia, by the sum of the quiescent is 186., of the divellent 195. &c. In mixing vitriolated tartar with solution of magnesia in nitrous or marine acids, a double decomposition takes place though invisibly, as the vitriolic Ephom salt is very soluble in water, and therefore cannot be precipitated like selenite. In the former case the sum of the quiescent powers is 290., of the divellent 295; in the second 296 and 295.

Other decompositions take place in the same manner; and from all the facts which our author had occasion to observe, he concludes, that the quantity of each affinity, as determined in the above table, coincides exactly with experience; and that these decompositions are perfectly consistent with the superior affinity which has been hitherto observed in the vitriolic and nitrous acids with fixed alkalies over the calcareous earths; nor do they infringe in the least the known laws of affinity, as has been intimated by some chemists.

One fact only, mentioned in Dr Crell’s Journal, seems to be repugnant to what is here advanced; and that is, that if solutions of one part of alum and two of common salt be mixed together, evaporated, and set to cryallize, a Glauber’s salt will be formed; though, in this case, the sum of the quiescent affinities is 233, and that of the divellent only 223. Mr Kirwan repeated this experiment without success; and Dr Crell himself owns that it will not succeed but in the most intense cold. If it does succeed at all, he says the decomposition must arise from a large excess of acid in the alum, which acted upon and decomposed the common salt; and this explanation is confirmed by the small proportion of Glauber’s salt found to be obtained by this process; for from 30 lb. of common salt and 16 of alum, only 1 lb. of Glauber’s salt were produced; whereas, if the whole of the alum had been decomposed, there should have been formed, according to Mr Kirwan’s computation of the quantity of acid in the different salts, 29 lb. or, according to Mr Bergman’s, 22 lb. of Glauber’s salt.

In some cases, the neutral salts have a power of uniting, without any decomposition, or with only a very small one, to a third substance; thus forming triple salts, and sometimes quadruple; which often causes anomalies that have not yet been sufficiently investigated. Volatile alkalies in particular are possessed of the power of uniting with neutral salts in this manner. Hence they seem to precipitate magnesia from Ephom salt, even when perfectly calcine; but this is owing to their combination with that salt, and forming a triple one, which is insoluble in water.

It seems extraordinary, that, according to Mr Kirwan’s table, the three mineral acids should have the same affinity to vegetable fixed alkalies, when it is well known that the vitriolic will expel either of the other two from an alkaline basis. In explication of this, Mr Kirwan observes, that nitre is decomposed by the marine acid; and that Glauber’s salt and vitriolic ammomiac are decomposed by that of nitre; and these salts, as well as cubic nitre and nitrous ammomiac, are decomposed by the marine acid.

Mr Kirwan is of opinion, that these decompositions are the effect of a double affinity, or at least of compound forces. He supposed that they arose from the different capacities of the acids for elementary fire; solution and to determine this matter, he made the following experiments, in which the decompositions were not discovered by crystallization, but by tests.

1. Having procured a quantity of each of the three mineral acids containing the same proportion of real nitre to acid, and reduced them to the temperature of 68° of Fahrenheit, 100 grains of vitriolic acid, containing 26.6 of real acid, was projected upon 480 grains of oil of tartar at the same temperature, by which the thermometer was raised to 138°.

2. An hundred grains of spirit of nitre, containing also 26.6, projected on 480 grains of oil of tartar, produced only 120° of heat.

3. An hundred grains of spirit of salt, the specific gravity of which was 1220, and which contained the usual proportion of real acid, raised the thermometer from 69° to 129°.

"Hence (says he) it follows, that the vitriolic acid Vitriolic acid contains more specific fire, or at least gives out more heat than either the nitrous or marine; and therefore when the vitriolic acid comes in contact with either nitre or salt of Sylvius, its fire and passes into these acids, which are thereby rarified to a fine.

Difficulty of and Dr Crell to be repugnant to what is here advanced; and that is, M. Kirwan's explanation, the marine acid, as giving out more specific heat, ought to expel the nitrous from an alkaline basis; which, however, is not the case. Something else, therefore, besides the mere quantity of specific heat, must here be taken into consideration. Mr Kirwan, however, goes on to prove the truth of his theory by the following experiments.

4. To 400 grains of vitriolic acid, whole specific gravity was 1.26, sixty grains of nitre were added; on the introduction of which the thermometer fell from 68° to 60°. During the time of this descent, the nitrous acid was not expelled; for some filings of copper, put into the mixture, were not acted upon in the least; but in five minutes afterwards they visibly effervesced, which showed that the nitrous acid began to be expelled; for the vitriolic acid does not act upon copper but by a boiling heat.

5. Sixty grains of nitre were put to 400 of oil of By the fame vitriol, whole specific gravity was 1.870; the thermometer infinitely rose from 68° to 105°, and the nitrous acid was expelled in a visible flame. These experiments (says Mr Kirwan) prove, 1. That neutral salts are not decomposed by mere solution in an acid different from their own. 2. That the nitrous acid, being converted into vapour, had imbibed a large quantity of fire. But as the vitriolic acid, on both these experiments, was used in much larger quantities than was necessary to saturate the alkali of the diluted nitre, sixty grains of the latter were put into 64 of the abovementioned dilute spirit of vitriol, which contained the same quantity of real vitriolic acid that the 60 grains of nitre did of the nitrous; with the addition of 40 grains of water and a few copper filings. Marine acid, in less than two hours the copper was acted upon, and consequently the nitrous acid was expelled.

6. To 400 grains of oil of vitriol, of the specific gravity of 1.870, 100 grains of common salt were added. An effervescence immediately ensued,
and the marine acid rose in white vapours. A thermometer held in the liquor rose only 4 degrees, but in the froth it ascended to 10°, and fell again upon being replaced in the liquor. Hence Mr Kirwan concludes, that the vitriolic acid gives out its fire to the marine; and that this latter received more than it could absorb even in the state of vapour, and therefore communicated heat to the contiguous liquor. It appears to him also, that the nitrous and marine acids receive fire from the vitriolic, and are thrown into a vaporous state, or at least rarefied to such a degree as to be expelled from their alkaline bases, though their affinity with that base may be equally strong with the vitriolic.

7. To ascertain the manner in which vitriolated tartar and Glauber's salt are decomposed by spirit of nitre, 60 grains of powdered tartar of vitriolic were put into 400 grains of nitrous acid, whose specific gravity was 1.355, and which contained about 105 grains of real acid. The thermometer was not affected by the mixture; but in 24 hours the vitriolic acid was in part disengaged, as appeared by the acid mixture acting upon a regular affinity, which neither pure nitrous acid nor pure vitriolic acid will do by themselves. On putting the same quantity of vitriolated tartar into 400 grains of spirit of nitre whose specific gravity was 1.4789, the thermometer rose from 57° to 79°; the vitriolated tartar was quickly disengaged, and the regular affinity showed that the vitriolic acid was disengaged. Hence it appeared that the nitrous acid, having the same affinity with the bases of vitriolated tartar as the vitriolic, but giving out, during the solution, more fire than was necessary to perform the solution, the vitriolic, receiving this fire, was disengaged: for as it cannot unite with alkalies without giving out fire; so when it receives back that fire, it must quit them. The reason why the nitrous acid, which specifically contains less fire than the vitriolic, gives out so much is, that its quantity in both these experiments is far greater than that of the vitriolic; it being in the first as 105 to 17, and in the last as 135 to 17.

8. To 60 grains of spirit of nitre, whose specific gravity was 1.355, Mr Kirwan added 1000 grains of water; and into this dilute acid put 60 grains of vitriolated tartar, containing exactly the same quantity of real acid that the 60 grains of nitrous acid did. In eight days the vitriolated tartar was almost entirely disengaged, and without any sign of its decomposition; and no nitre was found upon evaporating the liquor. Hence he concludes, that the nitrous acid can never decompose vitriolated tartar, without the assistance of heat, but when its quantity is so great that it contains considerably more fire, and by the action of solution is determined to give out this fire, its salt is also decomposed, in similar circumstances; by the marine acid; though still more slowly and with more difficulty than by the nitrous, as appears by the following experiments.

9. Into 400 grains of spirit of salt, whose specific gravity was 1.220, were put 60 grains of vitriolated tartar. The thermometer was not affected in the least, and the salt dissolved very slowly. Some pulverized bismuth was added to try whether the vitriolic acid was disengaged; and in 12 hours part of it was dissolved, so that it could not be precipitated by water. Solution and precipitation. This showed, that part of the vitriolic acid was disengaged; for this semi-metal cannot be kept in solution when much diluted with water, excepting by a mixture of marine and vitriolic acids.

In this experiment the quantity of marine acid was much greater than that of the vitriolic; and therefore it was capable of disengaging it. This circumstance alone, however, is not sufficient; the acid must be dissolved to give out by solution that quantity of fire which it is necessary the vitriolic should receive in order to its quitting the basis to which it is united; and therefore when Mr Cornette added two ounces of spirit of salt to half an ounce of vitriolated tartar already dissolved, in water, no decomposition took place. The reason of this was, that as the vitriolated tartar was already disengaged, no cold nor heat was generated by the mixture; and therefore the spirit of salt could not give out any fire. Glauber's salt is more easily decomposed by marine acid than vitriolated tartar; and thus the marine acid is more capable of disengaging the vitriolic, under the circumstances of this experiment.

Accordingly, during the solution of marine and vitriolic acids, the vitriolic ammoniac is also decomposed by means of marine acid; but in this case, the quantity of marine acid must greatly exceed that of the vitriolic acid contained in the salt to be decomposed; and it must be remarked, that according to the observations of Mr. Bergman, the decomposition of Glauber's salt or vitriolic ammoniac by this acid is never complete. On the same principles the marine acid decomposes salts which have the nitrous acid for their basis. Mr Cornette found, that cubic nitre was more easily decomposed by it than that which has vegetable alkaline bases for its bases. Accordingly, during the solution of prismatic nitre, only three degrees of cold were produced; but by the solution of cubic nitre; which shows that the spirit of salt gave out more fire in the latter case than in the former; and its quantity must always be greater than that of the nitrous acid contained in the mineral alkaline bases; because this basis requires for its saturation more of the marine than of the nitrous acid. The nitrous acid, however, in its turn decomposes salt of Sylvius and common salt; but it must always be in greater quantity than the marine to produce that effect.

10. Sixty grains of common salt being added to marine 400 of colourless spirit of nitre, whose specific gravity was 1.478, the mixture quickly effervesced and grew red, yet the thermometer rose but two degrees; because this acid had absorbed the greater part of the fire given out by that of nitre; the decomposition was likewise hastened by the superior affinity of the nitrous acid to the alkaline bases of the sea-salt; hence the decomposition of sea-salt by means of nitre takes place without any solution; but spirit of salt will not decompose cubic nitre until it has first disengaged it. This mutual expulsion of the nitrous and marine acids by each other, is the reason why aqua-regia may be made by adding nitre or nitrous ammoniac to spirit of salt, and spirit of salt to ammoniac to spirit of nitre. Selenite cannot be decomposed either by nitrous or marine.
### Theory

Marine acid; because it cannot be dissolved in either without the assistance of foreign heat. It must likewise be observed, that in all decompositions of this kind, when the liquor has been evaporated to a certain degree, the vitriolic acid expels in its turn the nitrous or marine acid to which it had already yielded its bals. The reason of this is, that the free part of the weaker acids being evaporated, the neutral salts begin to crystallize, and then giving out heat, the vitriolic absorbs it; and thus reaching upon them expels them from the alkali or earth to which they are united. Mr. Kirwan found much more difficulty in determining the attractive powers of the different acids to the metals than to alkaline salts or earths. Some of the difficulties met with in this case arose from the nature of metallic substances themselves. Their calxes when formed by fire always contain a quantity of air, which cannot be extracted from them without great difficulty, and is very soon re-absorbed; and if formed by solution, they as constantly retain a part of their solvent or precipitant; so that the precise weight of the metallic part can scarce be discovered. Our author, therefore, and because metallic calxes are generally inferior in this respect to the metals in their perfect state, and even here they must lose a part of their phlogiston before they can be dissolved in acids, and a considerable part remains in the solution of the acid and calx; which last quantity he endeavoured to determine.

A new difficulty now occurred, arising from the impossibility of finding the real quantity of acid necessary to saturate the metal, for all metallic solutions contain an excess of acid; the reason of which is, that the calxes formed by a due proportion of acid and calx are insoluble in water without a further quantity of acid; and in some cases this quantity, and even its proportion to the aqueous part of the liquor, must be very considerable, as is evidenced in solutions of bismuth. It was in vain attempted to deprive these solutions of their excess of acid by means of caustic alkalies and lime-water; for when deprived of only part of it, many of the metals were precipitated, and all of them would be so if deprived of the whole. As the solution of silver, however, can be very much saturated, Mr. Kirwan began with it and found that 617 grains of this solution contained 100 grains of silver, and 31.38 grains of real acid, after making the proper allowance for the quantity diffused in nitrous air. Nine grains of this solution tinged an equal quantity of solution of lime as red as one of a grain of real acid of spirit of nitre would have done; whence our author concluded that 9 grains of his solution of silver contained an excess of \( \frac{1}{4} \) of a grain of real silver: according to which calculation, the whole quantity ought to have contained 5.6 grains; which deducted from 31.38, leaves 25.78 grains for the quantity of acid saturated by 100 grains of silver.

As the vitriolic solutions of tin, bismuth, regulus of antimony, nickel, and regulus of arsenic, contain a large excess of acid, Mr. Kirwan saturated part of it with caustic volatile alkali before he tried them with the infusion of lime; and the same method was used with solutions of iron, lead, tin, and regulus of antimony in the nitrous and marine acids. The proportion of vitriolic and marine acid taken up by lead, silver, and mercury, were determined by computing the quantity of real acid necessary to precipitate these metals from their solutions in the nitrous acid; which seemed to be the most exact method of determining this point. The result of all the experiments was, that 100 grains of each of these acids take up at the point of saturation of each metallic substance, dephlogisticated such a degree as is necessary for its solution in each acid, the quantities marked in the following table.

Though from this table, compared with the former, we might suppose that metals, having a greater attraction for acids than alkalies, could not be precipitated by them, yet Mr. Kirwan observes, that the common tables, which postpone metallic substances to alkaline calxes, are in reality just, though there can scarce be any reason to doubt that almost all metallic substances have a greater affinity with acids than alkalies have. The common tables, he says, are tables of precipitation rather than of affinity, as far as they relate to metallic substances. These precipitations, however, are constantly the result of a double affinity and decomposition; the precipitating metal yielding its phlogiston to the precipitated one, while the precipitated metal yields its acid to the other. Thus, though copper in its metallic form precipitates silver and mercury from the nitrous acid, yet the calx will precipitate neither.

The superior attraction the nitrous acid has to silver rather than fixed alkali, appears from the following experiment. If a solution of silver in nitrous acid be poured into a mixed solution of alkali and sea-salt, the silver will be precipitated by the sea-salt into a lunar cornua, and not by the loose alkali contained in the liquor. "Now (says Mr. Kirwan), if the nitrous acid had a greater affinity to the free alkali than to the silver, it is evident that the silver would be precipitated pure, and not in the state of lunar cornua; but from its being precipitated in this state, it is plain, that the precipitation was not accomplished by a single but by a double affinity. Hence also the marine acid appears to have a greater attraction to silver than the nitrous has to fixed alkalies. The result is similar when we make use of solutions of lead or mercury in the nitrous acid. Mr. Bayen has also shown, that vitriol of lead and corrosive sublimate mercury cannot be deprived of more than half their acid, even by caustic fixed alkalies.
Theory.

With regard to lead, if perfectly dry salt be projected on this metal heated to ignition, the common salt will be decomposed, and lead or calx formed. Nor can we attribute this to the volatilization of the alkali by heat; for the alkali is as fixed as the lead, and must therefore be caused by the superior attraction which the calx of this metal, even when dephlogisticated, has for the marine acid. Mr Scheele informs us, that if a solution of common salt be digested with litharge, the common salt will be decomposed, and a caustic alkali produced. It may also be decomposed simply by letting its solution pass slowly through a funnel filled with litharge; and the same thing happens to a solution of calcareous earth in marine acid; which shows that the decomposition takes place merely by the superior degree of attraction between the acid and metallic calx (A).

That acids have a greater attraction for metallic earths than volatile alkalis, is still more evident. Luna cornea is soluble in volatile alkalis; but if this solution be triturated with four times its weight of quicksilver, a mercurius dulcis, and not salt ammoniac, is formed. The reason why alkalis and earths precipitate all metallic solutions, is, that the metals are held in solution by an excess of acid. Even if the alkaline and earthy substanct did no more than absorb this excess of acid, a precipitation must necessarily ensue; but they not only take up this superabundant acid, but also the greater part of that which is necessary to saturate the metallic earth. This they are enabled to do by means of a double affinity; for during the solution of metals, only a small part of the phlogiston, comparatively speaking, escapes, the remainder being retained by the compound of acid and calx. When therefore an alkali or earth is added to a solution, the phlogiston quits the acid, and joins with the calx, while the greater part of the acid reunites to the precipitate. Norwithstanding this great affinity, however, of metallic earths to acids, there are but few instances of their decomposing those fats which have an alkali, or an earth for their bases; by reason of the inability of the acids, while combined with these bases, and thereby deprived of a great part of their specific fire, to volatilize the phlogiston combined with the metallic earths, which must necessarily be expelled before an acid can combine with them; and as to the metallic calces, they are generally combined with fixed air, which must also be partly expelled; but ammoniacal salts (containing much more fire, for they absorb it during their formation) for that reason act much more powerfully on metals. Allowing then the affinities of the mineral acids with metallic substances to be as above, all double decompositions, in which only fats containing these acids united to alkaline, terreene, or metallic bases, are concerned, admit of an easy explanation: may, says Mr Kirwan, I am bold to say, they cannot otherwise be explained. Thus, if a solution of tartar vitriolate, and of silver in the nitrous acid, be mixed in proper proportion, nitre and vitriol of silver will be formed; and this latter for the most part precipitated.

(4) These experiments have been repeated by many other chemists without success; and Mr Wiegebein informs, that none of those who have attempted to decompose sea-salt by means of lead, ever found their methods answer the purpose.

</table>

This point he likewise endeavoured to ascertain by other experiments. As silver loses a certain quantity of phlogiston, which escapes and separates from it during its solution in nitric acid, he concluded, that if the solution was exposed to nothing from which it could reobtain phlogiston, and this was distilled to dryness, and entirely separated from the acid, as much silver should remain unaltered as corresponded with the quantity of phlogiston lost by it; and if this quantity corresponded with that in the above table, he then had good reason to conclude that the table was just.

For this purpose 120 grains of standard silver were distilled in dephlogitificated nitrous acid diluted with water, and he obtained from it 24 cubic inches of nitrous air. This solution was gently evaporated to dryness; and he found that, during the evaporation, Solution about a quarter of a grain of the silver had been volatilized. The dry residuum was then distilled, and kept an hour in a coated green-glass retort heated almost to a white heat. Abundance of nitrous acid passed off during the operation, and a green and white sublimate rose into the neck of the retort, some of it even pasting over into the receiver. On breaking the retort, the nitride was penetrated with a yellow and red stinge, and partly covered over with an exceedingly fine silver powder, which could scarcely be scraped off. The remainder of the silver was white, and perfectly free from acid, but not melted into a button. On being collected, it weighed 94 grains; consequently 26 grains had been lost either by sublimation or vitrification; but of these 26 grains 9 were copper; for 100 grains of standard silver contain 75 of copper, therefore only 17 grains of pure silver remained unaltered, being either volatilized or vitrified. The whole quantity of pure silver in 120 grains of standard silver amounts to 111 grains; then if 111 grains of pure silver lose 17 grains by being deprived of its phlogiston, 100 grains of the same should lose 15.8; and by the above table 15.3 grains of silver should contain 0.945 of a grain of phlogiston. Now, 100 grains of pure phlogiston contain 14 cubic inches of nitrous air, which, according to our author's calculation, contain 0.938 of a grain of phlogiston; and this differs from 0.945 only by 0.007 of a grain. "In this experiment (says Mr Kirwan) only as much of the silver sublimed as could not regain phlogiston; the remainder regained it from the nitrous air absorbed by the solution, and by that which remained in the acid and calx. If this were not so, I do not see why the whole of the silver would not sublime."

Dr Priestley having several times dissolved mercury in the nitrous acid, and revivified it by distilling over that acid, constantly found a considerable portion of it reduced. To try whether that proportion corresponded with his calculation, Mr Kirwan examined Dr Priestley's experiment concerning the revival of the peculiar property of mercury.

This point he likewise endeavoured to ascertain by other experiments. As silver loses a certain quantity of phlogiston, which escapes and separates from it during its solution in nitric acid, he concluded, that if the solution was exposed to nothing from which it could reobtain phlogiston, and this was distilled to dryness, and entirely separated from the acid, as much silver should remain unaltered as corresponded with the quantity of phlogiston lost by it; and if this quantity corresponded with that in the above table, he then had good reason to conclude that the table was just.

For this purpose 120 grains of standard silver were distilled in dephlogitificated nitrous acid diluted with water, and he obtained from it 24 cubic inches of nitrous air. This solution was gently evaporated to dryness; and he found that, during the evaporation, Solution about a quarter of a grain of the silver had been volatilized. The dry residuum was then distilled, and kept an hour in a coated green-glass retort heated almost to a white heat. Abundance of nitrous acid passed off during the operation, and a green and white sublimate rose into the neck of the retort, some of it even pasting over into the receiver. On breaking the retort, the nitride was penetrated with a yellow and red stinge, and partly covered over with an exceedingly fine silver powder, which could scarcely be scraped off. The remainder of the silver was white, and perfectly free from acid, but not melted into a button. On being collected, it weighed 94 grains; consequently 26 grains had been lost either by sublimation or vitrification; but of these 26 grains 9 were copper; for 100 grains of standard silver contain 75 of copper, therefore only 17 grains of pure silver remained unaltered, being either volatilized or vitrified. The whole quantity of pure silver in 120 grains of standard silver amounts to 111 grains; then if 111 grains of pure silver lose 17 grains by being deprived of its phlogiston, 100 grains of the same should lose 15.8; and by the above table 15.3 grains of silver should contain 0.945 of a grain of phlogiston. Now, 100 grains of pure phlogiston contain 14 cubic inches of nitrous air, which, according to our author's calculation, contain 0.938 of a grain of phlogiston; and this differs from 0.945 only by 0.007 of a grain. "In this experiment (says Mr Kirwan) only as much of the silver sublimed as could not regain phlogiston; the remainder regained it from the nitrous air absorbed by the solution, and by that which remained in the acid and calx. If this were not so, I do not see why the whole of the silver would not sublime."

Dr Priestley having several times dissolved mercury in the nitrous acid, and revivified it by distilling over that acid, constantly found a considerable portion of it reduced. To try whether that proportion corresponded with his calculation, Mr Kirwan examined Dr Priestley's experiment, viz. that having dissolved 17 penny-weights 13 grains (321 grains) of mercury in nitrous acid, 56 grains remained unaltered. According to Mr Kirwan's calculation 56 grains should have remained unaltered; for 100 grains of mercury afford 12 cubic inches of nitrous air; of consequence 521 grains should afford 38.12, which contain 2.58 of phlogiston; and if, as according to the table, 4.56 grains of phlogiston be necessary to metallize 100 grains of mercury, 2.58 grains will be necessary to metallize 56 grains of the same metal; and our author is satisfied from his own trials, that more than 50 grains would have remained unaltered, if dephlogitificated nitrous acid had been used in dissolving the mercury, and the solution performed with heat and a strong acid: but that which the Doctor used was of Why so much of the metal was revivified in the smoking kind, and consequently contained a considerable quantity of phlogiston already, which undoubtedly contributed to revive more of the metal than would otherwise have been done. It is true, the Doctor's experiment afterwards revived a great part of what experience had originally remained unaltered, but this happened merely, for it had been some time exposed to the free air, from which the cales of metals always attract phlogiston; as is evident in luna cornea, which blackens on being exposed to the air.

By another experiment of Dr Priestley's, it was found
whence all its air was extracted, that is, about 118 grains, absorbed 40 ounce-measures, or 75.8 cubic inches of inflammable air, containing 2.05 grains of phlogiston, by which they were reduced. An hundred grains of minium, therefore, require for their reduction nearly 2.25 grains of phlogiston. In another experiment made with more care, he found, that 480 grains of minium absorbed 108 ounce-measures of inflammable air; so that, according to this, 100 grains of minum requires for their reduction 1.49 grains of phlogiston; and in two succeeding experiments he found the quantity still less. On this Mr Kirwan remarks, 1. That the whole of the minium was not dephlogisticated; for it is never equally calcined, and besides much of it must have been reduced during the expansion of its air. 2. The quantity of phlogiston in the inflammable air may have been greater, as this varies with its temperature and the weight of the atmosphere; so that on the whole these experiments confirm the results expressed in the table.

Mr Kirwan next proceeds to consider the attraction of metallic calces to phlogiston. Inflammable air, when condensed into a solid substance, he supposes not only equal, but much superior, to any metallic calce in specific gravity; and therefore, if we could find the specific gravity of any calce free both from phlogiston and fixed air, we would thus know the density which phlogiston acquires by its union with such calce. It has, however, hitherto proved impossible to procure calces in such a state; as, during their dephlogistication, they combine with fixed air or some particles of the menestium, whence their absolute weight is increased, and their specific gravity diminished. Hence it appears, that the specific gravity of the calces differs much less from that of their respective metallics, than the specific gravity which the phlogiston acquires by its union with those calces from that which it possesses in its uncombined state. Hence, instead of deducing the quantity of affinity between phlogiston and metallic calces from the following proposition, that "the affinity of metallic calces to phlogiston is in a compound ratio of its quantity and density in each metal," he is obliged to deduce it from this other, that "the affinity of metallic calces to phlogiston is directly as the specific gravity of the respective metallics, and inversely as the quantity of calce contained in a given weight of these metallics." This latter proposition is an approximation to the former, founded on this truth, that "the larger the quantity of phlogiston in any metal is, the smaller the solution of calx in a given weight of that metal and precipitate; and, that it is the density which the phlogiston acquires is as the specific gravity of the metal." This latter proposition, however, is not entirely true; for this density is much greater; but its defect is only sensible with regard to those metals which contain a considerable quantity of phlogiston, as gold, copper, cobalt, and iron. With regard to the rest, it is of no importance. The specific gravity of the different metals, then, being as represented in the first column of the following table, the affinity of their calces to phlogiston will be as in the second; and the third expresses the affinities in numbers homogeneous with those which express the affinities of acids with their bases.

From this table we may see why lead is useful in Why lead cupellation; namely, because it has a greater affinity is useful in phlogiston than the calces of any of the other imperfect metals; consequently after it has lost its own phlogiston, it attracts that of the other metals with which it is mixed, and thus promotes their calcination and vitrification.

The third point necessary for the explanation of the phenomena attending the solution of metals, and their phlogiston left by metallic calces during their precipitation, is to determine the proportion of phlogiston which they lose by solution in each of the acids, and the affinity which their calces bear to the part of the metal. Though our author was not able to determine this by any direct experiment, yet from various considerations he was led to believe that it was as follows:

<table>

\hline
\end{tabular}
\end{center}

336 Of the ex- cess of acid in solutions proper for making the experiments.

337 Why the metals are more depophilogiticated by mutual precipitation than by direct solution.

338 Why copper is dissolved by solution of silver, mercury, or iron.

339 Why iron and zinc are dissolved by vitriolic acid.

340 Nitrous acid decomposes all metals, and when concentrated.

341 In what cases the marine acid can dissolved metals, and when it cannot.

342 Why the metals are more depophilogiticated than by direct solution in their respective menstrua; and are even dissolved by menstrua which would not otherwise affect them. The reason of this is, that their phlogiston is acted upon by two powers instead of one: and hence, though copper be directly soluble in the vitriolic acid only when in its concentrated state, and heated to a great degree; yet if a piece of copper be put into a solution of silver, mercury, or even iron, though dilute and cold, and exposed to the air, it will be dissolved; a circumstance which has justly excited the admiration of several eminent chemists, and which is inexplicable on any other principles than those just now laid down. From this circumstance we may see the reason why vitriol of copper, when formed by nature, always contains iron. Mr. Kirwan now proceeds to consider the solutions of metallic substances in all the different acids.

Vitriolic acid, he observes, diarronizes only iron and zinc of all the metallic substances, because its affinity to their calxes is greater than that which they bear to the phlogiston they must lose before they can unite with it.

Nitrous acid has less affinity with all metallic substances than either the vitriolic or marine; yet it diarrones them all, gold, silver, and platinum excepted, though it has even less affinity with them than they have with that portion of phlogiston which must be lost before they can dissolve in any acid. The reason of this is, that it unites with phlogiston, unless when in too diluted a state; and the heat produced by its union with phlogiston is sufficient to promote the solution of the metal. On the other hand, when very concentrated, it cannot diarrone them: because the acid does not contain fire enough to throw the phlogiston into an aerial form, and reduce the solid to a liquid.

The marine acid depophilogiticates metals less powerfully than any other. It can make no solution, or at least can operate but very slowly; without heat, in those cases where the metallic calx has a stronger affinity with that portion of the phlogiston which must be lost, than the acid; nor can it operate briskly even where the attraction is stronger, provided, the quantity of acid be small; because such a little quantity of acid does not contain fire enough to volatilize the phlogiston: and hence heat is necessary to afford the marine acid in dissolving lead. When depophilogiticated, it acts more powerfully.

It has been observed, that copper and iron mutually precipitate one another. If a piece of copper be put into a saturated solution of iron fresh made, no solution will ensue for 12 hours, or even longer, if the liquor be kept close from the air; but if the liquor be exposed to the open air, the addition of volatile alkali will show, in 24 hours, that some of the copper has been dissolved, or foined, if heat be applied, and a calx of iron is precipitated. The reason of this will be understood from the following state of the affinities.

\begin{center}
\begin{tabular}{|l|l|}
\hline
Quiescent. & Diluent. \\
Vitriolic acid to calx of iron & Vitriolic acid to copper \\
Copper to its phlogiston & Calx of iron to phlogiston \\
\end{tabular}
\end{center}

344 In this case no decomposition can take place, because the sum of the diluent affinities is less than that of the quiescent; but in the second, when much of the phlogiston of the iron has escaped, the affinity of the calx of iron to the acid is greatly diminished, at the same time that the affinity of the calx to phlogiston is augmented. The state of the affinities may therefore be supposed as follows.

\begin{center}
\begin{tabular}{|l|l|}
\hline
Quiescent. & Diluent. \\
Vitriolic acid to calx of iron & Vitriolic acid to copper \\
Copper to its phlogiston & Calx of iron to phlogiston \\
\end{tabular}
\end{center}

345 The increase of affinity of the calx of iron to phlogiston is not a mere supposition; for if we put some fresh iron to a solution of the metal far depophilogiticated as to refuse to crystallize, so much of the phlogiston will be regained that the impoverished solution will now yield crystals. The reason why the increased quantity of phlogiston does not enable the acid to precipitate on the metal, is, because it is neither sufficiently large, nor attracted with a sufficient degree of force, to which the access of air and heat employed contribute considerably. The diminution of attraction in calxes of iron for acids is evident, not only from this but many other experiments; and particularly from the necessity of adding more acid to a turbid solution of iron in order to re-establish its transparency.

A depophilogiticated solution of iron is also precipitated by the calxes of copper. The same thing happens when copper is dissolved by a solution of iron in nitrous acid; only as the acid is more depophilogiticated as to refuse to crystallize, so much of the phlogiston is precipitated, and the solution becomes turbid, and precipitated from solution of iron in the marine acid, though exposed to the open air for 24 hours.

Solution of copper in the vitriolic acid is instantly precipitated by iron; the reason of which is plain from the common table of affinities; and hence the foundation of the method of extracting copper, by means of the triol, from some mineral waters. The precipitated solution affords a vitriol of iron, but of a paler kind than that commonly met with, and less fit for dyeing; it is only fit for dyeing, if being more depophilogiticated; the reason of which is, that copper contains more phlogiston than iron; for dyeing than old iron is also used which has partly lost its phlogiston, and induced.
Why a saturated solution of silver can scarcely be precipitated by iron.

Zinc cannot precipitate iron, as Mr Bergman has shown, until the solution of the latter loses part of its phlogiston. Hence we may understand why Newmann denied that iron can be precipitated by means of zinc. Mr Kirwan, however, has found, that zinc does not precipitate iron from the nitrous acid; but on the contrary, that iron precipitates zinc. In a short time the acid redissolves the zinc and lets fall the iron, owing to the calx of iron being too much dephlogisticated. Iron, however, will not precipitate zinc either from the vitriolic or marine acids. Most of the metallic substances precipitated by iron from the nitrous acid are in some measure redissolved shortly after; because the nitrous acid soon dephlogisticates the iron too much, then lets it fall, reacts on the other metals, and dissolves them.

Dr Lewis observes, that silver is sometimes not precipitated by copper from the nitrous acid which happens either when the acid is suphafurated with silver by taking up some in its metallic form, or when the silver is not much dephlogisticated. In this case, the remedy is to heat the solution and add a little more acid; which dephlogisticates it further; but the nitrous acid always retains a little silver.

It has commonly been related by chemical authors, that blue vitriol will be formed by adding filings of copper to a boiling solution of alum. Mr Kirwan, however, has shewed this to be an error; for after boiling a solution of alum for 20 hours with copper filings, not a particle of the metal was dissolved; the liquor standing even the left of the volatile alkali. The alum indeed was precipitated from the liquor, but still retained its saline form; so that the precipitation was occasioned only by the division of the superfusious acid.

No metal is capable of precipitating tin in its metallic form; the reason of which, according to Mr Kirwan, is, because the precipitation is not the effect of a double affinity, but of the single greater affinity of its metal to every other metallic earth. Me. and precipitations from the nitrous acid by tin are afterwards redissolved, because the acid soon quites the tin by reason of its becoming too much dephlogisticated.

Lead precipitates metallic solutions in the vitriolic and marine acids but slowly, because the first portion of lead taken up forms falls very difficult of solution which covers its surface, and prevents it from falling in the solution. At the same time it contains precipitated phlogiston, that a great quantity of it must be dissolved before it will disolve other metals. A solution of lead very much sufactuated cannot be precipitated by iron but with difficulty, if at all. Mr Kirwan conjectures that this may arise from some of the lead also being taken up in its metallic form, as is the case with mercury and silver. Iron will not precipitate lead from marine acid; for though a precipitate appears the acid is still adhering to the metal. On the contrary, iron is precipitated from its solution in this acid by lead, though very slowly.

Mercury is quickly precipitated from the vitriolic acid by copper, though the difference between the fusibility of the quick composing the metallic form; which Mr Kirwan observes, that silver does not precipitate mercury from the nitrous acid, though the difference between the fusibility of the usual dwellers powers, but by reason of the attraction of mercury and silver for each other; for they form partly an amalgam and partly a vegetation, scarcely any thing of either remaining in the solution.

Silver does not precipitate mercury from the solution of corrosive sublimate; but, on the contrary, mercury precipitates silver from the marine acid: and if a solution of luna cornea in volatile alkali is triturated with mercury, calomel will be formed; yet on distilling silver and mercury together, the mercury will fall in its metallic form, and luna cornea will be formed. The same thing happens on distilling silver and corrosive sublimate, the affinity of calx of mercury to phlogiston increasing with heat.

Bismuth precipitates nothing from vitriol of copper by the dry in 16 hours; nor does copper from vitriol of bismuth, way.

The two metallic substances, however, alternate to precipitate one another from the nitrous acid, which proceed from their different degrees of dephlogistication.

Nickel will scarcely precipitate any metal except it be reduced to powder. A black powder is precipitated by means of zinc from the solution of nickel precipitated by zinc.
in the vitriolic and nitrous acids, which has been shown by Bergman to consist of arsentic, nickel, and a little of the zinc itself. The latter, however, precipitates nickel from the marine acid.

The solutions of iron and nickel in the vitriolic acid mutually act upon these metals; but neither of them will precipitate the other in 24 hours, though on remaining longer at rest iron seems to have the advantage. Iron, however, evidently precipitates nickel from the nitrous acid, and though nickel seems to precipitate iron, yet this arises only from the gradual dephlogitisation of the iron.

Copper is precipitated in its metallic form from the vitriolic, nitrous, and marine acids, by nickel. The vitriolic and nitrous solutions of lead seem to act upon it without any decomposition, the calces uniting to each other. Lead seems for some time to be acted upon in the same manner by the vitriolic and nitrous solutions of nickel, but at last nickel seems to have the advantage; but a black precipitate appears which ever of them is put into the solution of the other. However, nickel readily precipitates vitriolic and nitrous solutions of bismuth, but it is the material that both these semimetals are soluble in the solutions of each other: yet nickel precipitates bismuth very slowly, and only in part; while bismuth precipitates a red powder, supplied by Mr Kirwan to be ochre, from the solution of nickel.

Cobalt is not precipitated by zinc either from the vitriolic or nitrous acids, though it seems to have some effect upon it when dissolved in that of sea-fall. Iron precipitates cobalt from all the three acids, yet much of the semimetal is retained in the vitriolic and nitrous solutions of it, particularly the latter; which, after letting fall the cobalt, takes it up again, and lets fall a dephlogiticated calx of iron. Nickel also, though it does not precipitate cobalt itself, as appears by the remaining redness of the solution, yet constantly precipitates some heterogeneous matter from it. Solution of cobalt in the marine acid becomes coloured by the addition of nickel. Bismuth is soluble in the vitriolic and nitrous solutions of cobalt, and throws down a small white precipitate, but does not affect the metallic part. Nor can we attribute these solutions in vitriolic acid to any excess in that acid, for they are dilute and made without heat. Copper also precipitates from the solution of cobalt a white powder supplied to be arsentic.

The regulus of antimony has no effect on solution of copper in vitriolic acid, nor is precipitated by it from the same acid; but it dissolves slowly in vitriol of antimony. With solution of vitriol of lead it becomes red in 16 hours, but is scarcely precipitated by lead from the vitriolic acid. Powdered regulus also precipitates vitriol of mercury very slightly. Bismuth neither precipitates nor is precipitated by the regulus in 24 hours from the vitriolic acid. Tin precipitates the regulus from the nitrous acid; but if regulus be put into a solution of tin in the same acid, neither of the metals will be found in the liquid in 16 hours, either by reason of the dephlogitisation or of the union of the calces to each other.

Iron does not precipitate regulus of antimony entirely from the marine acid; but seems to form a triple salt, consisting of the acid and both calces.

Contents, &c. of the Salt.

and that the weight so lost is just the same as that of an equal bulk of water; and consequently, that their specific gravity is equal to their weight in air, or absolute weight divided by their loss of weight in water.

3. That if a solid, specifically heavier than a liquid, be weighed first in air and then in that liquid, the weight it loses is equal to the weight of an equal volume of that liquid; and consequently, if such solid be weighed first in air, then in water, and afterwards in any other liquid, the specific gravity will be as the weight lost in it by such solid, divided by the loss of weight of the same solid in water. This method of finding the specific gravity of liquids, our author found more exact than that by the aerometer, or the comparison of the weights of equal measures of such liquids and water, both of which are subject to several inaccuracies.

4. That where the specific gravity of bodies is already known, we may find the weight of an equal bulk of water; it being as the quotient of their absolute weight divided by their specific gravities: and this he calls their loss of weight in water.

Thus where the specific gravity and absolute weight of the ingredients of any compound are known, the specific gravity of such compound may easily be calculated; as it ought to be intermediate between that of the lighter and that of the heavier, according to their several proportions: and this Mr Kirwan calls the mathematical specific gravity. But in fact the specific gravity of compounds, found by actual experiment, seldom agrees with that found by calculation; but is often greater, without any diminution of the lighter ingredient. This increase of density, then, Mr Kirwan supposes to arise from a closer union of the component parts to each other than either had separately with its own integral parts; and this more intimate union must, he thinks, proceed from the attraction of these parts to each other: for which reason he supposes, that this attraction might be estimated by the increase of density, or specific gravity, and was proportionable to it; but soon found that he was mistaken in this point.

Weights of different kinds of air. With regard to the absolute weights of several sorts of air, our author adheres to the computations of Mr Fontana, at whose experiments he was present; the thermometer being at 35°, and the barometer at 29; inches, or nearly so. These weights were as follow:

Cubic inch of common air, - 0.385
fixed air, - 0.654
marine air, - 0.390
nitrous air, - 0.788
vitreous acid air, - 0.2
alkaline air, - 0.2
inflammable air, - 0.3

Mr Kirwan begins his investigations with the marine acid; endeavouring first to find the exact quantity of pure acid it contains at any given specific gravity, and then by means of it determining the weight of acid contained in all other acids. For if a given quantity of pure fixed alkali were saturated, first by a certain quantity of spirit of salt, and then by determined quantities of the other acids, he concluded, that each of these quantities of acid liquor must contain the same quantity of acid; and this being known, the remain-

4. Method of finding the specific gravity of spirits of salt.

Two bottles were filled nearly to the top with distilled water, of which they contained in all 1399.7 grains, and successively introduced into two cylinders filled with marine air; and the process was renewed until the water had imbibed, in 18 days, about 794 cubic inches of the marine air. The thermometer did not rise all this time above 55°; nor sink, unless perhaps at night, above 50°; the barometer standing between 29 and 30 inches. This dilute spirit of salt then weighed 1920 grains; that is, 520.1 more than before; the weight of the quantity of marine air absorbed. The specific gravity of the liquor was found to be 1.225. Its loss of weight in water (that is, the weight of an equal bulk of water) should then be 1567.466 nearly; but it contained only, as we have seen, 1399.7 grains of water: subtracting this therefore from 1567.466, the remainder (that is, 167.466) must be the loss of 520.1 grains of marine acid; and consequently, the specific gravity of the pure marine acid, in such a condensed state as when it is united to water, must be 1.225, or 3.100.

Still, however, it might be suspected, that the density of this spirit did not entirely proceed from the mere density of the marine acid, but in part also from the attraction of this acid to water; and though the length of time requisite to make the water imbibe this quantity of marine acid air, naturally led to the supposition that the attraction was not very considerable, yet the following experiment was more satisfactory. He exposed 1440 grains of this spirit of salt to marine acid air for five days, the thermometer being at 50°, or below; and then found that it weighed 1562 grains, and consequently had imbibed 122 grains more. Its specific gravity was then 1.253, which was precisely what it should have been by calculation.

Being now satisfied that the proportion of acid in this spirit of salt was discovered, our author determined to find it in other acids also. For this purpose he took 180 grains of very strong oil of tartarper deignum, and found that it was saturated by 180 grains of spirit of salt, whose specific gravity was 1.225; and by calculation.

3 G
calculation it appeared, that 180 grains of this spirit contained 48.7 grains of acid, and 131.3 of water. Hence he drew up a table of the specific gravities of acid liquors containing 48.7 grains of pure acid, with different proportions of water, from 50 to 410 parts; the liquor with the first proportion having a specific gravity of 1.497, and the latter weighing only 1.074.

Mr Baume had determined the specific gravity of the strongest spirit of salt made in the common manner to 1.187, and Bergman 1.190; but we are told in the Paris Memoirs for 1790, that Mr Hubbem had produced a spirit whose specific gravity was 1.300; and that made by Dr Priestley, by saturating water with marine acid air, must have been about 1.500. The spirit of salt, therefore, whose specific gravity is 1.261, has but little attraction for water, and therefore attracts none from it; for which reason also it does not heat the ball of a thermometer, as the vitriolic and nitrous acids do; though Mr Cavallo found that this also had some effect upon the thermometer. Common spirit of salt, Mr Kirwan informs us, is always adulterated with vitriolic acid, and therefore unfit for these trials.

Mr Kirwan now set about investigating the quantity of acid, water, and fixed alkali in digestive salt, or a combination of the marine acid with vegetable alkali. For this purpose he took 100 grains of a solution of tolerably pure vegetable alkali, that had been three times calcined to whiteness, the specific gravity of which was 1.097; diluting also the spirit of salt with different portions of water; the specific gravity of one part being 1.015, and of another 1.068. He then found that the above quantity of solution of the vegetable alkali required for its saturation 27 grains of that spirit of salt whose specific gravity was 1.098, and 23.35 grains of that whose specific gravity was 1.115. Now, 27 grains of spirit of salt, whose specific gravity is 1.098, contain 3.55 grains of marine acid, as appears by calculation. The principles on which calculations of this kind are founded, our author gives in the words of Mr Cotes.

"The data requisite are the specific gravities of the mixture and of the two ingredients. Then, as the difference of the specific gravities of the mixture and the lighter ingredient is to the difference of the specific gravities of the mixture and the heavier ingredient; so is the magnitude of the heavier to the magnitude of the lighter ingredient. Then, as the magnitude of the heavier, multiplied into its specific gravity, is to the magnitude of the lighter multiplied into its specific gravity; so is the weight of the heavier to the weight of the lighter. Then, as the sum of these weights is to the weight of either ingredient; so is the weight given to the weight of the ingredient fought."

Thus, in the present case, 1.098<1.000<1.098 is the magnitude of the heavier ingredient, viz. the marine acid, and 0.983<1.000<3.038 is the weight of the marine acid; and on the other hand, 3.100<1.000<2.002, the magnitude of the water; and 2.002<1.000<2.002 its weight; the sum of these weights is 3.038; then if 2.358 parts of spirit of salt contain 0.308 parts of acid, 27 grains of this spirit of salt will contain 3.55 grains of acid. In the same manner it will be found, that 23.35 grains of spirit of salt, whose specific gravity is 1.115, contains 3.55 grains of acid.

Our author describes very particularly his method of making the saturation of the alkali with the acid; which, as it is always difficult to hit with precision, we shall here transcribe. "It was performed by putting the glass cylinder which contained the alkali solution on the scale of a very sensible balance, and at the same time weighing the acid liquor in another pair of scales; when the loss of weight indicated the escape of the nearly equal quantities of fixed air contained in the solution. Then the acid was gradually added by dipping a glass rod in it, to the top of which a small drop of the solution was stirred, and very small drops taken up and laid upon bits of paper stained blue with radish juice. As soon as the paper was in the left redden, the operation was completed; so that there was always a very small excess of acid, for which half a grain was constantly allowed; but no allowance was made for the fixed air, which always remains in the solution. But as on this account only a small quantity of the alkali solution was used, this proportion of fixed air must have been inconsiderable. If one ounce of the solution had been employed, this inappreciable portion of fixed air, would be sufficient to cause a sensible error; for the quantity of fixed air lost by the difference between the weight added to the 20 grains of fixed air, and the actual weight of the compound was judged of; and when this difference amounted to 2.2 grains, the whole of the fixed air was judged to be expelled: and it was found to be so; as 100 grains of the alkaline solution, being evaporated to dryness, in the heat of 500°, left a residuum which amounted to 104 grains, which contained 2.2 grains of fixed air."
proportion of acid in spirit of nitre to that in spirit of salt.

To find the specific gravity of the pure nitrous acid, we see that 11 grains of spirit of nitre, whose specific gravity is 1.419, contain the same quantity of acid with 27 grains of spirit of salt, whose specific gravity is 1.098, or 3.55 grains. The remainder of 11 grains, or 7.45 grains, is therefore mere water; and of consequence, if the density of the acid and water had not been increased by their union, the specific gravity of the pure nitrous acid should be 11.8729. But the specific gravity of the nitrous, as well as of the vitriolic acid, is augmented by its union with water; and therefore the loss of its weight in water is not exactly, as it would appear by calculation from the above premises, according to the rules already laid down. To determine therefore the real specific gravity of the acid in its natural state, the quantity of accreted density must be found, and subtracted from the specific gravity of the spirit of nitre, whose true mathematical specific gravity will then appear. This our author endeavoured to effect by mixing different portions of spirit of nitre and water, remarking the degree of diminution they sustained by such union; but was never able to attain a sufficient degree of exactness in the experiment. He had recourse therefore to the following method, as affording more satisfaction, though not altogether accurate. Twelve grains of the spirit of nitre, whose specific gravity by observation was 1.389, contained, as our author supposed from the former experiment, 3.55 grains of real acid, and 8.45 of water: then if the specific gravity of the pure nitrous acid were 1.572, that of this compound acid and water should be 1.771; for the loss of 3.55 should be 0.299, and the loss of the water 8.45, the sum of these losses is 8.749. Now, \( \frac{12}{8.749} = 1.371 \):

but the specific gravity, as already mentioned, was 1.380: therefore the accreted density was at least 0.018, the difference between 1.389 and 1.371. This calculation indeed is not altogether exact: but our author concludes, that 0.18 is certainly a near approximation to the degree of density that accrues to 3.55 grains of acid by their union to 7.45 grains of water: therefore, subtracting this from 1.419, we have nearly the mathematical specific gravity of that proportion of acid and water, namely, 1.401.

Again, since 11 grains of this spirit of nitre contain 3.55 grains of acid, and 7.45 of water, its loss of weight should be \( \frac{11}{1.401} = 7.855 \); and subtracting the loss of the aqueous part from this, the remainder 0.45 is the

fraction of the 3.55 grains acid; and consequently the true specific gravity of the pure and mere nitrous acid is

\[ \frac{3.55}{0.405} = 8.7654. \]

This being settled, the mathematical specific gravity and true increase of density of the above mixtures will be found. Thus the mathematical specific gravity of 12 grains of that spirit of nitre, whose specific gravity, by observation, was 1.380, must be 1.355; supposing it to contain 3.55 grains acid and 8.45 of water. For the loss of 3.55 grains acid is 3.55 = 0.405, and the loss of water 8.45; the

sum of these losses is 8.855. Then \( \frac{12}{8.855} = 1.355 \); and subsequently the accreted density is 1.389 - 1.355 = 0.034.

In the same manner it will be found that the mathematical specific gravity of 12.08 grains of that spirit of nitre, whose specific gravity by observation was 1.362, must be 1.315; and consequently its accreted density 0.047.

The whole of this, however, still rests on the supposition that each of these portions of spirit of nitre contain 3.55 grains of acid. To verify this supposition, our author examined the mathematical specific gravities of the first mixture he had made of spirit of nitre and water in large quantities; for if the mathematical specific gravities of these agreed exactly with those of the quantities he had supposed in smaller portions of each, he could not but conclude that the suppositions of such proportions of acid and water, as he had determined in each, were just.

This being determined by proper calculations, Mr. Table of Kirwan next proceeded to construct another table of specific gravities for the spirit of nitre, how constructed.

He had recourse therefore to the following method, as affording more satisfaction, though not altogether accurate. Twelve grains of the spirit of nitre, whose specific gravity by observation was 1.389, contained, as our author supposed from the former experiment, 3.55 grains of real acid, and 8.45 of water: then if the specific gravity of the pure nitrous acid were 1.572, that of this compound acid and water should be 1.771; for the loss of 3.55 should be 0.299, and the loss of the water 8.45, the sum of these losses is 8.749. Now, \( \frac{12}{8.749} = 1.371 \):

but the specific gravity, as already mentioned, was 1.380: therefore the accreted density was at least 0.018, the difference between 1.389 and 1.371. This calculation indeed is not altogether exact: but our author concludes, that 0.18 is certainly a near approximation to the degree of density that accrues to 3.55 grains of acid by their union to 7.45 grains of water: therefore, subtracting this from 1.419, we have nearly the mathematical specific gravity of that proportion of acid and water, namely, 1.401.

Again, since 11 grains of this spirit of nitre contain 3.55 grains of acid, and 7.45 of water, its loss of weight should be \( \frac{11}{1.401} = 7.855 \); and subtracting the loss of the aqueous part from this, the remainder 0.45 is the

fraction of the 3.55 grains acid; and consequently the true specific gravity of the pure and mere nitrous acid is

\[ \frac{3.55}{0.405} = 8.7654. \]

This being settled, the mathematical specific gravity and true increase of density of the above mixtures will be found. Thus the mathematical specific gravity of 12 grains of that spirit of nitre, whose specific gravity, by observation, was 1.380, must be 1.355; supposing it to contain 3.55 grains acid and 8.45 of water. For the loss of 3.55 grains acid is 3.55 = 0.405, and the loss of water 8.45; the

sum of these losses is 8.855. Then \( \frac{12}{8.855} = 1.355 \); and consequently the accreted density is 1.389 - 1.355 = 0.034.

In the same manner it will be found that the mathematical specific gravity of 12.08 grains of that spirit of nitre, whose specific gravity by observation was 1.362, must be 1.315; and consequently its accreted density 0.047.

The whole of this, however, still rests on the supposition that each of these portions of spirit of nitre contain 3.55 grains of acid. To verify this supposition, our author examined the mathematical specific gravities of the first mixture he had made of spirit of nitre and water in large quantities; for if the mathematical specific gravities of these agreed exactly with those of the quantities he had supposed in smaller portions of each, he could not but conclude that the suppositions of such proportions of acid and water, as he had determined in each, were just.

This being determined by proper calculations, Mr. Table of Kirwan next proceeded to construct another table of specific gravities for the spirit of nitre, how constructed.
CHEMISTRY.

Contents of acid, water, and fixed alkali in nitre, in a manner similar to what he had already done with digestive salt; and found that 100 grains of perfectly dry nitre contained 28.48 grains of acid, 5.2 grains of water, and 66.32 grains of fixed alkali.

Some experiments of the same kind had been made by Dr. Homberg; the results of which our author compared with those of his own. The specific gravity of the spirit of nitre which M. Homberg made use of was 1.249; and of this, he says, one ounce two drachms and 36 grains, or 621 troy grains, are required to saturate one French ounce (472.5 troy) of dry salt of tartar. According to Mr. Kirwan's computation, however, 63 grains of that whose specific gravity was 1.525, 7.465 of water, and 93.97 of fixed alkali, were required to saturate one French ounce of nitre. It was natural to expect the former proportion, since, Mr. Kirwan observes, that the proportion of fixed alkali with such a quantity of phlogiston as quite alters its properties.

It was next attempted to find the specific gravity of the pure vitriolic acid in a manner similar to that specific gravity by which the gravity of the nitrous acid was found; as it cannot be had in the state of air, unless when united with such a quantity of phlogiston as quite alters its properties. The loss of 6.5 grains of oil of vitriol, whose specific gravity is 1.819, is $\frac{6.5}{6.5} = 3.572$; but as there 6.5 grains contained, before 3.55 of acid, 2.95 of water, the loss of this must be subtracted from the entire loss; and then the remainder, or 0.622, is the loss of the pure acid part in that state or density to which it is reduced by its union with water. The specific gravity, therefore, of the pure vitriolic acid, in this state of density, is $\frac{3.55}{0.622} = 5.707$. But to find its natural specific gravity, we must find how much its density is increased by its union with this quantity of water: and in order to observe this, he proceeded as before with the nitric acid. 6.96 grains of oil of vitriol, whose specific gravity was 1.771, contained 3.55 of acid and 3.41 of water; and its specific gravity by calculation should be 1.726; for the loss of 3.55 grains of acid is $\frac{3.55}{5.707}$; the loss of 3.41 grains of water is 3.41; the sum of these is 0.622; the loss of 3.41 grains of water is 3.41; therefore the accurate density is 1.771. 4.032, 1.726; 0.45. Taking this therefore from 1.819, its mathematical specific gravity will be 1.774. Then the loss of 6.5 grains of oil of vitriol, whose specific gravity by observation is 1.819, will be found to be $\frac{6.5}{1.774} = 3.667$; but of this, 2.95 grains are the loss.
Theory.

Contents, &c. of the salts.

of the water it contains, and the remainder 0.714 are the loss of the mere acid part. Then \[ \frac{3.55}{0.714} \] is nearly

ly the true specific gravity of the pure vitriolic acid. The specific gravity of the most concentrated oil of vitriol yet made, is, according to M. Baume and Bergman, 2.125.

Mr. Kirwan now constructed a table of the specific gravities of vitriolic acids, of different strengths, in a manner similar to others constructed for spirit of salt and spirit of nitre; but for which, as well as the others, we must refer to Phil. Trans. vol. 71. He then proceeded to find the proportion of acid, water, and fixed alkali, in vitriolated tartar as he had before done in the same acid and nitre. He found the salts resulting from the saturation of the same oil of tartar, with portions of oil of vitriol, of different specific gravities, to weigh at a medium 12.45 grains. Of this weight only 11.83 grains were alkali and acid. The remainder, therefore, was water, 0.62 of a grain. Consequently 100 grains of perfectly dry tartar vitriolate contain 21.58 grains acid, 4.82 of water, and 66.67 of fixed vegetable alkali. In drying this salt, a heat of 240 degrees was made use of, to expel the adhering acid more thoroughly. It was kept in this heat for a quarter of an hour.

According to Mr. Homberg, one French ounce, or 472.5 grains troy, of dry salt of tartar, required 297.5 grains troy, of oil of vitriol, whose specific gravity was 1.674, to saturate it: but by Kirwan’s calculation, this quantity of fixed alkali would require 325 grains; a difference which, considering the different methods they used for determining the specific gravities (Homberg’s method by menurination, giving it always less than Mr. Kirwan’s) the different defecation of their alkalis, &c. may be accounted inconsiderable.

The salt produced, according to Mr. Homberg, weighed 182 grains troy above the original weight of the fixed alkali; but by Kirwan’s experiment, it should weigh but 87.7 grains more. “It is hard to say (adds Mr. Homberg) how Mr. Kirwan could find this great excess of weight, both in nitre and tartar vitriolate; unless he meant by the weight of the salt of tartar the weight of the mere alkaline part distinct from the fixed air it contained: and indeed one would be tempted to think he did make the distinction; for in that case the excess of weight would be nearly such as he determined it.”

From Mr. Homberg’s calculations, he inferred that one ounce (472.5 grains) of oil of vitriol contains 291.7 grains of acid. Mr. Kirwan computes the acid only at 213.3 grains; but Homberg made no allowance for the water contained in tartar vitriolate; and imagined the whole increase of weight proceeded from the acid that is united in it to the fixed alkali. Now the aqueous part in 560 grains of tartar vitriolate amounts to 36 grains; the remaining difference may be attributed to the different degrees of defecation, &c.

On the acetic acid Mr. Kirwan did not make any experiment; but by calculating from those of Homberg, he finds that the specific gravity of the pure acetic acid, free from superfluous water, should be 2.30. “It is probable (says Mr. Kirwan), that its affinity to water is not strong enough to cause any irregular increase in its density; at least what can be expressed by three decimals: and hence its proportion of acid and water may always be calculated from its specific quantity and absolute weight.”

An hundred parts of vitriolated tartar, or, as it should rather be called, acetous tartar, contain, when well dried, 32 of fixed alkali, 19 of acid, and 49 parts of water. The specific gravity of the strongest vitriolated vinegar made is 1.069. It is more difficult to find the point of saturation with the vegetable than with the mineral acids, because they contain a nurse that prevents their immediate union with alkalis; and hence they are commonly used in too great quantity: they should be used moderately hot, and sufficient time allowed them to unite.

From all the experiments above related, Mr. Kirwan concludes, 1. That the fixed vegetable alkali takes up an equal quantity of the three mineral acids, and probably all pure acids; for we have seen that 8.2 grains of pure vegetable alkali, that is, free from fixed air, take up 3.55 grains of each of these acids; and consequently 100 parts of caustic fixed alkali would require 42.4 parts of acid to saturate them. But Mr. Bergman has found that 100 parts of caustic fixed vegetable alkali take up 47 parts of the aerial acid; which, considering that his alkali might contain some water, differs but little from that already given. It should seem, therefore, that alkalis have a certain determined capacity of uniting to acids; that is, to a given weight of acids; and that this capacity is equally satisfied by a given weight of any pure acid indiscriminately. This weight is about 2.33 of the vegetable alkali.

2. That the three mineral acids, and probably all quantities of pure acids, take up 2.253 times their own weight of the alkali, pure vegetable alkali, that is, are saturated by that quantity.

3. That the density accruing to compound substances, from the union of their compound parts, and exceeding its mathematical ratio, increases from a minimum, when the quantity of one of them is very small in proportion to that of the other; to a maximum, when their qualities differ less: but that the attraction, on the contrary, of that part which is in the smallest quantity to that which is in the greatest, is at its maximum when the accrued density is at its minimum; but not reciprocally: and hence the point of saturation is probably the maximum of density and the minimum of the decomposition operated by means of a substance that has a greater affinity with one part of a compound than with the other, and than these parts have with each other. It can be complete, unless the minimum affinity of the third substance be greater than the maximum affinity of the parts already united. Hence also few compositions are complete, unless a double affinity intervenes; and hence the last portions of the separated substance adhere so obstinately to that with which it was first united, as all chemists have observed. Thus, though acids have a greater affinity to phlogiston than the earths of the different metals have to it, yet they can never totally dephlogisticate these earths but only to a certain degree; so, though atmospheric air, and particularly dephlogisticated air, attracts phlogiston more strongly than the nitrous acid gitates does, yet even dephlogisticated air can deprive the metallic nitrous acid totally of its phlogiston; as is evident from the
the red colour of the nitrous acid, when nitrous air and dephlogisticated air are mixed together. Hence mercury precipitated from its solution in any acid, even by fixed alkalis, constantly retains a portion of the acid to which it was originally united, as Mr Bayen has shown. Thus also the earth of alum, when precipitated in like manner from its solution, retains part of the acid; and thus several anomalous decompositions may be explained.

4. That concentrated acids are in some measure phlogisticated, and evaporate by union with fixed alkalis.

5. That, knowing the quantity of fixed alkali in oil of tartar, we may determine the quantity of real pure acid in any other acid substance that is difficultly decomposed; as the feditive acid, and those in vegetables and animals. For 10.5 grains of the mild alkali will always be saturated by 3.55 grains of real acid; and reciprocally, the quantity of acid in any acid liquor being known, the quantity of real alkali in any vegetable alkaline liquor may be found.

Having thus determined the quantity of acid contained in the liquids of that kind usually employed in chemistry, as well as the specific gravities of the acids themselves, Mr Kirwan became desirous of investigating the gravity of fixed and volatile alkalis. But as these substances are not easily preserved from uniting themselves with fixed air, he was led to consider the gravity of this in its fixed state, as an element necessary for the calculation of the quantities of the alkalis.

To find the specific gravity of the fixed vegetable alkali, our author proceeded in a manner similar to that already described, excepting that he weighed it in ether instead of spirit of wine. The results of his experiments are.

1. That 100 grains of this alkali contain about 6.7 grains of earth; which, according to Mr Bergman, is fucicicous. It Palmer the filter along with it when the alkali is not saturated with fixed air; so that it seems to be held in solution in the same manner as in the liqour fucicum.

2. The quantity of fixed acid in oil of tartar and dry vegetable fixed alkali is various at various times, and in various parcels of the same salt; but in the purer alkalis it may be reckoned at a medium 21 grains in 100; and hence the quantity of this alkali is nearly guised at in any solution, by adding a known weight of any dilute acid to a given weight of such a solution, and then weighing it again; for as 21 is to 100, so is the weight lost to the weight of mild alkali in such solution. The specific gravity of mild and perfectly dry vegetable fixed alkali, four times calcined, free from fucicous earth, and containing 21 per cent. of fixed acid, was found to be 5.0527. When it contains more fixed air the gravity is probably higher, except when it is not perfectly dry; and hence the specific gravity of this alkali, when calcus, was supposed by Mr Kirwan to be 4.234. For this reason the fixed alkali, when united to pure acid, solution is more than when united either to the vitriolic or nitrous. Thus Mr R. Watfon, in the Philosophical Transactions for 1770, informs us, that he found the specific gravity of dry salt of tartar, including the fucicous earth it naturally contains, to be 2.761; whereas the specific gravity of vitriolated tartar was only 2.356, and that of nitre 1.923. The reason why nitre is so much lighter than tartar vitriolate, is, that it contains much more water, and the union of the acid with the water is less intimate.

Impure vegetable fixed alkalis, such as pearl-ash, potashes, &c. contain more fixed air than the purer kind. According to Mr Cavendish, pearl-ash contains 28.4 or 20.7 per cent. of fixed air. Hence in lye made from these salts, of equal specific gravities with those of a purer alkali, the quantity of saline matter will probably be in the ratio of 28.4 or 20.7 to 21; but this additional weight is only fixed air. Much also depends on their age; the oldest containing most fixed air. Our author also gives a table of the specific gravities of different solutions of vegetable fixed alkali, in a manner similar to what he had done before with the acids. He begins with 64.92 grains of a solution containing 21.23 grains of salt, and 36.67 of water. The accreted density he finds to be 0.50, the mathematical specific gravity 1.145, and the specific gravity by observation 1.145. By continually diluting the solution containing the same quantity of salt, he brings the absolute weight of it at last to 241.04 grains, of which 317.49 are water; the accreted density 0.01, the mathematical specific gravity 1.061, and the specific gravity by observation 1.062.

In a subsequent paper on this subject, Philosophical Transactions, vol. 72, p. 179, our author corrects a small mistake concerning the quantity of acid taken up by 10.5 grains of mild vegetable alkali. In his former computations he had made no allowance for the small quantity of earth contained in this quantity of alkali; which, though inconsiderable in itself, becomes of consequence where the quantities are large. The error, however, occasioned by this omission, is solvable by his calculations concerning the quantities of acid alkali, &c. contained in the neutral salts, as well as in that concerning the vegetable alkali. When the correction is properly made, he says, it will be found that 100 grains of such alkali, free from earth, water, and fixed air, take up 46.77 grains of the mineral acids, that is, of the mere acid part; and 100 grains of common mild vegetable alkali take up 36.23 grains of real acid. An hundred grains of perfectly dry tartar vitriolate contain 30.37 of real acid, 64.61 of fixed alkali, and 5.18 of water. Crystallized tartar vitriolate loses only one percent. of water in a heat in which its acid is not separated in any degree; and therefore contains 6.18 of water. An hundred grains of nitre, perfectly dry, contain 30.86 of acid, 66 of alkali, and 3.14 of water; but in crystallized nitre the proportion of water is somewhat greater; for 100 grains of those crystals being exposed to a heat of 180° for two hours, lost three grains of their weight without exhalting any acid fume; but when exposed to a heat of 200 degrees, the fume of the nitrous acid is distinctly perceived. Hence 100 grains of crystallized nitre contain 29.89 of mere acid, 6.47 of alkali, and 6.14 of water. An hundred grains of digestive salt perfectly dry, contain 26.68 of marine acid, 65.47 of alkali, and 6.85 of water. One hundred grains of crystallized digestive salt lose but one grain of their weight before the fume of the marine acid is perceived; and hence they contain 7.85 grains of water.

Another mistake, more difficult to be corrected, was his supposing the mixtures of oil of vitriol and water, and spirit of nitre and water, had attained their maximum of density when they had cooled to the temperature...
Theory.

Alteration of the density of acids by various degrees of heat.

The mixture with oil of vitriol had been suffered to stand six hours; but when the acid was so much diluted as to occasion little or no heat, it was allowed to stand only for a very little time. Several months afterwards, however, many of these mixtures were found much denser than when he first examined them; and it was discovered, that at least twelve hours rest was necessary before concentrated oil of vitriol, to which even twice its weight of water is added, can attain its utmost density; and still more when a smaller proportion of water is used. Thus when he made the mixture of 2519.75 grains of oil of vitriol, whose specific gravity was 1.819, with 180 of water, he found its density six hours after 1.771, but after 24 hours it was 1.798: and hence, according to the methods of calculating already laid down, the accurred density was at least .064 instead of .045. But by using oil of vitriol still more concentrated, whose specific gravity was 1.8846, he was enabled to make a still nearer approach; and found, that the accurred density of oil of vitriol, whose specific gravity is 1.819, amounts to 0.104, and consequently its mathematical specific gravity is 1.715. Six grains and a half of this oil of vitriol contained, as has been already observed, 2.55 of mere acid, and the remainder was water. The weight of an equal bulk of water is 5.79 grains; and subtracting from this the weight of the water that enters into the composition of the oil of vitriol, it will be found, that the weight of a bulk of water equal to the acid part is 0.84; and consequently the specific gravity of the mere acid part is 4.226. Thus, by constantly allowing the mixtures to rest at least 12 hours, until the oil of vitriol was diluted with four times its weight of water, and then only six hours before the density of the mixtures was examined, he confructed another table, in which 1000 grains of liquid contained 612.05 of pure acid, 387.95 of water, the accurred density being .07, and the mathematical specific gravity 1.877. Increasing the quantity of water till the acid weighed 7000 grains, and the water 6287.95, he found the accurred density .075, and the mathematical specific gravity 1.669. By a similar correlation of his experiments on the acid of nitre, he found its density to be 5.320; a similar table was constructed for it, for which we refer our readers to the 72d volume of the Philosophical Transactions.

The total expansion of this spirit of nitre, therefore, from 30 to 120 degrees, that is, by 90° of heat, was 0.0527; for 1.4535=1.4123=.0407. By which we infer, that the dilatations are nearly proportional to the degrees of heat; for beginning with the first dilatation from 30 to 46 degrees, that is, by 16 degrees of heat, we find that the difference between the calculated and observed dilatations is only 0.0004; a difference of no confquence in the present case, and which might arise from the immixture of the cold glass-ball filled with mercury in the liquor. In the next case the difference is still less, amounting only to 0.0000. With another, and somewhat stronger spirit of nitre, the specific gravities were as follow:

<table>
<thead>
<tr>
<th>Degrees of heat</th>
<th>Specific gravity</th>
</tr>
</thead>
<tbody>
<tr>
<td>34</td>
<td>1.4750</td>
</tr>
<tr>
<td>49</td>
<td>1.4653</td>
</tr>
<tr>
<td>150</td>
<td>1.3792</td>
</tr>
</tbody>
</table>

Here also the expansions were nearly proportional to the degrees of heat; for 116° of heat, the difference between 34 and 150, produce an expansion of 0.0958; and 15° of heat, the difference between 34 and 49, produce an expansion of 0.0097; and by calculation 0.0123: which last differs from the truth only by 0.0001.

From this experiment we see, that the stronger the spirit of nitre is, the more it is expanded by the same degree of heat than it is expanded by heat than the former, its dilatation, by 116 degrees of heat, weak, and should be 0.0679; whereas it was found to be 0.0958.

As the dilatation of the spirit of nitre is far greater than that of water by the same degree of heat, and as it confits only of acid and water; it clearly follows, that its superior dilatability must be owing to the acid part: and hence the more acid that is contained in any quantity of spirit of nitre, the greater is its dilatability. We might therefore suppose, that the dilatation of nitre was intermediate between the quantity of water it contains and that of the acid. But there exists another power also which prevents this simple result, viz. the attraction of the acid and water to each other, which makes them occupy less space than the sum of their joint volumes; and by this condensation our author explains his phrase of accurred density. Taking this into the account, we may consider the dilatation of the spirit of nitre as equal to those of the quantities of water and acid it contains, minus the condensation they acquire from their mutual attraction; and this rule holds as to all other heterogeneous compounds.

To find the quantities of acid and water in spirit of nitre, whose specific gravity was found in degrees of quantities temperature different from those for which the table of specific gravity of nitre was constructed, viz. 54°, 55°, or 56° of Fahrenheit, there is a certain method of finding how much that spirit of nitre is expanded or condensed by a greater or lesser degree of heat; and then, by the rule of proportion, find what its density would be at 55°. But if this cannot be done, we shall approach pretty near the truth if we allow for every 15° degrees of heat above or below 55° of Fahrenheit, when the specific gravity is between 1.400 and 1.500, and .5, when the specific gravity is between 1.600 and 1.800. The dilatations of oil and spirit of vitriol were found to be exceedingly irregular, probably by reason of a white foreign matter, which is more or less suspended or dissolved in it, according to its greater or lesser dilution:
and this matter our author did not separate, as he intended to try the acid in the state in which it is commonly used. In general he found that 15° of heat caused a difference of above $+\frac{3}{4}$, in its specific gravity, when it exceeds 1.000, and of $+\frac{1}{4}$, when its specific gravity is between 1.400 and 1.500.—The dilatations of spirit of salt are very nearly proportional to the degrees of heat, as appears by the following table.

Hence $+\frac{1}{4}$ should be added or subtracted for every 21° above or below 55°, in order to reduce it to 55°, the degree for which its proportion of acid and water was calculated. The dilatability of this acid is much greater than that of water, and even than that of the nitrous acid of the same density.

Our author next proceeds to consider the quantity of pure acids taken up at the point of saturation by the various substances they unite with.—He begins with the mineral alkali. Having rendered a quantity of this caustic in the usual manner, and evaporating one ounce of the caustic solution to perfect dryness, he found it to contain 20.25 grains of solid matter. It was observed, that the watery part alone alkali during evaporation, as the quantity of fixed air contained in it was very small, and to dissipate this a much greater heat would have been requisite than that which he used. This dry alkali was dissolved in twice its weight of water; and saturating it with dilute vitriolic acid, he found it to contain 2.25 grains of fixed air; that being the weight which the saturated solution wanted of being equal to the joint weights of water, alkali, and spirit of vitriol employed.

The quantity of pure vitriolic acid necessary to saturate 100 grains of pure mineral alkali was found to be 60 or 61 grains; the saturated solution thus formed being evaporated to perfect dryness weighed 56.5 grains; but this weight only 28.58 were alkali in one of the experiments; the remainder, that is, 8.12 grains, therefore

<td>60 or 61 grains</td>
</tr>
</tbody>
</table>

Hence 100 grains of Glauber’s salt, perfectly dried, contained 20.12 of pure vitriolic acid, 48.6 of mere alkali, and 22.28 of water. But Glauber’s salt crystallized contains a much larger proportion of water; for 100 grains of these crystals heated red hot lost 55 grains of their weight; and this loss Mr Kirwan supposes to arise merely from the evaporation of the watery part, and the remaining 45 contained alkali, water, and acid, in the same proportion as the 100 grains of Glauber’s salt perfectly dried abovementioned. Then these 45 contained 13.19 grains of vitriolic acid, 21.87 of fixed alkali, and 9.94 of water; consequently 100 grains of crystallized Glauber’s salt contains 13.19 of vitriolic acid, 21.87 of alkali, and 6.404 of water.

On saturating the mineral alkali with dephlogitized nitrous acid, it was found that 100 grains of the alkali took up 57 of the pure acid in the experiment he most depended upon; though in some others this quantity varied by a few grains: he concludes, therefore, that the quantity of alkali taken up by this acid is nearly the same as that taken up by the vitriolic.

Supposing this quantity to be 57 grains, then 100 grains of cubic nitre, perfectly dry, contain 50 of acid, 52.18 of alkali, and 17.82 of water: but cubic nitre crystallized contains something more water; for 100 grains of these crystals lose about four by gentle drying; therefore 100 grains of the crystallized salt contain 28.8 of acid, 50.09 of alkali, and 21.11 of water.

An hundred grains of mineral alkali require from 63 to 66 or 67 grains of pure marine acid to saturate it; but Mr Kirwan supposes that one reason of this variety is, that it is exceeding hard to hit the true point of saturation. Allowing 66 grains to be the quantity required, then 100 grains of perfectly dry common salt contain nearly 55 grains of real acid, 53 of alkali, and 13 of water; but 100 grains of the crystallized salt lose five by evaporation; so that 100 grains of these crystals contain 33.5 of acid, 50 of alkali, and 16.7 of water.

The proportion of fixed air, alkali, and water, was thus investigated: 200 grains of these crystals were fixed air, dissolved in 240 of water; the solution was saturated alkali, and by such a quantity of spirit of nitre as contained 40 water, insoluble vitriolic acid, and 35 of its water; whence it was inferred that these 200 grains of salt of soda contained 70 of pure alkaline salt. The saturated solution weighed 40 grains less than the sum of its original weight, and that of the spirit of nitre added to it; consequently it lost 40 grains of fixed air. The remainder of the original weight of the crystals therefore must have been water, viz. 90 grains. Consequendy 100 grains of these crystals contained 55 of alkali, 20 of fixed air, and 45 of water. This proportion differs considerably from that assigned by Mr Bergman and Lavoisier, which our author imputes to their having made use of soda recently crystallized; but Mr Kirwan’s had been made for some months, and probably lost much water and fixed air by evaporation, which altered the proportion of the whole. According to the calculations of Bergman and Lavoisier, 100 grains of this alkali take up 80 of fixed air. The specific gravity of the crystallized mineral alkali, weighed in ether, found to be 1.421.

The proportion of the different ingredients in volatile alkalies can only be had from the experiments lately made by Dr Priestley concerning alkaline air. He informs us, that $\frac{4}{5}$ of a measure of this, and one measure of fixed air, saturate one another. Then supposing the measure to contain 100 cubic inches, 185 cubic inches of alkaline air take up 100 of fixed air; but 185 cubic inches of alkaline air weigh at a medium 42.53 grains, and 100 cubic inches of fixed air weigh 57 grains; therefore 100 grains of pure volatile alkali, free from water, take up 134 of fixed air.

On expelling its aerial acid from a quantity of this volatile alkali in a concrete state, and formed by sublimation, he found, that 53 grains of it were fixed air; according to the preceding calculation, 100 grains of it should contain 39.47 of real alkali, and 7.53 of water, the rest being fixed air.—On saturating a quantity with the vitriolic, nitrous, and marine acids, 100 grains of the mere alkali were found to take up 106 of mere vitriolic acid, 115 of the nitrous, and 130 of the marine acid. The specific gravity of the volatile alkali
Theory.  

In making experiments on calcareous earth, it was first dissolved in nitrous acid; and after allowing for the loss of fixed air and water, 100 grains of the pure earth was found to take up 104 of nitrous acid; but only 91 or 92 of mere vitriolic acid were required to precipitate it from the nitrous solution.

Of the marine acid 100 grains of the pure calcareous earth require 112 for their solution. The liquor at first is colourless, but acquires a greenish colour by standing.

Natural gypsum varies in its proportion of acid, water, and earth; 100 grains of it containing from 32 to 34 of acid and like wise of earth, and from 26 to 27 of water. The artificial gypsum contains 32 of earth, 29.44 of acid, and 38.56 of water. When well dried, it loses about 24 of water; and therefore contains 42 of earth, 39 of acid, and 19 of water, per hundred.

In nitrous felenite.

In marine felenite.

Calcined magnesia will not dissolve in acids without heat.

An hundred grains of this earth, deprived of the fixed air, require 112 of the pure vitriolic acid to dissolve them. The solution was made in a very dilute spirit of vitriol, whose specific gravity was 1.003, and in which the proportion of acid to the water was nearly as 1 to 10. It contained a slight excess of acid, turning the vegetable blues to a brownish red; but it crystallized when cold, and the crystals were of the form of alum. Our author, therefore, is of opinion, that this is the true proportion of acid and earth to be used in the formation of that salt, though there was not water enough to form large crystals. Perceiving this fault—that the liquor contained an excess of acid, more way was contained an excess of acid.

In the experiments made by our author on metals, the acids employed were far dephlogisticated as 10 grains of carbonic acid were added, but thus it was found impossible to prevent it from turning vegetable blue of a red colour until a precipitation was formed: and even when this was the case, though one part of the salt fell in the form just mentioned, yet the rest would still redden vegetable blues as before; though here our author doubts whether this be a mark of acidity. An hundred grains of alum, when dried, contain 42.74 of acid, 3.21 of earth, and 25.02 of water; but crystallized alum loses 44 per cent. by dehydration: therefore 100 grains of it contain 23.94 of acid, and 58.06 of water. An hundred grains of this pure earth take up, as near as can be judged, 153 of pure nitrous acid. The solution still reddened vegetable blues; but after the above quantity of earth was added, an infoluble salt began to precipitate. The solution, when cold, became turbid, and could not be rendered quite clear by 500 times its quantity of water. An hundred and seventy-three grains of pure calcareous earth are required for the dilution of 100 grains of earth of alum, but the liquor still reddened vegetable blue. After this an infoluble salt was formed; but it is difficult to ascertain the beginning of its formation, particularly both in this and the preceding cases. The specific gravity of pure argillaceous earth, containing 25 per cent. of fixed air, is 1.0091.

In the experiments made by our author on metals, the acids employed were far dephlogisticated as 10 grains of carbonic acid were added, but thus it was found impossible to prevent it from turning vegetable blue of a red colour until a precipitation was formed: and even when this was the case, though one part of the salt fell in the form just mentioned, yet the rest would still redden vegetable blues as before; though here our author doubts whether this be a mark of acidity. An hundred grains of alum, when dried, contain 42.74 of acid, 3.21 of earth, and 25.02 of water; but crystallized alum loses 44 per cent. by dehydration: therefore 100 grains of it contain 23.94 of acid, and 58.06 of water. An hundred grains of this pure earth take up, as near as can be judged, 153 of pure nitrous acid. The solution still reddened vegetable blues; but after the above quantity of earth was added, an infoluble salt began to precipitate. The solution, when cold, became turbid, and could not be rendered quite clear by 500 times its quantity of water. An hundred and seventy-three grains of pure calcareous earth are required for the dilution of 100 grains of earth of alum, but the liquor still reddened vegetable blue. After this an infoluble salt was formed; but it is difficult to ascertain the beginning of its formation, particularly both in this and the preceding cases. The specific gravity of pure argillaceous earth, containing 25 per cent. of fixed air, is 1.0091.

After this an infoluble salt was formed; but it is difficult to ascertain the beginning of its formation, particularly both in this and the preceding cases. The specific gravity of pure argillaceous earth, containing 25 per cent. of fixed air, is 1.0091.
CHEMISTRY

The air produced by this solution is entirely inflammable, and generally amounts to 115 cubic inches. By the affinities of a strong heat, iron is also soluble in the concentrated vitriolic acid, though in smaller quantity; and instead of inflammable air, a large quantity of vitriolic air is produced, and a little sulphur is sublimed towards the end. The reason of this is, that the concentrated vitriolic acid, containing much less specific fire than the dilute kind, cannot expel the phlogiston in the form of inflammable air (which absorbs a vast quantity of fire), but unites with it when further dephlogismated by heat, and thus forms both vitriolic air and sulphur. An hundred grains of iron dissolved without heat afford more than 400 of vitriol; and 100 grains of vitriol, when crystallized, contain 25 of iron, 20 of real acid, and 55 of water. When calcined nearly to redness, these crystals lose about 40 per cent. of water.

The calxes of iron are soluble in the vitriolic acid according to the quantity of phlogiston they contain; the more phlogisticated being more readily soluble, and those which are dephlogisticated least of. The latter not only require more real acid for their solution, but afford only a thick liquor or magma by distillation, instead of crystals like the others. Hence also solutions of iron, when newly made, diminish, and consequently phlogisticate, the superincumbent air by their gradual emulsion of phlogiston; at the same time that the calx, becoming more and more dephlogisticated, gradually falls to the bottom, unleas more acid be added to keep it in solution.

An hundred grains of iron require for their solution in nitrous acid 1/2 grains of real acid, so diluted that its proportion to water should be as 1 to 13 or 14; and when this last proportion is used, the heat of a candle may be employed for a few seconds, and the access of common air prevented. Thus about 18 cubic inches of nitrous acid are produced, the rest being absorbed by the solution, and no red vapours appear. But if the proportion of acid and water be as 1 to 8 or 10, a much greater quantity of metal will be dephlogisticated by the application of heat, though very little of it be held in solution. Thus, from 100 grains of iron Mr Kirwan has obtained 83.87 cubic inches of nitrous acid; and by distilling the solution, a still greater quantity may be obtained which had been absorbed.

The reason that nitrous solutions of iron or other metals yield no inflammable air is, because this acid has less affinity to water, and more to phlogiston, than the vitriolic, and likewise contains much less fire than that or the marine (see p. 278); and therefore unites with phlogiston, instead of barely expelling it. Hence also the vitriolic acid, though united with 30 times its weight of water, will still visibly act on iron, and separate inflammable air in the temperature of 55°, whereas nitrous acid, diluted with 15 times its weight of water, has no perceptible effect on the metal in that temperature. The calxes of iron, if not too much dephlogisticated, are also soluble in the nitrous acid.

Two hundred and fifteen grains of real marine acid are required for the solution of 100 grains of iron. When the proportion of water to the acid is as four to one, it effervesces rather too violently with the metal; and heat is rather prejudicial, as it volatile isot the acid.

Theory.

An hundred and eighty-three grains of real vitriolic acid are required to dissolve an hundred grains of copper; the proportion of acid to that of water being as 1 to 1.5, or at least as 1 to 1.7; and a strong heat must also be applied. Mr Kirwan says he never could dissolve the whole quantity of copper; but to dissolve a given quantity of it, a still greater heat must be employed in the proportion of 28 to 100; but this residuum also is soluble by adding more acid. Copper dephlogisticated in this manner is soluble by adding warm water to the mass.

By treating 128 grains of copper in this manner, we obtain 11 cubic inches of inflammable air and 65 of vitriolic acid. When inflammable air was obtained, our author tells us the acid was a little more aqueous. The reason why copper cannot be dephlogisticated by dilute vitriolic acid, or even by the concentrated kind without the assistance of heat, is its vitriolic acid attraction to phlogiston, and the great quantity it contains.

An hundred grains of vitriol of copper contain 25 of metal, 30 of acid, and 43 of water; 28 of which last are lost by evaporation or slight calcination. An hundred grains of copper, when dissolved, afford 376 cubic inches of blue vitriol.

An hundred grains of copper require 130 of pure nitrous acid for their dissolution. If the acid be so far diluted that its proportion of water be as 1 to 14, the affinity of heat will be necessary, but not otherwise. This solution affords 675 cubic inches of nitrous triacid.

The calxes of copper are soluble in the nitrous acid, though less easily than in the nitrous.

The vitriolic acid dissolves tin but in small quantity; an hundred grains of the metal requiring for its solution 872 of real acid, whose proportion to water should not be less than 1 to 0.9. A strong heat is also required. When the action of the acid has ceased, some hot water should be added to the turbid solution, and the whole again heated. The metal is soluble in a more dilute acid, but not in such quantity. The solution above-mentioned affords 70 cubic inches of inflammable air. — The calxes of tin, excepting that precipitated from marine acid by fixed alkalies, are insoluble in the vitriolic acid.

An hundred grains of tin require 1200 of real nitrous acid, whose proportion of water should be at least 25 to 1, and the heat employed not exceeding 60°. The quantity of air afforded by such solution is only 10 cubic inches, and it is not nitrous. The solution...
Mr Kirwan has never been able to dissolve silver in the marine acid, though Dr Kaye says he effected the dissolution of three grains and a half of it by digested for some days with two ounces of strong spirit of wine, and immersed it in a solution of the nitrous acid. It is dissolved, however, by the dephlogisticated spirit of salt, as well as by the phlogisticated acid when reduced to a state of vapour. An hundred grains of luna coneia contain\(75\) grains of silver, \(18\) of acid and \(7\) of water.

Mr Kirwan found that kind of aqua regia to succeed best kind best in the dissolution of gold, which was prepared by of aqua re-

mixing together three parts of the real marine acid for dissol-

ving with one of the nitrous acid. Both of them ought also to be as concentrated as possible; though, when this is the case, it is almost impossible to prevent a great quantity from escaping, as a violent effervescence takes place for some time after the mixture. Aqua regia made with common salt or sal ammoniac and spirit of nitre, is much less aequous than that proceeding from an immediate combination of both acids; and hence it is the fittest for producing crystals of gold. Very little air is produced by the solution of this metal, and the operation goes on very slowly. It is, however, better promoted by allowing it sufficient time, than by applying heat. An hundred grains of gold require for their solution \(487\) grains of real acid, the two acids being in the proportion abovementioned. An hundred grains of real acid contain \(77\) of gold, \(18\) of acid, and \(7\) of water.

With spirit of nitre, \(78\) grains of real acid are required for the solution of \(100\) grains of lead, with the assistance of heat towards the end. The proportion of acid to that of water may be about \(1\) to \(11\) or \(12\). This solution produces but eight cubic inches of air, which is nitrous. The calces of the metal are soluble in this acid, but less so when much dephlogisticated. An hundred grains of minium require \(81\) of real acid. An hundred grains of nitrous falt of lead contain about \(60\) of the metal.

With nitrous acid. An hundred grains of the real marine acid are required for the solution of \(100\) grains of lead; the specific gravity of the acid being \(1.141\), though more would be dissolved by a stronger acid. The calces of lead are more soluble in this acid than the metal itself. An hundred grains of minium require \(327\) of real acid; but white lead is much less soluble. The same quantity of plumbum corneum, found by precipitation, contain \(72\) of lead, \(18\) of marine acid, and \(10\) of water. An hundred grains of silver require \(520\) of real vitriolic acid to dissolve them; the proportion of acid to water being not less than \(1\) to \(10\); and when such a concentrated acid is used, it acts slightly even in the temperature of \(60^\circ\); but a moderate heat is required in order to procure a copious solution. The calces of silver formed by precipitation from the nitrous acid with fixed alkalis are soluble even in dilute vitriolic acid without the assistance of heat. An hundred grains of vitriol of silver, formed by precipitation, contain \(74\) grains of metal, about \(17\) of real acid, and \(9\) of water. An hundred grains of the purest silver require for their solution \(36\) of nitrous acid, diluted with water in the proportion of one part of real acid to six of water, applying heat only when the solution is almost saturated. If the spirit be much more or much less dilute, it will not act without the assistance of heat. The last portions of silver thus taken up afford no air. Standard silver requires about \(38\) grains of real acid to dissolve the same proportion of it; and the solution affords \(20\) cubic inches of nitrous air; whereas 100 grains of silver revived from luna cornea afford about \(14\) cubic inches of air.

Silver with nitrous acid. In spirit of nitre, \(100\) grains of mercury are dissolved by \(28\) of real acid, whose proportion to the water it contains is \(21\) to \(1\). In this acid the solution takes place without heat; but it may also be dissolved in a much more dilute acid, provided heat be applied. About \(12\) cubic inches of air are produced when heat is not applied; but M. Lavoisier found the produce much greater. This, says Mr Kirwan, was evidently caused by his using red or yellow spirit of nitre, which already contains much phlogiston. Precipitate per \(fe\) is still less soluble. An hundred grains of vitriol of mercury, produced by precipitation, contain \(77\) of metal, \(19\) of acid, and \(4\) of water.

With nitrous acid.
Zinc with vitriolic acid;

A weak quantity of the nitrous air is produced. An hundred grains of vitriol of zinc contain 100 grains of real nitrous acid. The calces of zinc, if not too much dephlogistered, are also soluble in this acid.

A hundred and twenty-five grains of real nitrous acid, whose proportion to water is that of 1 to 12, are required for the solution of 100 grains of this semimetal, applying heat slightly from time to time. A concentrated acid dissolves less of the metal, as a great quantity of black powder remains in all cases undissolved. An hundred cubic inches of inflammable air are produced. An hundred grains of vitriol of zinc contain 20 of zinc, 22 of acid, and 38 of water. The calces of zinc, if not exceedingly dephlogistered, are also soluble in this acid.

Three grains of bismuth were dissolved by 200 cubic inches of vitriolic acid. The calces of bismuth are also soluble in this acid.

Only three grains of bismuth were dissolved by 200 cubic inches of vitriolic acid, whose specific gravity was 1.863, though a strong heat was used at the same time. A greater quantity was indeed less dephlogistered; but when the gravity of the acid was reduced to 1.220, only a single grain of the metal was dissolved by 400 of it. The calces of this semimetal are much more soluble. Four cubic inches of vitriolic acid were afforded by the solution of three grains of bismuth.

In spirit of nitre, 100 grains of real acid are only required to dissolve 100 grains of the metal. The proportion of water to the acid ought to be as 8 or 9 to 1, in which case a gentle heat may be applied. The solution affords 44 cubic inches of nitrous airs. The calces of bismuth are also soluble in this acid.

Only three or four grains of it were dissolved in a large cubic inch of spirit of salt, in which case a gentle heat may be applied. A moderate heat is necessary for the dissolution of the metal; but a concentrated acid acts so rapidly, that much of it is dissolved. Only four or five grains of nickel are dissolved by 200 cubic inches of spirit of salt whose specific gravity was 1.220. An acid of this degree of strength acts without the assistance of heat, though a weaker acid requires it, and dissolves still less of the metal. The calces of nickel are also soluble with difficulty in this acid.

Four hundred and fifty grains of real vitriolic acid, whose proportion to water is not less than 1 to 7, are required for the dissolution of 100 grains of the metal, all of which is dissipated during the operation. A solution is obtained by pouring warm water on the dephlogistered mass. The calces of cobalt, however, are more soluble; so that even a dilute acid will serve.

In spirit of nitre, the like quantity of cobalt requires 220 grains of real acid, whose proportion to water is as 1 to 4; giving a heat of 180 towards the end. The calces of the metal are soluble in the nitric acid.

An hundred grains of spirit of salt, whose specific gravity is 1.78, dissolve, with the assistance of heat, two grains and a half of cobalt; and a greater quantity will be dissolved by an acid more highly concentrated. The calces of cobalt are more soluble.

An hundred grains of regal of antimony require 75 grains of real vitriolic acid, whose proportion to water is as 1 to 7, affixed by a heat of 400°. A large quantity of regal should be put into the acid; and the resulting salt requires much water to dissolve it, as the concentrated acid lets fall much when water is added to it. A less concentrated acid will likewise dissolve this semimetal, but in smaller quantity. The calces of antimony, even on diaphoretic antimony, are somewhat more soluble. Nine with nitrous acid, solution of 100 grains of regal of antimony require 150 grains of real nitrous acid are required for the solution of 100 grains of regal, the proportion of acid to the water of the solvent being as 1 to 12, and affixed by a heat of 110°; but the solution becomes turbid in a few days. The calces are much less soluble in this acid. Only one grain of the regal is dissoluble in the marine acid, which is only 1.178 dissolves fifty lefs; but Mr. Kirwan is of opinion that the concentrated acid would, in a long time, and by the assistance of a gentle heat, dissolve much more. The calces dissolve more easily in the marine acid.

Eighteen grains of regal of arsenic are dissolved of regal of in a heat of 250° by 200 grains of real vitriolic acid, whose specific gravity is 1.871. About seven of these parts crystallize on cooling, and are soluble in a large quantity of water. The calces of arsenic are more soluble in this acid. An hundred and forty grains of regal of real nitrous acid are requisite for the solution of 100 grains of regal of arsenic; the proportion of acid to the water being as 1 to 11. The solution affords 102 cubic inches of nitrous air, the barometer being at 26° and the thermometer at 60°. Calces of arsenic are likewise soluble in this acid.

An hundred grains of spirit of salt, whose specific gravity is 1.220, dissolve a grain and half of regal of arsenic; but the marine acid, in its common state, that is, when its gravity is under 1.17, does not at all affect it. The arsenical calces are less soluble in this than in the vitriolic or nitrous acids.
quantity of different ingredients contained in the compounds resulting from their union, we ought next to give an account of our author’s experiments on phlogi
ton; but as his sentiments on that subject are taken notice of elsewhere, we shall content ourselves with briefly mentioning the very ingenious methods by which he discovers the quantities of it contained in various kinds of air and in sulphur.

Having proved that inflammable air, in its concrete state, and phlogiston are the same thing, Mr Kirwan proceeds to estimate the quantity contained in nitrous air in the following manner.

"An hundred grains of filings of iron, dissolved in a sufficient quantity of very dilute vitriolic acid, produced, with the assistance of heat gradually applied, 155 cubic inches of inflammable air; the barometer being at 29.5, and the thermometer between 50 and 60°. Now, inflammable air and phlogiston being the same thing, this quantity of inflammable air amounts to 5.42 grains of phlogiston.—Again, 100 grains of iron dissolved in dephlogisticated nitrous acid, in a heat gradually applied and raised to the utmost, afford 83.87 cubic inches of nitrous air. But as this nitrous air contains nearly the whole quantity of phlogiston which iron will part with (it being more completely dephlogisticated by this than any other means), it follows, that 83.87 cubic inches of nitrous air contain at least 5.42 grains of phlogiston. But it may reasonably be thought, that the whole quantity of phlogiston which iron will part with is not expelled by the vitriolic acid, but that nitrous acid may expel and take up more of it. To try whether this was really the case, a quantity of green vitriol was applied and raised to the heat in a heat produced by vitriolic acid and phlogiston are the same thing, Mr.

Dr Priestley, in the fourth volume of his Observations, p. 306, has satisfactorily proved, that nitrous air parts with as much phlogiston to common air, as an equal bulk of inflammable does when fixed in the same proportion of common air. Now, when inflammable air unites with common air, its whole weight unites to it, as it contains nothing else but pure phlogiston. Since, therefore, nitrous air phlogisticates common air to the same degree that inflammable air does, it must part with a quantity of phlogiston, equal to the weight of a volume of inflammable air, similar to that of nitrous air. But 100 cubic inches of inflammable air weigh three grains and a half; therefore 100 cubic inches of nitrous air part with 3.5 grains of phlogiston, when they communicate their phlogiston to as much common air as will take it up. In this process, however, the nitrous air does not part with the whole of the phlogiston it contains, as appears by the red colour it constantly assumes when mixed with common or dephlogisticated air; which colour belongs to the nitrous acid, combined with the remainder of its phlogiston, whence the acid produced is always volatile.

"One measure of the purest dephlogisticated air and two of nitrous air occupy but 1/3 of one measure, as Dr Priestley has observed. Suppose one measure to contain 100 cubic inches, then the whole, very nearly, of the nitrous air will disappear (its acid uniting to the water over which the mixture is made), and 97 cubic inches of the dephlogisticated air, which is converted into fixed air by its union with the phlogiston of the nitrous air; therefore 97 cubic inches of dephlogisticated air take up all the phlogiston which 200 cubic inches of nitrous air will part with; and this we have found to be seven grains: therefore a weight of fixed air equal to that of 97 cubic inches of dephlogisticated air, and 7 of phlogiston, will contain seven grains of the latter. Now, 97 cubic inches of dephlogisticated air weigh 40.74 grains; to which adding 7, we have the whole weight of the fixed air, 47.74 grains; 83.755 cubic inches; and consequently 100 cubic inches of fixed air contain 8.357 grains of phlogiston, the remainder being dephlogisticated air. An hundred grains of fixed air, therefore, contain 14.663 of phlogiston, and 8.339 of elementary or dephlogisticated air. Hence also 100 cubic inches of dephlogisticated air are converted into fixed air by 7.2155 grains of phlogiston, and will be then reduced to the bulk of 86.34 cubic inches.

To find the quantity of phlogiston in vitriolic acid air, our author pursued the following method.

1. He found the quantity of nitrous air afforded by a given weight of copper, when dissolved in the dephlogisticated nitrous acid, and by that means how much phlogiston it part with.

2. He found the quantity of copper which a given quantity of the dephlogisticated vitriolic acid could dissolve; and observed, that it could not entirely saturate itself with copper without dephlogisticating a further quantity which it does not dissolve.

3. He found how much it dephlogisticates what it thoroughly dissolves, and how much it dephlogisticates what it barely calcines.

4. How much inflammable air a given quantity of copper affords when dissolved in the vitriolic acid to the greatest advantage.

5. He deduces from the whole quantity of phlogiston expelled by the vitriolic acid the quantity of it contained in the inflammable air; the remainder shows the quantity of it contained in the vitriolic acid air.

The conclusion deduced from experiments, conducted after this manner is, that 100 cubic inches of vitriolic air contain 6.6 grains of phlogiston, and 71.2 grains of acid; and 100 cubic inches of this air weighing 77.8 grains, 100 of it must contain 8.48 grains phlogiston, and 91.52 of acid.

To find the quantity of phlogiston in sulphur, Mr Kirwan proposed to estimate that of the fixed air produced during its combustion. For this purpose he firmly tied and cemented to the open top of a glass bell a large bladder, designed to receive the air expanded by combustion, which generally escapes when this
This precaution is not used. Under this bell, containing about 3000 cubic inches of air, a candle of sulphur, weighing 347 grains, was placed; its wick, which was not contained, weighing half a grain. It was supported by a very thin concave plate of tin, to prevent the sulphur from running over during the combustion, and both were supported by an iron wire fixed in a shelf in a tub of water. As soon as the sulphur began to burn with a feeble flame, it was covered with the bell, the air being squeezed out of the bladder. The inside of the bell was soon filled with white fumes, so that the flame could not be seen; but in about an hour after all the fumes were thoroughly subducted, and the glass become cold, as much water entered the bell as was equal to 87.2 cubic inches; which space our author concludes to have been occupied by fixed air, and which must have contained 7.287 grains of phlogiston. The candle of sulphur being weighed was found to have lost 20.75 grains; therefore 20.75 grains of sulphur contain 3.414 grains of phlogiston, besides the quantity of phlogiston which remained in the vitriolic air. This air must have amounted to 20.75 — 7.287 = 13.463 grains, which, as already shewn, contain 1.41 grains of phlogiston. Therefore the whole quantity of phlogiston in 20.75 grains of sulphur is 8.428; of consequence 100 grains of sulphur contain 59.39 of vitriolic acid, and 40.61 of phlogiston.

The quantity of phlogiston contained in marine acid air was found by the following method. — Eight grains of copper dissolved in colourless spirit of salt afforded but 4.9 inches of inflammable air; but when the experiment was repeated over mercury, 91.28 cubic inches of air were obtained. Of these only 49 cubic inches were inflammable; and consequently the remainder, 86.32 inches, were marine air, weighing 56.49 grains. — Now as spirit of salt certainly does not dephlogisticate copper more than the vitriolic acid does, it follows, that these 49 cubic inches of inflammable air, and 86.38 of marine air, do not contain more phlogiston than would be separated from the same quantity of copper by the vitriolic acid; and since 100 grains of copper contain 3.28 grains of phlogiston, 8.5 grains of copper would yield 0.367 grains of phlogiston. This therefore is the whole quantity extracted by the marine acid, and contained in 91.28 cubic inches of air; and, deducting from this the quantity of phlogiston contained in 49 cubic inches of inflammable air 0.171 grains, the remainder, viz. 0.367 - 0.171 = 0.196, is all the phlogiston that can be found in 86.38 cubic inches of marine air. Then 100 cubic inches of it contain but 0.227 of a grain of phlogiston, 65.173 grains being acid. — Hence we may see why it acts so finely on oils, spirit of wine, &c. and why it is not dissolved from any body by uniting with phlogiston, as the vitriolic and nitrous acids are, its affinity to it being incomparably.

§ 4. Remarks on the Doctrines of the Quantity and Specific Gravities above delivered.

To this doctrine of the specific gravity and quantity of acid contained in different substances, Mr Kirwan has made several objections. 1. Mr Kirwan supposes, that marine acid gas is the pure and solid marine acid, divedfed of all water and other matter. Its apparent dryness in this respect, however, is no argument that it really contains no water; for water itself, reduced to a state of vapour, possesses no moistening property. On the contrary, there is great reason to believe that water is a constituent part of some gases, and it is certain that all of them are capable of holding it in solution. As moist materials, therefore, are employed in the preparation of marine acid air, there seems no reason to believe, that in any way in which Mr Kirwan could obtain it, there was reason to suppose it perfectly free of water; in which case the density of the acid would be greater, and its quantity smaller than he supposes.

2. A considerable part of the density of the acid absorbed in the experiment, probably arose from the condensation which always accompanies the union of a concentrated acid with water. Mr Kirwan allows this to be the case with the nitrous and vitriolic acids, but thinks it too inconvenient to deferve notice in the marine. His reasoning, however, does not appear satisfactory, or his experiments on the subject conclusive. He observes, that the length of time taken up in effecting an union between the marine gas and water, is no argument against their attracting one another strongly when once united; and it is certain that part of this acid gas is very quickly absorbed by water. He also finds fault with his accuracy in calculation; and afferts, that if matters are fairly stated, the real density of the marine acid gas will be considerably less than Mr Kirwan makes it.

3. A great obstacle even to an approximation towards the real density of the acid, arises from the condensation which the water, as well as the acids, must suffer in the process; and in this case, where a general condensation takes place, he asks, "How shall we determine the part of the condensation that belongs to the water, and the part of the acid sustains?" This, with other considerations, makes Mr Keir "doubt of the possibility of solving the question concerning the actual density of pure and solid acids." The investigation of the question, indeed, he does not consider as a matter of great conquence, as every useful application may be obtained, by first investigating the comparative strengths of the acids, and the marine acid rendered more or less dilute; and then by finding out the strength of the vitriolic, nitrous, and marine acids of known densities, so that they may be compared together. "Homer (says he) has the merit of making the first essay towards this investigation. Bergman and Wenzal have supplied the defects of Homer, by taking into consideration the gas united with alkaline substances; and Mr Kirwan, by using determinate quantities of acid liquors of known densities, has considerably improved the method of Bergman: and whoever succeeds in these able chemists five, in this inquiry, may avail himself greatly of their labours, particularly those of Mr Kirwan." He concludes with stating the results of the inquiries made by the chemists abovementioned; on which he makes the following remarks.

"The discrepancy of these results is very striking, and gives but an humiliating representation of the precautions in collision of our present knowledge in chemistry. A great part of the difference ariseth undoubtedly from the different views in which these authors considered the dry, different nesses or purity of the acids. Mr Kirwan, as we have seen, endeavoured to find their density and quantity in
a state of perfect dryness and purity; which he supposed to exist in the marine acid gas; with which he compared, and inferred the densities and quantities of the nitrous and vitriolic acids, upon the supposition that equal quantities of these several acids are saturated by a given weight of fixed alkali. Besides the uncertainty of his principles, from which he deduces the density and quantity of the marine acid, his applications from thence to deduce the densities of the pure nitrous vitriolic acids, being founded on the above supposition, must partake of its defects. The alkali which he happened to fix on as the standard by which he compared the strengths of the different acid liquors, in order to determine the quantity of real acid they contained, and thence to determine their density in a solid state, was the fixed vegetable. Having found that 100 grains of his real marine acid could saturate 215 grains of this alkali, he infers, that the same proportion is applicable to the other acids; and accordingly we find that 100 grains of each of the pure and real mineral acids are saturated by an equal quantity, viz. 215 grains of this alkali. But if we examine the other columns of his table, we shall at once see, that in other substances soluble by acids, this equality does not exist; and that every such substance has a ratio peculiar to itself, with respect to the proportions of these acids necessary for its saturation. It is evident, therefore, that if Mr Kirwan had fixed on the mineral alkali, the volatile alkali, lime, or any other substance, as a standard, instead of vegetable alkali, his determination of the densities of the real vitriolic and nitrous acids would have been different; and as no reason can be assigned why the vegetable alkali or any other substance should have the preponderage over the rest, it is obvious that there can be no such general standard, but that each substance points solely to the capacity of determining the proportions of the several acids necessary for its saturation.

The other chemists were contented to consider as the pure and dry acid, that which actually remains in the neutral salt, after this has been rendered as dry as possible by exposure to a red heat; and having made their alkalies as dry as they could, they supposed these alkalies to retain the same weight in the dried neutral salt; and that the augmentation of the weight gained by the alkali during the formation of the neutral salt showed the weight of the dry acid. The uncertainty which affects this method arises from the different capacities which different neutral salts may possess of retaining more or less water, either as a constituent part of the dry salt, or merely by the strength of adhesion or affinity. Nevertheless, this method being founded solely on experiment, without any theoretical inductions, seems to furnish some approximation, not perhaps of the absolute quantity of the acids in their driest possible state, but of the acids as they actually exist in these salts comparatively with each other. Though the disagreements between Bergman's and Wenzel's results are little in comparison of the difference between them and Kirwan's, yet their experiments were made nearly in the same manner, and upon the same grounds, there seems to be sufficient reason to wish for a careful repetition of their experiments, or of others with the same view, and least liable to objections.

"The only difference in the methods employed by remarks these two celebrated chemists consisted in the mode of the for- saturation. Bergman probably used the common method, but Wenzel employed a very peculiar one. He added to his alkali a greater quantity of acid than was necessary for the saturation; and after the alkali was dissolved, he added a lump of zinc, or of oyster-shell, in order to saturate completely the superfluous acid. By observing how much of the zinc or oyster-shell the acid dissolved, and knowing how much of these substances was soluble in his acid by former experiments, he inferred the quantity of acid left for the saturation of the alkali. Having thus ascertained the quantity necessary to saturate the alkali, he mixed together the proper proportions of these, and formed his neutral salt by evaporating the mixture and drying the salt with a red heat. Perhaps the difference in the results obtained by these two chemists might arise from their different modes of saturation. The common method of ascertaining the point of saturation by means of limus or other blue vegetable juices, appears sufficiently exact, is simpler, and therefore preferable to that used by Wenzel.

"The standard for comparing the strengths of acids, and likewise of alkalies with one another, may be either an acid or an alkaline substance; and if we had one of each, the proportion of whose quantities requisite for their mutual saturation were well ascertained, the convenience in making the experiments would be obvious, and the certainty greater. Alkaline, and the earthy substances that are soluble in acids, are seldom pure enough for this purpose. They generally contain quantities, which are not constant, of fixed air, siliceous earth, magnesia, neutral salts, and inflammable matter, which render any of those that are commonly met with unfit for the purpose without a very skilful and careful purification. The chemists who have made experiments to determine the proportions of acids and alkalies requisite for each other's saturation, have scarcely been explicit enough in explaining the means of purifying the alkalies which they employed; and those in commerce are quite uncertain in strength and purity; and as to the general rules of making allowances for any heterogeneous substances they may contain, they are quite inapplicable to delicate experiments. No other method seems proper for ascertaining the purity of alkalies but that of crystallization: of which both the vegetable and mineral alkalies are susceptible, especially the latter, which on account of its being more easily reducible into crystals, is therefore preferable. These alkaline crystals, however, are not fit to be used as a standard, because they either are apt to be sufficiently dried, or, upon exposure to air, to lose a part of the water of their crystallization, and to fall into powder. Even if they should be taken, as is possibly with due care, at the exact state of dry but entire crystals, another uncertainty arises from a property which seems to be common to them all, namely, that of retaining a greater or smaller quantity of water, according to the degree of heat in which they were crystallized; the colder the weather the greater quantity of water entering into the composition of the crystals. It seems possible, however, to make a pretty method of an accurate standard of mineral alkali in the following manner: Let the alkali be purified by repeated solution.
tion and crystallization, using only such as are formed first, and rejecting the remaining liquors. Let the pure crystals be exposed to a dry air until they have completely effloresced or fallen into a dry white powder; which alteration may be facilitated by bruising the crystals and changing the surface of the powder. Let this powder be then exposed for a certain and determined time to a constant heat, as that of boiling water for 12 hours; letting the surface exposed be in some given proportion, suppose of a square inch to an ounce of the powder of crystals, and let it be stirred every two hours. When thus dried, let them be put while hot into a bottle, and well stopped. This powder I have found to be an uniform and constant standard for ascertaining the strength of acids; and also, by comparison with means of acids, of other alkaline substances.

With regard to an acid standard, our author recommends oil of vitriol; which, he says, as it comes from the hands of the British manufacturers, is of the specific gravity of about 1.846, but soon becomes weaker, unless carefully kept from the external air; and in general he rates it at 1.850. One part of this acid mixed with nine of water, is of a very convenient strength for use; and as every ten grains of the mixture contain one of the standard acid, the computations are thus rendered easy: and by these standards, the strength of all acids, alkalies, and substances soluble in acids, may be measured and compared together.

To determine the specific gravity of liquors with accuracy, our author recommends the method of weighing them in a phial fitted with a glass-stopper, which can only enter a certain length into the neck. In this way, he observes, no other inconvenience can ensue than the slightest, that the glass-stopper, by very frequent use, is apt to wear itself and the neck of the phial also; so that after a great number of experiments, it will at last diminish, in some measure, the capacity of the phial itself. This, however, is but very trifling, and may be corrected at any time. Mr. Keir has besides found, that after some hundreds of experiments, the error amounted only to one quarter of a grain in 101 grains.

The methods hitherto practised (says he) for ascertaining the quantities of acids and alkalis contained in neutral salts, seem to be liable to several objections besides those above-mentioned, arising from the different proportions of water remaining in a neutral salt, after exposure to a red-heat, which heat is also very indefinite. In boiling the saturated mixture of acid and alkali to dryness, and afterwards in exposing this salt to a red-heat, it has been supposed that nothing but water is expelled; and some chemists, who have given the results, have also determined the weight of the alkali which enters into the neutral mixture, by evaporating to dryness an equal quantity of the alkaline solution which had been employed in the saturation, and weighing the dry solution, on the supposition that nothing is expelled but water. It is certain, however, that in the evaporation both of alkalies and neutral salts, a considerable portion of the saline matter is elevated towards the end, when the liquor becomes concentrated and acquires a degree of heat considerably above that of boiling water. The following method appears best for determining the relative quantities of acid and alkali, or other substance existing in neutral salts.

To a given number of grains, suppose 100 of the standard vitriolic acid, or to a proportional quantity of any other acid, add as much of the alkali or other soluble substance as is requisite for the saturation, and note the quantity required, which suppose to be 150 grains. We have thus a solution of the neutral salt, which is the object of the experiment; the quantities of acid and bases contained in which are known, and the general proportion of the quantity of the acid to its bases in the neutral salt determined, viz. as 100 to 150. The next thing to be discovered is the weight of the dry neutral salt contained in this solution, in order to know the proportion of the dry neutral salt to its acid and bases. For this purpose, let a given quantity of the same neutral salt, either in the state of crystals or dried to any given degree, be dissolved in water. Let this solution be brought to the same density as the former, by adding water to the heavier of the two: then, by knowing the weight of each solution, and the quantity of dry neutral salt which was actually dissolved in one of them, the quantity contained in the other may be deduced; and hence the quantities of standard acid, or of other acid proportioned to it, and of the alkali employed, or other soluble substance contained in a given quantity of the neutral salt, are determined; also the quantity of water contained in the neutral salt, that is greater or less than what is contained in the quantity of acid employed, will be known, over and above any water that may have been contained in the alkali or other bases of the neutral salt; the quantity of which water, if any, cannot be determined.

By this method may be ascertained the proportion of the acid, of the bases, and of the neutral salt, to each other; not indeed the quantity of acid and of alkali deprived of all water, but the quantity of acid, equal in intensity of acidity to a known portion of the standard acid; and also the quantity of such alkali or other soluble substance as was employed; the relative strength of which is known from its ratio to the standard acid.

The translator of Wiegles's System of Chemistry totally disagrees with Mr. Kirwan's calculation of the quantity of phlogiston contained in sulphur; but as his objection seems to arise rather from an inclination to the antiphlogistic doctrine that a real diffusion of the subject, this can have but little weight. It is possible indeed that Mr. Kirwan may have over-rated the quantity of phlogiston this substance contains, which is indeed larger than that allowed by other chemists.

"Brandt (says the translator), who has been most generally followed, reckons it only at 7/9; and it has always appeared to me, that the weight of phlogiston in sulphur is almost infinitely small."

His objection proceeds on a maxim which he thinks he has demonstrated, viz. that sulphur is composed, not of the vitriolic acid and phlogiston, but of the base of vitriolic acid and phlogiston. No experiments hitherto made, however, have been able to show this base distinctly from the acid; nor have we any reason to suppose that the increase of weight in the vitriolic acid above the sulphur from
The other species of earths, viz. the flinty, fusible, and taly, being no other way the subjects of chemistry than as they are subservient to the making of glasses, all that can be said of them will most properly come under that article. For their different species, see Mineralogy.

Besides the abovementioned species of earths, there are others which may be called anomalous, as having some resemblance of the calcareous and argillaceous, and yet being essentially different from them. These are the earth called magnesia alba, the earth of burnt vegetables, and that produced from burning animal substances.

Magnesia alba was at first prepared from the thick liquor remaining after the crystallization of nitre; and is now found to be contained in the liquor called bittern, which is left after the separation of common salt from sea-water. In the former case it was united with the nitrous, in the latter with the vitriolic, acid. It is also found naturally in the soft kind of stone called flinty or 'soap-flint,' and in the concrete used for taking spots out of cloaths, called French chalk. It differs from the calcareous earths in not acquiring any hardness when deprived of its air, of which it contains so large a quantity as to lose two-thirds of its weight when calcined. From the argillaceous it differs in not burning hard when mixed with water, nor forming a tough ductile paste. It is easily fusible in all the acids, even the vitriolic; with which it forms the bitter purging salt called Esphom salt, from its being first discovered in the waters of Epsom. With all the other acids it likewise forms purgative compounds, which are either very difficult or not at all crystallizable. Like other pure earths, it cannot be melted by itself; but, on proper additions, runs into a beautiful green glass.

The earth of burnt vegetables is thought by Dr. Lewis to be the same with magnesia alba; but on try, and animaling the common wood ashes, they were found to be very different. This kind of earth is fusible, by reason of the alkaline salts contained in it. Animal earth is both very difficult of solution in acids, and imposible to be melted in the strongest fire. It dissolves, however, in acid liquors, though slowly; but the nature of the compounds formed by such an union are as yet unknown. The softer parts of animals, such as blood, flesh, &c. are said to yield a more fusible earth than the others. Animal earth has lately been supposed to be compounded of calcareous earth and phosphoric acid; but this opinion is shewn to be erroneous under the article Bones. The phosphoric acid produced from these, is with reason supposed to be only the vitriolic acid changed.

Sect. V. Inflammable Substances.

These comprehend all vegetable, animal, and some Phenomeno-mineral substances. They are distinguished from all others, burning.
Inflammable Substances.

On distillation.

Treated with different acids.

Singular Productions.

Neither the nature of these flowers, however, nor that Metallic of the falt of amber, is fully known.

Metals forming inflammable substances.

These are distinguished from all other bodies by their great specific gravity, exceeding that of the most dense and compact stones. The heaviest of the latter do not exceed the specific gravity of water in a greater proportion than that of 4 to 1; but tin, the lightest of all the metals, exceeds the specific gravity of water in the proportion of 7 to 1. They are also the most opaque of all known bodies, and reflect the rays of light most powerfully.

Metallic bodies possess the quality of dissolving in and uniting with acid salts, in common with earths and alkalies; but, in general, their union is less perfect, and they are more readily separable. They effervesce with acids, as well as calcareous earths and alkalies; but their effervescence is attended with very different appearances. In the effervescence of acids with alkalies, or with calcareous earths, there is a discharge of the fluid called fixed air, which is so far from being inflammable, that it will immediately extinguish a candle or other small flame immersed in it. The mixture also is notably diminished in weight. When a metallic substance is dissolved in an acid, the weight of the mixture is never very much diminished, and sometimes it is increased. Thus, an ounce of quicksilver being slowly dropped into as much aquafortis as sufficient to dissolve it, and the solution managed so as to take up almost a whole day, the whole was found to have gained seven grains. There is also a remarkable difference between the nature of the vapour discharged from metals and that from alkalies; the former, in most cases, taking fire and exploding with violence; the latter, as already observed, extinguishing flame.

The metallic substances, at least such as we are able to decompose, are all composed of a certain kind of phlogiston. The earthy part by itself, in whatever way it is procured goes by the name of calx. The other principle has already been proved to be the same with charcoal. When these two principles are separated from one another, the metal is then said to be calcined. The calx being mixed with any inflammable substance, such as tannin and powdered charcoal, and urged with a strong fire, vivification melts into metal again; and it is then said to be reduced, or revivified: and this takes place whether the metal has been reduced to a calx by dissolving in an acid or by being exposed to a violent fire. If, however, the calcination by fire has been very violent and long continued, the calx will not then so readily unite with the phlogiston of the charcoal, and the reduction will be performed with more difficulty. Whether, by this means, viz. a long continued and violent calcination, metallic earths might entirely lose their property of combining with phlogiston, and be changed into tho' of another kind, deserves well to be inquired into.

When a metallic substance is dissolved in any kind of Calcina- acid, and an alkali or calcareous earth not deprived of its fixed air is added, the alkali will immediately create of weight by acids.
Exactly 12 ounces of quicksilver (says he) were put into a matras, and 12 ounces of spirit of nitre poured on it. Immediately a spontaneous effervescence ensued, attended with heat. The red vapours of the nitrous acid arose from the mixture, and the liquor assumed a greenish colour. I did not wait till the solution was entirely accomplished before I weighed it; it had lost one drachm 18 grains. Three hours after, the mercury was nearly all dissolved; but having again weighed the solution, I was much astonished to perceive that it had increased instead of being diminished in weight; and that the loss, which was one drachm 18 grains at first, was now only 54 grains. The next day the solution of the mercury was entirely finished, and the loss of weight reduced to 18 grains; so that in 72 hours the solution, though confined in a narrow necked matras, had acquired an augmentation in weight of one drachm. I added some distilled water to my solution, to prevent it from crystallizing; the total weight of it was then found to be 48 ounces 1 drachm and 18 grains.

I weighed separately, in two vessels, 8 ounces 71 grains of the above solution, each of which portions, according to the preceding experiment, ought to contain 2 ounces of nitrous acid and 2 ounces of quicksilver. On the other side I prepared 6 drachms 36 grains of chalk, and 4 drachms 36 grains of lime; these proportions having been found by former experiments just necessary to saturate two ounces of nitrous acid. I put the chalk in the one vessel, and the lime in the other.

An effervescence attended the precipitation by chalk, but without heat; the mercury precipitated in a light yellow powder, at the same time the chalk was dissolved in the nitrous acid. The precipitation by the lime was effected without effervescence, but with heat; the mercury was precipitated in a brownish powder. When the precipitates were well sublimed, Metallic Substances I decanted off the liquors from them, and carefully dried them. After which, I caused them to be dried in a heat nearly equal to that in which mercury boils.

"The precipitate by the chalk weighed 2 ounces 2 drachms 45 grains; that by the lime weighed 2 ounces 1 drachm 45 grains."

"Sixteen ounces of the nitrous acid, the same as employed in the former experiments, were placed in a matras, and some iron filings gradually added. The effervescence was brisk, attended with great heat, red vapours, and a very rapid discharge of elastic fluid: the quantity of iron necessary to attain the point of saturation was 2 ounces 4 drachms; after which, the loss of weight was found to be 4 drachms 19 grains. As the solution was turbid, I added as much distilled water as made the whole weight of the solution to be exactly 6 pounds."

"I took two portions, each weighing 12 ounces of the above solution, and containing 2 ounces of nitrous acid, and 2 drachms 36 grains of iron filings. I placed them in two separate vessels. To one were added 6 drachms 36 grains of chalk; and to the other 4 drachms 36 grains of slaked lime, being the quantities necessary to saturate the acid."

"The precipitation was effected by the chalk with effervescence and tumefaction, that by the lime without either effervescence or heat. Each precipitate was a yellow brown rust of iron. They were washed in several parcels of distilled water, and then dried in an heat somewhat superior to that used in the last experiment."

"The precipitate by the chalk, when dried, was a greyish rust of iron, inclining even to white by veins. It weighed 6 drachms 35 grains. That by the lime was rather yellower, and weighed 4 drachms 69 grains."

"The result of these experiments (says M. Lavoisier) are, 1. That iron and mercury dissolved in aquafortis the nitrous acid acquire a remarkable increase of weight, whether they be precipitated by chalk or by lime. 2. That this increase is greater in respect to iron than mercury. 3. That one reason for thinking that the elastic fluid contributes to this augmentation is, that it is constantly greater when an earth is employed saturated with elastic fluid, such as chalk, than when an earth is used which has been deprived of it, as lime. 4. That it is probable that the increase of weight which is experienced in the precipitation of lime, although not so great as that by chalk, proceeds in part from a portion of the elastic fluid which remains united to the lime, and which could not be separated by the calcination."

But though we are naturally enough inclined to think that the increase of weight in the precipitates founded by lime proceeds from some quantity of elastic fluid or fixed air which remained combined with the lime, it is by far too great to be accounted for in this way, even according to the experiments mentioned by M. Lavoisier himself, and which, from the manner in which they are told, appear to have been performed with the greatest accuracy. He found, that 1 ounce 3 drachms and 36 grains of flaked lime contained 3 drachms and 3 quarters of a grain of water,
and only 16 grains and an half of elatic fluid were separable from it. In the experiments above related, where only 4 drachms and 36 grains were employed, the quantity of elastic fluid could not exceed 6 or 8 grains. Yet the salt was increased in mercury by no less than 103 grains, and in iron by 203 grains; a quantity quite unaccountable from the elastic fluid or fixed air which we can suppose to be contained in the liquid made use of. It is much more probable, that the increased weight of metallic precipitates, formed by lime, arises from an adhesion of part of the acid.

Metals are found to be compounded of a kind of earth mixed with the inflammable principle or phlogiston; and by a dissipation of the latter, all metallic bodies, gold, silver, and platina excepted, are capable of being reduced to a caulk, but very different degrees of heat are required for calcining them. Lead and tin begin to calcine as soon as they are melted, long before they are made red-hot. The same happens to the semifmetals bismuth and zinc; the latter indeed being combustible, cannot bear a greater heat in open vefiils than that which is barely sufficient to melt it. Iron and copper require a red heat to calcine them; though the former may be made partly to calcine by being frequently wetted in a degree of heat considerably below that which is sufficient to make it red.

When metals undergo a kind of spontaneous calcination in the open air, which is called their rusting; and which has given occasion to various conjectures. But M. Lavoisier has shown, that this arises from the fixable part of the atmosphere attaching itself to their earthy part, and discharging the phlogiston. According to him, no metallic body can rust but where there is an absorption of air; and consequently metals can be but imperfectly rusted when kept under a receiver.

If two metals are mixed together, the compound generally turns out more fusible than either of them was before the mixture. There are indeed great differences in the degrees of heat requisite to melt them. Thus, lead and tin melt below that degree of heat which is required to make quicksilver or linseed-oil boil. Silver requires a full red heat, gold a low white heat, copper a full white, and iron an extreme white heat, to make it melt. The semifmetals called bismuth melts at about 460° of Fahrenheit’s thermometer, and tin at about 422°. When mixed in equal quantities, the compound melted at 283°.

When the tin was double the bismuth, it required 334° to melt it; with eight times more tin than bismuth, it did not melt under 392°. If to this compound lead is added, which by itself melts in about 450°, the fusibility is surprizingly incrased. Mr Homberg proposed for an anatomical injection a compound of lead, tin, and bismuth, in equal parts; which he tells us keeps in fusion with a heat so moderate that it will not tinge paper. Sir Isaac Newton contrived a mixture of the abovementioned metallic substances, in such proportions that it melted and kept fluid in a heat still smaller, not much exceeding that of boiling water. A compound of two parts of lead, three parts of tin, and five of bismuth, did but just effluent at that very heat, and so would have melted with very little more; and when the lead, tin, and bismuth, were to one another in the proportions of 1, 4, and 5, the compound melted in 246°. We have seen, however, a piece of metal compounded of these three, the proportions unknown, which melted, and even underwent a flight degree of calcination, in boiling water, and barely fifteen minutes in a degree of heat so gentle that the hand could almost bear it.

A slight degree of calcination seems to give the substances a greater power over metallic substances; a greater makes them less fusible; and if long and violently calcined, they are not acted upon by acids at all. Of all the acids, the marine has the greatest attraction for metallic cedres, and volatilizes almost every one of them.

 Sulphur readily unites with most metals, destroys their malleability, and even entirely dissolves them. On gold and platina, however, it has no effect, till united with a fixed alkaline salt, when it forms the compound called halper fulphurate, which is a very powerful solvent, and will make even gold and platina themselves fusible in water, so as to pass the filter. This preparation is thought to be the means by which Mofes dissolved and gave the Israelsites to drink the golden calf which they had idolatrously set up.

When a metal is dissolved in an acid, it may be precipitated, not only by means of calcareous earth and alkalies, but also by some other metals; for acids do not attract all metals with equal strength; and it is remarkable, that when a metal is precipitated by another, the precipitate is not found in a calcined state, but in a metallic one. The reason of this is, that the precipitating metal attracts the phlogiston which is expelled from that which is dissolving, and immediately unites with it, so as to appear in its proper form. The various degrees of attraction which acids have for the different metals, is not as yet fully determined. The best authenticated are mentioned in the Table of Affinities or elective attractions (Sec. IX.)

Metalline substances are divided into metals and semifmetals. The metals which are distinguished from the semifmetals by their malleability or fusibility, are in number seven; metals.

Great fusibility of compounds of tin and bismuth.

One fusible by the heat of boiling water.

Properties of arsine.

Sulphur readily unites with most metals, destroys their malleability, and even entirely dissolves them. On gold and platina, however, it has no effect, till united with a fixed alkaline salt, when it forms the compound called halper fulphurate, which is a very powerful solvent, and will make even gold and platina themselves fusible in water, so as to pass the filter. This preparation is thought to be the means by which Mofes dissolved and gave the Israelsites to drink the golden calf which they had idolatrously set up.

When a metal is dissolved in an acid, it may be precipitated, not only by means of calcareous earth and alkalies, but also by some other metals; for acids do not attract all metals with equal strength; and it is remarkable, that when a metal is precipitated by another, the precipitate is not found in a calcined state, but in a metallic one. The reason of this is, that the precipitating metal attracts the phlogiston which is expelled from that which is dissolving, and immediately unites with it, so as to appear in its proper form. The various degrees of attraction which acids have for the different metals, is not as yet fully determined. The best authenticated are mentioned in the Table of Affinities or elective attractions (Sec. IX.)

Chemical Theory.

The general chemical properties of these have been already taken notice of under the name of inflammable substances. They agree in giving out a very thick fume, when diffused by a strong fire; but in other respects they differ very considerably. Most kinds of vegetables give out an acid along with the oil; but all animal substances (ants, and perhaps some other insects, excepted) yield only a volatile alkali. Some kinds of vegetables, indeed, as mustard, afford a volatile alkali on distillation, similar to that from animal substances; but instances of this kind are very rare, as well as of animals affording an acid. Both animal and vegetable substances are susceptible of a kind of fermentation, called putrefaction, by which a volatile alkali is produced in great plenty: there is, however, this remarkable difference between them, that many vegetable substances undergo two kinds of fermentation before they arrive at the putrefactive stage. The first is called the evil, when the vegetable acid called vinegar is produced in plenty: and by this putrefactive stage succeeds when a volatile alkali is only produced; not the finest volatile vegetable spirit or of vinegar remaining. On the other hand, animal substances seem susceptible of only the putrefactive fermentation; no instance having ever occurred where there was the least drop, either of ardent spirit or of vinegar, produced from a purified animal substance. (See fermentation and putrefaction.)

Sect. IX. Of the Chemical Characters, and Tables of Elective Attraction.

The numerous marks or characters by which the ancient chemists used to denote many different substances of marks were invented rather from a superstitious and fantastical principle than from any real necessity: or, perhaps, from the etymological language used by the alchemists, they have thereby sought to conceal their mysteries from the vulgar. In contriving these marks, they affected a great deal of ingenuity; intending them as symbols of the qualities possessed by each of the different substances. A circle being figuring was therefore used to represent the perfect metal in nature, that is, gold. Silver being likewise a perfect and indestructible metal, is placed next to gold; but, on account of its inferiority, is expressed only by a crescent, as if but half gold. A circle was likewise used to denote salt of any kind, as being something elaborate and perfect. A crose was used to denote acrimony of any kind, and consequently employed for the acrimonious fumes of vitriol, alkali, &c. Hence all the inferior metals have the crose both before or after combined with the marks designed to represent them. Thus, the mark for quicksilver denotes, that it hath the splendor of silver, the weight of gold, but its perfection is hindered by an acrimony represented by the crose at bottom, &c. Fire is represented by an equilateral triangle, having one of its angles uppermost. This may be considered as a rude representation of flame, which is always pointed at top. Water, again, is represented by a triangle, with an angle downwards, showing the way in which that element exerts its strength, &c. All these marks, however, as they were of no real use at first, so they are now becoming every day more and more neglected. Such of them, however, as may most readily occur in chemical books are represented and explained on Plate CXXXII.

The French chemists have of late attempted to introduce a kind of new chemical language; and by adopting it themselves, may perhaps make it at last universal, etc.

Reg. of sulphur.  
Quicksilver.

III. Those which happen in mixtures by fusion.

1. Tin   Iron
2. Silver  Lead.
3. Copper  Sulphur
5. M. S.  Sulphur

The first of these tables requires very little explanation. The names printed in small capitals, are those of the substances which have the affinity with or attract those below them. Thus, vitriolic acid attracts most powerfully the phlogion, or inflammable principle; next, fixed alkali; then, calcareous earth; and so on, in the order in which they are marked. — The tables of double elective attractions cannot be made quite so distinct; though an explanation of one example will make this likewise easy to be understood. Thus in Table I. the first case is, if a combination of acids with calcareous earths or metallic substan­ces is mixed with a combination of volatile alkali and fixed air, the acids will unite themselves to the volatile alkali, and the fixed air to the calcareous earth or metallic substance.

Sect. X. Of the different operations in practical chemilory, and the proper instruments for performing each.

The most remarkable operations in chemistry, and by which the greatest changes are made upon those bodies which are the objects of that science, may be comprehended under the following names. 1. Solution. 2. Filtration. 3. Precipitation, or coagulation. 4. Evaporation. 5. Crystallization. 6. Distillation. 7. Sublimation. 8. Defagration. 9. Calcination. 10. Fusion. 11. Maceration, or digestion. To which we may add, 12. Trituration, or levigation.

Before we proceed to a particular account of each of these operations, it is necessary to take notice, that there are two different things proposed by those who enter on the practice of chemistry. Some have nothing farther in view than the enlargement of their knowledge, or making improvements in arts which are to be practised by others for their own advantage. Others design to follow chemistry as a trade, by which they hope to enrich themselves, or to get a comfortable livelihood. But the apparatus and utensils necessary for performing the very same operations are exceedingly different when experiments only are to be made, from what they must be when these operations are performed with a view to profit; and so great is this difference, that those who pursue chemistry with a view to advantage, will always find themselves very considerable losters if they follow the plan of an apparatus or a laboratory delineated only for making experiments. Along with the apparatus, therefore, which is commonly described in chemical books, and proper only for experiments, we shall also give that which is necessary for preparing great quantities of any chemical article in the way of trade.

In general, those who practice chemistry merely with an experimental view, ought, as much as possible, to make use of glass vessels, as not being liable to be corroded by the most powerful solvents; and, by their transparency, giving an opportunity of observing what passes within them during the operation. But by those who practice chemistry with a different view, these vessels ought, with equal care, to be avoided, on account of their expense and brittleness. This last quality, indeed, is posseied by glasses in the greatest degree, that glass vessels will sometimes fly to pieces, and that with considerable violence, when standing by themselves, and nothing touching them. The principle objects which a chemist ought to have in view, in performing his operations, ought to be to save time and fuel, especially the former; and for this purpose, he would find himself a considerable gain, though he should be at much greater expense in his apparatus than he would otherwise have occasion for.

On the subject of chemical vessels Dr Black observes, that with regard to the material of which these are composed, we are very much at a loss; and indeed there are no such materials in nature as are capable of answering the purposes of chemists in absolute perfection. — The qualities are, 1. Translu­cency, to allow us to see the changes going on; 2. The power of retarding the action of acids and corrosive substances; 3. That they bear sudden alterations of heat and cold without breaking; 4. That they be strong, in order to confine elastic vapours; and, 5. That they bear very great heat without melting. As these qualities, however, are not to be met with united in any one substance, the chemists are obliged to have recourse to different substances which possess some of them differently. These are, glass, metal, and earthen ware.

Glass is posseied of the two first properties, but has the inconvenience of being apt to crack and fly in pieces, on any sudden transition from heat to cold, or from cold to heat. The best method of remedying this defect, is to have the glasses made very thin, and of a round figure, that it may be all heated as equally as possible; and it is the unequal application of the heat which causes it break. Another requisite in the choice of chemical glasses, is that they be well annealed. If this is not done, the glasses will either immediately fly to pieces, or be liable to break on the smallest accident. That such glasses should be liable to be broken on every occasion, is a phenomenon that has hitherto received no explanation. If you touch them with a diamond, with a piece of flint, glasses, &c. or expose them to the heat of the sun, they break immedi­ately. Dr Black has had great vessels of glass, which broke immediately on his throwing a little sand into them to clean them. This manifestly depends upon the same principles as the qualities of what are called glass tears.

Glass when well annealed is universally to be pre­ferred, where great and sudden changes of heat, or much strength, are not required. Flint-glasses is the best; but the coarser kinds, as bottle-glasses, are very apt to break.

The metals have the third and fourth qualities in perfection, but are deficient in all the rest. The most troublesome properties of those are, that they are liable to be corroded by acids and other bodies as in a cafe with iron and copper; though this is in some measure...
measure remedied by tinning, which, though it wants some of the qualities from its melting too soon, yet refists the action of many acid substances without being so readily injured by them; but it is not entirely free from this imperfection, and is liable to some what corroded and rusted. In nice operations, therefore, recourse is had to silver, and even to gold vessels.

Earthen ware possesses only the fifth quality in perfection, viz. that of bearing a violent heat without fusion. The basis of these vessels is clay, which, when good, is very convenient for the formation of vessels, and it has been used from the earliest ages of chemistry for this purpose. The requisite qualities are: 1. A considerable degree of toughness when mixed with water. 2. A great degree of hardness when burnt in the fire with a violent degree of heat. The best kind of clay thus conveys a degree of hardeness scarcely inferior to flint, as is the case with that of which tobacco-pipes are made; but most other kinds, as that of which bricks are constructed, are apt to melt with a strong heat into a fpongy matter. Clay, however, can seldom be used alone; for when burnt to extreme hardnees, the vessels are very liable to crack. This is remedied by mixing sand reduced to a particular degree of fineness, with the clay of which the vessels are made. For this purpose both the finest and the coarsest particles of the sand must be thrown away.

Another substance known by the name of black lead, joined in the making of pencils, refists the fire exceedingly. This, however, does not contain an ore of lead, but sulphur, and some mineral substances; when mixed with clay, however, it makes it refist the fire surprizingly. But there are some particular vessels in which neither sand nor black lead can be used as a material; for the sand is easily corroded by acid matters, and the black lead would produce other inconveniences. Clay is therefore to be taken in its unburnt state, reducing it to a powder before hand; then burning this powder with a violent heat, so as to convert it into sand. Mixing it then with raw clay, it forms a composition which answers very well for making chemical vessels, and may be employed in those particular cases where sand would not answer. Pot of Berlin has written upon the different kinds of earthen ware proper to be employed in the construction of chemical vessels. There is a French translation of it in four or five volumes. In cases where the utmost compactness of texture is required, porcelain vessels are to be chosen; which is composed of the finest clay, mixed with a fomy matter, that has the quality of melting in a violent heat, and gives more compactness to the clay than it is naturally capable of receiving; but these are rather too costly for most operations. Reaumur has taught a way of converting glass into porcelain.

We shall now proceed to a particular description of each of the operations abovementioned.

1. Solution. By this is understood the dissolving a solid substance in a fluid, so as that the fluid shall totally disappear, and become part of a transparent liquor. This operation applies particularly to salts, earths, and metals; as well as to several noxious and inflammable substances. For performing this operation in a small way, common vials are in many cases sufficient. Where the solution is attended with effervescence and a discharge of vapours, the long-necked glass called Flaschetrit, or bolt-heads, (fig. 5.), are necessary. Florence flasks are indeed exceedingly well adapted for this operation, as being of the proper shape, and capable of bearing heat so well, that they may be filled with any fluid, and set on a common fire like a metal vessel. Solution is much promoted by agitating the vessel, and by heat. In some cases, indeed, it will not take place till the mixture becomes very hot; and in such cases it will be proper to make the fluid boiling hot by itself, and then slowly to add the substance to be dissolved.

When large quantities of saline matter are to be dissolved, metallic vessels must be used; but before any are made use of for this purpose, it will be necessary to make an experiment whether the salt receives any impregnation from the metal of which the vessel intended to be made use of is formed; and if this is found to be the case, it must not be used. The metals most liable to be corroded by saline bodies are iron and copper; and indeed, unless it be for the single purpose of dissolving fixed alkaline salts, iron vessels seem totally unfit for saline solutions of any kind. Copper vessels are also very liable to be corroded, and to communicate very mischievous qualities to the liquors which corrode them; for which reason, they ought never to be made use of for the purposes of solution. The metal least liable to be corroded, next to gold and silver, is lead; and therefore a chemist ought rather to provide himself with leaden vessels than those of any other metal. But though lead is not apt to be corroded by many kinds of salts, there are some which are found to act upon it, and to form therewith a very dangerous poison. The vegetable acid of vinegar is particularly apt to receive a dangerous impregnation from this metal; and therefore no solution of any salt containing this acid ought to be made in leaden vessels. It appears to be very little affected by the vitriolic or marine acids; and therefore any saline substance containing either of these acids may be safely enough dissolved in vessels made of lead.

In order to save time in making solutions, the vessels ought to be as large as possible; though even in this there must be a certain limit: for two small vessels filled with water will sooner acquire the necessary degree of heat than one large one; and in proportion as the vessel is made more capacious, the sides and bottom must be thicker, which considerably increases the expense. Fifteen or twenty English gallons is the utmost capacity of which they ever will be required; and it is rather above what will on most occasions be necessary. They ought to be of a conical figure round at the bottom; and to have a cover of thick plate-iron all around that part which is exposed to the action of the fire, that the lead may not bend on the application of heat, which it would otherwise be very apt to do. When the solution is to be made, the leaden vessel is first to be filled up with water so far as to have room for the quantity of salt intended to be dissolved; a fire is then to be applied so as to make it boil: and then the salt is to be added slowly, so as scarcely to hinder the boiling; for if a great quantity was thrown in at once, so as to cool the liquor very much, great part of the salt would concretie on the bottom, in such

CHEMISTRY.

Theory.

Dr Black observes, that for the purpose of solution, if no particular nor uncommon consequence follow the application of the two bodies to each other, and if none of them be very volatile, any glass or porcelain vessel that can reseat the action of the substances will answer the purpose; but it often happens that they break out into violent ebullition, which produces steam; and here a common vessel is not so proper, as we would wish to have the vapour confined or condensed. We therefore choose a close vessel that will bear the heat suddenly produced by the mixture, or the heat that may be necessary to promote the action of such bodies upon one another. Of this kind is the phiala chemica, or matras, in which the vapours will have time to circulate and to be condensed again, without being allowed to escape. Where the matter is in small quantity, smaller vessels somewhat of the same form are used, as Florentine flasks, which bear sudden changes of heat and cold remarkably well, on account of their thinness. In order to promote the action of bodies, it is sometimes necessary to make the fluids boil; and for this purpose we must have a matras with a large neck, or apply another vessel to it that will receive these streams, and give them still more room for their condensation, and direct them to fall back again, when condensed, into the matras. This is called circulation. Macquer describes another vessel called the pelican, which has been made ufe of for this purpose; but it is hardly ever employed, on account of its being too troublesome to procure and manage it; and the advantages arising from it may be obtained by a more simple apparatus.

To this head we must refer Papin’s digester, which is represented Fig. 4. It is generally made of copper, very thick and strong, open at the top, with a lid fitted to it, which applies very exactly. There are usually two projections on the sides, designed to make the lid go in a particular manner, but they are unnecessary. There are other two, to which are fitted the two sides of a crofs bar B B; in which crofs bar there is a strong screw D, by which the lid can be pressed down very strongly. Its ufe is to force water to bear a stronger heat than it can do under the ordinary pressure of the atmosphere. It is sometimes furnished with an apparatus for letting out the beam, left it should be in danger of bursting the vessel. A pipe is passed through the lid which is fitted with a valve, on which paffes a lever at a very small distance from its centre of motion; and this can be made to apace on the valve with different weights, according to the distance of these weights from the centre. In one constructed by Dr Black, there was another pipe below, into which a thermometer could be introduced, in order to measure the degree of heat to which the beam was raised. This machine was pretty much employed some time ago, and its effects were much admired; but we find that most things which can be dissolved in this way, can likewise be dissolved in the ordinary way by boiling water, provided it is continued for a longer time, as animal bones, from which the gelatinous parts are indeed extracted very quickly by this vessel; but the same change is produced by boiling them in water for a long time in the ordinary degree of heat.

II. Filtration. This operation is generally the attendan upon of filtration: very few substances, of the saline kind especially, are capable of being dissolved without leaving some impurities, from which they must be freed; and the doing of this, so as to render the solution perfectly transparent, is what is understood by the word filtration. For purposes merely experimental, a glass funnel and piece of paper are generally sufficient. The paper is formed into a conical cap, which being placed in the funnel with its point downwards, the funnel is then placed in the mouth of a vial; and the solution or other liquor to be filtered is poured into the paper cap, through which the liquor passes transparent, leaving its impurities on the paper. For the purpose of filtration, paper has come into such general use, that a particular kind of it is prepared under the name of filtering paper. This is of a reddish colour; but Dr Lewis prefers the whitish grey paper which comes from Holland about the pill boxes, as not giving any colour to the solutions which pass through it.

This operation though apparently so simple and easy, is nevertheless attended with very troublesome circumstances, on account of the great time it takes up. Even where very small quantities of liquor are to be filtered, merely

Vol. IV.
Chemical Operations

merely for experiment's sake, the impurities frequently settle on the paper so soon, and obstruct its pores to such a degree, that the operator is often quite wearied out: often, too, the paper breaks; and thus the whole is spoiled, and the operation must be begun over again.

To avoid these inconveniences, another method of filtration has been proposed; namely, to use a number of cotton threads, the ends of which are to be immersed in the liquor, and the other ends are to hang over the side of the vessel which contains it, and to hang lower than the surface of the liquor. By this means they will act as so many capillary syphons, (see SYPHON;) the liquor will arise in them quite pure, and be discharged from their lower extremities into a vessel placed to receive it. That the liquor may flow freely into the cotton, it will be proper to wet the threads before they are used.

In point of efficacy, no doubt, this method excels every other; and where the operator has abundance of time and patience, may be proper for experiments; but, in the way of trade, such a contrivance is evidently useless. For filtering large quantities of liquor, therefore, recourse has been had to large funnels; earthen cullenders, or basins full of holes in the bottom, lined with filtering paper; and to conical bags of flannel or canvas.

The inconveniences attending funnels, when used only in the way of experiment, are much greater when they are employed for filtering large quantities of liquor; and therefore they are generally laid aside. The earthen cullenders, too, do not answer any good purpose; nor indeed does filtration through paper in general succeed well. The conical flannel or canvas bags are greatly preferable; but they have this inconvenience, that the pressure of the liquor is directed chiefly against one particular point, or a small part of the bottom, and therefore the impurities are forcibly driven into that place; and thus the operation becomes insufferable tedious.

The best method of obviating the inconveniences of filtration seems to be the following. Let a wooden frame of about three feet square be made, having four holes, one in each corner, about three quarters of an inch in diameter. This frame is to be supported by four feet, the ends of which must project an inch or two through the holes. Thus the whole may be opened up and taken down so as to go into very little compass; for if the feet are properly placed, each with a little projection onwards, there will be no danger of its falling. A square piece of canvas must also be procured, somewhat less than the wooden frame. On each corner of it there must be a very strong loop, which slips on one of the projecting ends of the feet, so that the canvas may hang a little slack in the middle of the frame. The liquor to be filtered is now poured into the canvas, and a vessel placed underneath to receive it. At first it will pass through very foul; but being returned two or three times will become perfectly transparent, and will continue to run with great velocity, if the filter is kept constantly full. A filter of the size just now mentioned will contain ten gallons of liquid; which is a very great advantage, as the heat of such a quantity of liquor is not soon dissipated, and every solution filters much faster when hot than when allowed to cool.

The advantages of a filter of this kind above others Chemical arite from the pressure of the liquor being more equally diffused over a large space, by which the impurities are not forced so strongly into the cloth as to flop it up entirely. Yet even here, where large quantities of liquor require filtration, the cloth is apt to be stopped up so as to make the operation not a little tedious and disagreeable. It will be proper therefore to have several cloths, that one may be applied as soon as another is taken off.

To promote the operation of filtration, it is very proper to let the liquors to be filtrated settle for some time; for their greater fecultencies may fall to the bottom, and thus there will be the fewer to retard the last part of the operation. Sometimes, however, these fecultencies refuse to settle till after a very long time; and where this happens to be the case, a little powdered quicklime thrown into the boiling liquor remarkably promotes the separation. This, however, can only be used in certain cases.

In some cafes, the difficulty of a ready way of filtering a large quantity of liquor would be a matter of great inconvenience; as where a town is supplied with large quantities of river water, which is generally far from being clear, and often imparts a disagreeable colour to clothes washed with it. Some years ago, a scheme was proposed by a chemist for filtering muddy water in any quantity. His method was, to have a large cask covered over in the bottom with straw to the depth of four inches, and then filled up with sand. This cask was entirely open at one end, and had a hole in the other, which, by means of a leaden pipe, communicated with a large reservoir of the water to be filtered, and which flowed considerably higher than the cask. The water which descended through the pipe into the cask, having a tendency to rise up to the same level with that in the reservoir, would press violently against the sand, and, as he thought, run over the mouth of the cask perfectly filtrated, and free from its impurities. By this contrivance, indeed, a very violent pressure was occasioned, if the height of the reservoir was considerable: but the consequence was, not a filtration, but a greater degree of impurity in the water; for the sand was forced out of the cask along with it, and, however confined, the water always arose as muddy as it went in.

Where water is to be filtered in large quantity, as for the purposes of a family, a particular kind of soft spongy flint called filtering flakes, are employed. These, however, though the water percolates through them very fine, and in sufficient quantity at first, are liable to be obstructed in the same manner as paper, and are then rendered useless. A better method seems to be, to have a wooden vessel, lined with lead, three or four feet wide at top, but tapering so as to end in a small orifice at the bottom. The under part of the vessel is to be filled with very rough sand, or gravel, well freed from earth by washing. Over this, pretty fine sand may be laid to the depth of 12 or 14 inches, but which must likewise be well freed from earthy particles. The vessel may then be filled up to the top with water, pouring it gently at first, left the sand therefore be much displaced. It will soon filter thro' the sand, and run out at the lower orifice exceedingly transparent, and likewise in very considerable quantity. When the upper part of the sand begins to be stopped up, so as not to allow...
Chemical Operations.

A free passage to the water, it may occasionally be taken off, and the earthy matter washed from it, when it will be equally serviceable as before.

III. Precipitation of Coagulation. This operation is the very reverse of solution, and is the bringing a body suddenly from a fluid to a solid state. It differs from crystallization, in that it generally requires less time; and in crystallization the substance assumes regular figures, whereas precipitates are always in the form of powders.

Precipitation is generally preceded by solution and filtration: it is used for separating earths and metals from the acids which had kept them suspended. When a precipitation is made of the more valuable metals, can be known with certainty by measuring that portion of the precipitate which is very requisite for precipitation evaporated in a small quantity, wooden ones answer every purpose. (See the detached articles Solution and Distillation.) With regard to vessels for evaporation, the same thing must be applicable which was mentioned above under Solution. No saline liquor must be evaporated in a vessel which would be corroded by it; and hence iron vessels are absolutely improper for evaporations of any kind of saline liquor whatever.—Lead is in this case the metal most generally useful. It must only be used, however, where the evaporation is not carried to dryness; for, on account of the great fusibility of this metal, nothing could be extricated in it without great danger of its melting. Where a saline liquor therefore is to be perfectly exsiccated, the evaporation, if performed in lead vessels, must be carried on so far only as to form a saline pellicle on the surface of the liquor. It is then to be drawn off; for which purpose, all evaporating vessels should have a cock near the bottom. The liquor must now be put into a number of stone ware basons, set on warm sand, where the exsiccation may be finished.

V. Crystallization. This, though commonly Crystallization accounted one of the processes in chemistry, is in reality only a natural one, and which the chemist can only prepare for, leaving the operation entirely in the hands of nature.—By crystallization is meant the separation of a salt from the water in which it has been dissolved, in transparent masses regularly figured, and differently formed, according to the different nature of the salts.

This process depends upon the constitution of the atmosphere more than any other; and therefore is difficult to be performed, nor does it always succeed equally well; neither have there yet been laid down any rules whereby beautiful and regular crystals can with certainty be formed at all times.

As the different salts assume very different figures when crystallized, they are not subject to the same general rules in crystallization. Nitre, Glaeber's salt, vitriol of iron, and many others, crystallize best on having their solutions set in a cold place after proper evaporation. Sal polychreph, and common salt, require the solution to be kept as hot as the hand can bear it during the time of crystallizing. Soluble tartar too, and other deliquescent salts, require to be kept warm while this operation is going on: and there are many saline substances, such as the combinations of calcareous earths and magnesia with acids, which can scarcely be crystallized at all.

Mr Beaumé has discovered, that when two or more

Chemical Operations.

Precipitation.

Educoration.
CHEMISTRY.

falts are distilled in the same quantity of water, when one crystallizes, the crystals of that salt will not contain the least quantity of any of the others; neither, although the liquor was acid or alkaline, will the crystals for that reason be either acid or alkaline, but will remain perfectly neutral; and the acid or alkaline liquor which adheres to the outside of the crystals may be removed and obtained by filtering paper.---Hence we are furnished with a better method of distilling salts into large and well formed crystals than merely by distilling them in water; namely, by adding to the solutions, when fet to crystallize, a certain quantity of acid or alkaline liquor, according to the nature of the salts themselves. These additions, however, are not equally proper for all salts; and it is not yet determined what kinds of salts ought to be crystallized in alkaline, and what in acid liquors.---Soluble tartar and Seignette's salt crystallize best when the liquor is alkaline. Sal sedativus, sal Glaberi, and sal polychrest, require an acid if crystallized in the cold, but sal polychrest forms in very fine and large crystals when the solution is alkaline, and kept as hot as the hand can easily bear.

The best general direction that can be given with regard to the regular crystallization of salts is, that they ought to be set to crystallize in as large a quantity at once as possible; and this, as far as we have observed, without any limit; for by this means, the crystals are formed much larger and better figured than they possibly can be by any other method hitherto known.

As to the form of the vessels in which the crystals are to be crystallized, little can be said with certainty. They are generally flat and wider at the bottom. The only proper material, in the large way, is lead.

Distillation. This is a kind of evaporation; only in such a manner, that the part of the liquor evaporated is not distilled in the air, but preferred by making the steam pass through a spiral pipe, which goes through a large vessel full of cold water, or into cold glass receivers.

This is one of the most common chemical operations; and as there are a variety of subjects which require to be distilled, there is consequently a considerable variety both in the form of the distilling vessels to be used on different occasions, and likewise in the materials of which they are made, as well as the management of the fire during the time of the operation.

The most simple and easily performed distillation is that by the common copper still, (fig. 3). It consists of two parts: one called the body, and the other the head. The body is a cylindrical vessel of copper, which is sometimes tinned over in the inside; but where distillation is performed without any regard to the residuum, the tinning is useless. The upper part of the body terminates in a kind of arch, in the middle of which is a circular aperture, about one half, or something less, in diameter, of the breadth of the whole body.---Into this aperture, a round head, made likewise of copper, is fitted, so as to be removable at pleasure. In the top, or sometimes in the side of the head, is inserted a pewter pipe, which communicates with a spiral one of the same metal, that passes through a large wooden vessel, called the refrigeratory, filled with cold water; each of its ends projecting a little above and below. The still is to be filled two-thirds full of the substance to be distilled, the head put on, and the junctures well closed with mixture of Chemical limited meal and water, or common flour or chalk and water will answer the same purpose. This mixture is called the luting, or sete. A fire being kindled under the still, the vapours will arise; and, being condensed by the cold water, through which the spiral pipe called the worm passes, will run in a stream more or less strong as the fire is properly urged, and is caught in a receiver set underneath.

This kind of distilling vessels is proper for procuring the essential oils of vegetables, vinous spirits from fermented liquor, and for the rectification of these after they are once distilled. Even the acetic acid may be very conveniently distilled in a copper vessel, provided the vessel and all the descending parts of the pipe which communicates with it be of pewter, otherwise a mischievous impregnation of copper would be communicated to the distilled vinegar. The reason of this is, that copper is not dissolved by vinegar, or in very small quantity, when that acid is boiled in it; but if the metal is exposed to the action of the acid, when cold, or to its vapour, a considerable dissolution takes place. For this reason, too, the still must be washed out after the operation while it continues hot, and must be very carefully freed from the least remains of acid, otherwise it will be much corroded.

Copper-stills ought to be as large a size as possible: but Dr Lewis very justly observes, that, in common ones, the width of the worm is by no means proportional to the capacity of the still: hence the vapour which issues from a large surface being violently forced through a small tube, meets with so much resistance as sometimes to blow off the still-head. This inconvenience is ridiculously endeavour'd to be prevented by strongly tying or otherwise forcing down the head; by which means, if the worm should happen to be choked up, a terrible explosion would ensue: for no ligatures, or any other obstacle whatever, have yet been found strong enough to resist the elastic force of steam, and the greater obstacle it has to overcome, the greater will the explosion be.

Dangers of this kind might be totally avoided by having the worm of a proper degree of wideness.

Sometimes, however, matters are to be distilled, Mineral such as mineral acid spirits, which would corrode any kind of metalline vessels; and for those only earths, or the closed kind of stone-ware, can be used. These are more easily condened than the stems of aqueous or vinous liquors, and therefore do not require to be passed through a pipe of such a length as is used for condensing the stems from the common still. In these cases, where a violent heat is not necessary, and the distillation is to be performed in glass vessels, the retort is used. (fig. 4.) When a fluid is to be put into this vessel, the retort must be laid upon its back on sand, or any other soft matter that will support it without breaking. A funnel must also be procured with a long stem, and a little crooked at the extremity, that the liquor may pass at once into the belly of the retort, without touching any part of its neck; otherwise, the quantity which adhered to the neck would pass into the receiver when the vessel was placed in a proper situation for distilling, and foul the produce. When the vessel is properly filled, which ought never to be above two-thirds, it is to be set in a sand-bath: that is, in an iron pot, of a proper thick-
Theory.

Chemical Operations.

Of one or two inches, with dry sand. When the retort is put in, so as to stand on its bottom, the pot is to be filled up with sand, as far as the neck of the retort. A glass receiver is then applied, which ought to be as large as possible, and is called a coccus, for which reason it will be proper not to let the capacity of it be above what is necessary to hold ten gallons. In the hinder part of it should be drilled a small hole, which may be occasionally shut by a small wooden peg. The mouth of the receiver ought to be so wide as to let the nofe of the retort enter to the middle of it, or very near to it; for if the vapours are discharged very near the luting, they will act upon it much more strongly than when at a distance. It is likewise proper to have the neck of the retort as wide as may be; for this has a great very effect in the condensation, by presenting a larger surface to the condensing vapour.

The luting for acid spirits ought to be very different from that used in other distillations; for these will generate the common lutes thus to make them liquid and fall down into the receiver. Some have used retorts the necks of which were ground to the receive.

The proportions recommended by the Doctor for luting the joints of vessels, are four parts of sand and one of clay; but for lining the inside of furnaces, and we should think, likewise for coating glass vessels, he directs 6 or 7 of sand to 1 of clay, that the contraction of the clay in drying may thereby be the more effectually prevented. Besides this, he directs a mixture of three parts of charcoal-dust with one of clay to be put next the furnace itself, as being more apt to confine the heat; but probably the first composition might be sufficient for glases.

The coating of large glases must be a very troublesome and tedious operation; and therefore coated glases is never used but in experiments. When large distillations are to be performed in the way of trade, recourse must be had either to iron pots, or to earthen ware. Of the most proper kinds of earthen ware for refilling violents heat, we shall take notice under the article Fusion.

In all distillations by the retort, a considerable quantity of air, or other incomendable vapour, is extracted; and to this it is absolutely necessary to give vent, or the vessel would be burst, or the receiver thrown off. For this purpose, Dr. Lewis recommends an open pipe to be inflected at the luting, of such an height as will not allow any of the vapour to escape; but this we cannot approve of, as by that means a constant communication is formed between the external atmosphere and the materials contained in the retort and receiver, which is at all times to be avoided as much as possible, and in some cases, as the distillation of phosphorus, would be very dangerous. Having a small
IX. Calculation. This is the subjecting any matter to a heat so violent as to disperse some part of it, without melting what remains. It is often practised on metallic substances, particularly lead, for obtaining the calc of that metal called minimum, or red lead.

This operation, as indeed all other chemical ones, is best performed in large quantities, where a particular furnace is constructed on purpose, and a fire kept on day and night without interruption. The flame is made to play over the surface of the metal, and it is continually stirred so as to expose different parcels of it to the action of the heat.

X. Fusion. This is when a solid body is exposed to such a degree of heat as makes it pass from a solid to a fluid state; and as different substances are exposed to very different degrees of fusibility, the degrees of melting heat are very various.

Besides the true fusion, there are some kinds of fairs which retain so large a proportion of water in their crystals, as to become entirely fluid upon being exposed to a very small degree of heat. This is commonly called the water fusio; but is really a fusion: of the falt in that quantity of water retained by it in its crystalline form; for such fairs afterwards become solid by the evaporation of the water they contained: and then require a strong red heat to melt them thoroughly, or perhaps are absolutely infusible.

Of all known substances, unctuous and inflammable ones become fluid with the least heat: then come the more fusible metals, lead, tin, and antimony; then some of the more fusible fairs; and then the harder metals, silver, gold, copper, and iron; then the mixtures for making glafs; and last of all, the metal called platina, which has hitherto been incapable of fusion, except by the violent action of the sun-beams in the focus of a large burning glafs. This substance seems to be the most refractory of all others, even the hardest flints melting into glafs long before it. (See Platina.)

Fusion of small quantities of matter is usually performed in pots called crucibles; which, as they are required to stand a very violent heat, must be made of the most refractory materials possible.

The making of crucibles belongs properly to the Crucibles, potter; but as a chemist ought to be the judge of their proper materials for composition, we shall here give some account of the different attempts to make their vessels of the necessary strength.

All earthen vessels are composed, at least partly, of that kind which is called the argillaceous earth or clay, because thefe only have the necessary ductility, and can be formed into vessels of the proper form. Pure clay is, by itself, absolutely infusible; but is exceedingly apt to crack when exposed to sudden changes of heat and cold. It is also very apt to melt when mixed with other substances, such as calcareous earths, &c.

When mixed in a certain proportion with other materials, they are changed with violent heat into a kind of half-melted substance, such as our flint-bottles. They cannot be melted completely, however, by almost any fire; they are also very compact, and will contain the most fusible substances, even glafs of lead itself; but as they are very apt to crack from sudden changes of heat and cold, they are not so much used; yet, on particular occasions, they are the only ones which can be made use of.

The more dense any kind of vessels are, the more apt they are, in general, to break by a sudden application of heat or cold: hence crucibles are not in general, made of the greatest density possible: which is not at all times required. Those made at Heide, in Germany, have had the best reputation for a long time. Mr Pott, member of the Academy of Sciences at Berlin, hath determined the composition of these crucibles to be, one part of good refractory clay, mixed with two parts of sand, of a middling fineness, from which the finest part has been sifted. By fitting the finer particles from the sand, too great compactness is avoided.
but at the same time this mixture renders them apt to be corroded by vitrifying matters kept a long time in fusion; for these do not fail to act upon the sand contained in the composition of the crucible, and, forming a vitreous mass, at last run through it.

This inconvenience is prevented, by mixing, instead of sand, a good baked clay in gross powder. Of a composition of this kind are made the glafs-house pots, which sometimes sustain the violent heat employed in making glaſs for several months. They are, however, gradually consumed by the glaſs, and become constantly more and more thin.

As the containing vessel, however, must always be exposed to a more violent heat than what is contained in it, crucibles ought to be formed of such materials as are not vitrifiable by the heat of any furnace whatever. But from the attempts made to melt platina, it appears, that all known substances it would be the most defirable for a melting vessel. Heſſian crucibles, glaſs-house pots, Sturbridge clay, in short every substance which could be thought of to refiſt the most violent heats, were melted in such a manner as even to stop up the pipes of large bellows, while platina was not altered in the least; and Meffrs Macquer and Beame have shown, that though platina cannot be melted fo as to caſt crucibles, glaſs-houſe pots, and one part of fusible spar. Theſe crucibles muſt however, be exposed too suddenly to a violent heat. 6. Crucibles capable of containing glaſs of lead very well, were made of 24 parts of unburnt clay, four parts of burnt clay, and one part of chalk. These require to be armed. 7. Plume alum powdered, and mixed with whites of eggs and water, being applied to the internal furface of a Heſſian crucible, enabled it to retain for a long time glaſs of lead in fusion. 8. One part of clay, and two parts of Spaninl chalk, made very good crucibles. The ſubſtance called Spa niſh chalk is not a calcareous earth, but appears to be a kind of ſteatites. 9. Two parts of Spaninl chalk, and one part of powdered tobacco-pipes, made good lining for common crucibles. 10. Eight parts of Spaninl chalk, as much burnt clay, and one part of litharge, made folid crucibles. 11. Crucibles made of black lead are fitter than Heſſian crucibles for melting metals; but they are fo porous, that fuscd faſts pafs entirely thro' them. They are more tenacious than Heſſian crucibles, and are not fo apt to burst in pieces, and are more durable. 12. Crucibles placed with their bottoms upwards, are leſs apt to be cracked during the baking, than when placed differently. 13. The patte of which crucibles are made, ought not to be too moil; else, when dried and baked, they will not be fuficiently compact; hence they ought not to be made too moil as to be capable of being turned on a poſter's lathe; but they must be formed in brass or wooden moulds.

On this ſubjeft Dr Lewis hath alſo made feverai obſervations; the principal of which are, 1. Pure clay obſerves a due confiftence for being worked, onl only coheres together, but sticks to the hands. In drying, it contracts 1 inch or more in 12; and hence it is very apt to crack, unleſs it is dried exceeding flowly. In burning, it is ſubjeft to the fame inconvenience, unleſs very fowly and gradually heated. When thoroughly burnt, if it has escaped thoſe imperfections, it proves folid and compact; and fo hard as to strike fire with ſteel. Vessels made of it are not penetrated by any kind of liquid; and refist fæts and glaſses brought into the thinneſt folution, excepting thoſe which by degrees corrode and difolve the earth itſelf, as glaſs of lead; and even this penetrating glaſs is reflifted by it better than by almôt any other earth; but, in counterbalance to theſe good qualities, they cannot be heated or cooled, but withſuch precautions as can rarely
CHEMISTRY.

2. Clay that has been once exposed to any considerable degrees of heat, and then powdered, has no longer any tenacity. Fresh clay, divided by a due proportion of this powder, proves less tenacious than by itself; not flocking to the hands, though cohering sufficiently together. It shrinks less in drying, is less apt to crack, and less susceptible of injury from alteration of heat and cold: but at the same time is less solid and compact. Considerable differences are observed in these respects; not only according to the quantity of dividing matter, but according as it is in finer or coarser powder.

3. Vessels made with a moderate proportion of fine powder, as half the weight of the clay, are compact and solid, but still very apt to crack, from sudden heat or cold: those with a larger proportion, as twice or thrice the quantity of the clay, are free from that imperfection, but so friable as to crumble between the fingers. Nor does there appear to be any medium between a disposition to crack and to crumble; all the compounds made of clay and fine powders having the one or the other imperfection. Coarser powders of the size of middling sand, form with an equal weight of clay, compounds sufficiently solid, and much less apt to crack than the mixtures with fine powders. Two parts of coarse powder, and one of clay, prove moderately solid, and but little disposed to crack: a mixture of three parts and one, tho' heated and cooled suddenly, does not crack at all, but suffers very fluid substances to transude through it; solidity, and resistance to quick vicissitudes of heat and cold, seeming here also to be incompatible.

4. Pure clay, mixed with pure clay that has been burnt, is no other than one simple earth; and is neither to be melted nor softened, nor made in any degree transparent with the most intense fires.

5. Mixtures of clay with gypseous earths burn whiter than clay alone; in certain proportions, as two parts of clay to three of gypseum, they become, in a moderate fire, semi-transparent, and in a strong one they melt.

6. Calcareous earths in small proportion bake tolerably compact and white; and added to other compositions, seem to improve their compactness. If the quantity of the calcareous earth nearly equals that of the clay, the mixture melts into a yellow glass; if it considerably exceeds, the product acquires the qualities of quicklime.

7. Vessels made from clay and sand, in whatever proportion, do not melt in the strongest fire: but they sometimes bend or bend, so as to yield to the tongs. Glasses in thin fusion penetrate them by dissolving the sand. If gypseous or calcareous earths urged in such crucibles with a vehement heat, the vessels and their contents run all into one mass. In moderate fires, these vessels prove tolerably compact, and retain most kinds of fusions in f buttock are liable to crack, especially when large; and do not long retain melted metals, being burst by their weight. Such are the Helenian crucibles.

8. Mixtures of clay and black-lead, which seems a species of tlect, are not liable to crack from alternations of heat and cold; but are extremely porous. Hence lead-crude crucibles answer excellently for the melting of metals, and stand repeated fusions: whilst Chemical salts flowing thin, transude through them almost as operations of water through a sieve: sulphurous bodies, as antimony, corrode them.

9. Pure clay, softened with water, and incrustated on earthen vessels, that have been burnt, does, not adhere to them, or scales off again upon exposure to the fire: applied to unburnt vessels, it adheres and incorporates. Divided clay unites with them in both states. Chemical matters, melted in vessels of pure clay, adhere so firmly as not to be separated from vessels of divided clay they may be knocked off by a hammer.

10. The saline fluxes which promote the fusion of clay, besides the common ones of all earths, alkali and borax, are chiefly arsine fixed by nitre, and the fusible salt of urine; both which have little effect on the other earths though mixed in a larger proportion. Nitre, which readily builds the crystalline earths into fusion, and sal mirabile and sandiver, powerful fluxes for the calcareous earths, do not perfectly vitrify with clay. Burnt clay does not differ in their respects from such as has not been burnt; nor in that singular property of vitrifying with gypseous or calcareous earths, with or without any saline or metallic addition; the utmost vehemence of fire seeming to destroy only its fluidity, or that power by which it coheres when its parts are moistened with water.

But though it seems impossible to make perfect vessels from mixtures of clay in its two different states, of burnt and unburnt, more is to be hoped from the mixtures which are employed in making porcelain. Many manufacturers of this kind of ware have been attempted, and vessels in different countries, (see Porcelain) and in some to be hoped for, places the qualities requisite for chemical vessels have been given to it in a very surprising degree. The count de Lauraguais, a French nobleman, and member of the academy of sciences, has distinguished himself in a very eminent manner by attempts of this kind. The translator of the chemical dictionary assures us, that he had it from a gentleman of undoubted veracity, that this nobleman having heated a piece of his porcelain red hot, threw it into cold water, without breaking or cracking it. The most useful attempt, however, for the purposes of chemistry, seems to be the discovery by Mr Reaumur of converting common green glasses into porcelain. Mr Reaumur. This was published as long ago as the year 1739; yet we have scarce heard of any chemist, no not claim, Dr Lewis himself, who has made trial of chemical vessels formed of this sort of porcelain, although the very use to which Mr Reaumur thought the preparation could be applicable was that of bringing chemical vessels to a degree of perfection which could not otherwise be done. The following is the result of Mr Reaumur’s experiments.

Green glasses, surrounded with white earthy matters, as white sand, gypseum, or plaster of Paris, &c. and exposed to a considerable heat not strong enough to alter its figure, as that of a potter’s furnace, acquires different shades of blue, and by degrees begins to grow white. On breaking the glass, the white coat appears to be composed of fine, white, glozy, satiny-like fibres, running transversely, and parallel to one another; the glass in the middle being fearfully altered. On continuing the combustion, the change proceeds further and further, till at length the white fibrous parts...
parts from both sides meet in the middle, and no appearance of glass remains. By this means, entire vessels of glass may be changed into porcelain.

The substance into which glass is thus converted, is opaque, compact, internally of great whiteness, equal to that of the finest china-ware; but, externally, of a much duller hue. It is considerably harder than glass, much less fusible in the fire, and sustains alterations of heat and cold without injury. Vessels of it, cold, bear boiling liquors; and may be placed on the fire at once, without danger of their cracking. "I have put a vessel of this porcelain (says the author) into a forge, surronded it with coals, and kept vehemently blowing for near a quarter of an hour; I have melted glass in this vessel, without its having suffered any injury in its figure." If means could be found of giving the outside a whiteness, equal to the internal part, glass vessels might thus be converted into a valuable kind of porcelain superior to all that have hitherto been made. Chemistry, says he, may receive from this discovery, in its present state, such vessels as have been long wanted; vessels which, with the compactness and impenetrability of glass, are also free from its inconveniences.

The common green glasses bottles yield a porcelain of tolerable beauty; window-glasses, and drinking-glasses, a much inferior one; while the finer kinds of crystaline glasses afforded none at all. With regard to the cementing materials, he found white sand and gypsum, or rather a mixture of both, to answer best. Coloured earths generally make the external surface of a deeper or lighter brown colour; foot, and charcoal, of a deep black, the internal part being always white.

The account of this kind of porcelain given by Mr. Reaumur, induced Dr. Lewis, who had also observed the same changes on the bottom of glass-retorts exposed to violent heat in a sand-bath, to make further experiments on this matter; an account of which he has published in his *Philosophical Transactions of Arts*. The results of his experiments were, 1. Green glasses, cemented with white sand, received no change in a heat below ignition. 2. In a low red heat, the change proceeded exceedingly slowly; and in a strong red heat, approaching to white, the thickest pieces of glass bottles were thoroughly converted in the space of three hours. 3. By continued heat, the glasses suffered the following progressive changes: first, its surface became blue; its transparency was diminished, and a yellowish hue was observable when it was held between the eye and the light. Afterwards it was changed a little way on both sides into a white substance, externally still bluish; and, as this change advanced still further and further within the glass, the colour of the vitreous part in the middle approached nearer to yellow: the white coat was of a fine fibrous texture, and the fibres were disposed nearly parallel to one another, and transverse to the thickens of the piece: by degrees the glasses became white and fibrous throughout, the external bluishness at the same time going off, and being succeeded by a dull white or dun colour. By a still longer continuance in the fire, the fibres were changed gradually from the external to the internal part, and converted into grains; and the texture was then not unlike that of common porcelain. The grains, at first fine and somewhat glossy, became by degrees, larger and duller; and at last the substance of the glass became porous and friable, like a mass of white sand.

Concerning the qualities of this kind of porcelain, Dr. Lewis observes, that, while it remained in the fibrous state, it was harder than common glass, and more able to resist the changes of heat and cold than glass, or even porcelain; but, in a moderate white heat, was fusible into a substance not fitous, but vitreous and smooth, like white enamel, that when its texture had become coarsely granulated, it was now much softer and fusible: and lastly, that when some coarsely granulated un fusible pieces, which, with the continuance of a moderate heat, would have become porous and friable, were suddenly exposed to an intense fire, they were rendered remarkably more compact than before; the solidity of some of them being superior to that of any other ware.

It seems surprizing that this able chemist, who on other occasions had the improvements of the arts so well studied, did not put some vessels of this kind of porcelain to other severe trials, besides attempting to fuse it by itself with a violent fire; for though pieces of it were absolutely fusible, we are not sure but they might have been corrupted by alkaline salts, acids, calcareous earths, or glass of lead: nay, it should seem very probable that they would have been so: in which case they would not be much superior to the vessels made from earthy materials. When a first-rate chemist publishes anything in an imperfect state, inferior ones are discouraged from attempting to finish what he has begun; and thus, notwithstanding that these experiments have been so long published, nobody has yet attempted to investigate the properties of this kind of porcelain, by getting chemical vessels made of it, and trying how they answer for crucibles, or retorts.

All that has been said concerning the proper materials for crucibles, must likewise be applicable to the materials for retorts, which are required to stand a very violent heat. Mr. Reaumur's porcelain bids fair for answering the purpose of retorts as well as crucibles. The great disadvantage of the common, earthen ones, is, that they suffer a quantity of volatile and penetrating vapours to pass through them. This is very observable in the distillation of phosphorus; and though this substance has not hitherto been used for any purpose in medicine, and very little in the arts, it is of value, being sometimes used as a flux, if vessels could be made capable of confining all the steam and at the same time bearing the heat necessary for its distillation, phosphorus, perhaps, might be obtained in such quantity, as to show that it is a preparation not altogether useless.

With regard to stone-ware vessels, and all those into which the composition of sand or flint enters, we shall only further observe, that they will be corrupted by fixed alkaline salts, especially of the caustic kind, in a very moderate heat. Dr. Black, having evaporated some caustic ley in a stone-ware bason, and then melted the dry salt in the same vessel, found it to corrode, as afterwards to be full of small holes; and he found nothing to reftist the action of this salt so well as silver. On Wedgewood's stone-ware vessels, we have now, however, to add the improved earthen ware of Mr. Wedgewood, in which the properties of compacts, inexpedibility, and the power of resisting sudden changes of heat and cold, are said to be united, so that it promises to be a very valuable addition to the chemical apparatus.
11. Maceration, or Digestion. This is the mixing two bodies, generally a solid and a fluid, together, and then expelling them to a moderate degree of heat for a considerable length of time, that they may have the better opportunity of acting upon one another. Digestion is usually performed in the glases already mentioned, called mortarese or bolt-heads; and is done in a sand-heat. When any of the substances are very volatile, as spirit of wine; or when the matter requires to be heat so considerably that a quantity of vapour will be raised, the necks of the bolt-heads ought to be pretty long; or a tin pipe may be inferred, of sufficient length to prevent the escape of any part of the steam.

12. Levigation. This is the reducing any body to a very fine powder, which shall feel quite soft between the fingers or when put into the mouth. It is performed by grinding the substance upon a flat marble stone, with some water, or by rubbing it in a marble mortar. In the large way, levigation is performed by mills drawn by horses, or driven by water; in this operation, when the matters are reduced to the finest degree, they wear off a part of the mortar, or marble stone, with some water, or by rubbing a smooth stone, called a levigator, by a funnel, which is fixed into a hole in the upper part of the mill, and turns along with it. The under millstone has round it a wooden ledge, whereby the levigating matter is confined for some time, and at length discharged, by an opening made for that purpose, when it has accumulated in a certain quantity.

In this operation, when the matters to be levigated are very hard, they wear off a part of the mortar, or stone on which they are levigated; so that a substance perfectly hard, and which could not be worn by any attrition, is as great a delideratum for the purposes of levigation, as one which could not be melted is for those of fusion. Dr. Lewis proposes the porcelain of Mr. Reamur as an improvement for levigating planes, mortars, &c. because, while in its fibrous state, it is considerably harder than glasts, and consequently much less liable to abrasion by the harder powders.

In many cases levigation is very much accelerated by what is called attrition. This is the method by which many of the painters' colours are prepared of the requisite fineness, and is performed by mixing any substance not totally reduced to the necessary degree of fineness, with a sufficient quantity of water, and stirring them together. The finer parts of the powder remain some time suspended in the water, while the groser particles fall to the bottom. The separation is then easily made, by pouring off the water impregnated with these fine parts, and committing the rest to the levigating mill, when it may again be washed; and this may be repeated till all the powder is reduced to the utmost fineness. Substances soluble in water cannot be levigated in this manner.

Of Chemical Furnaces.

The two general divisions we have already mentioned of those who practice chemistry, namely, those who have no other view than mere experiment, and those who wish to profit by it, render very different kinds of furnaces necessary. For the first, those furnaces are necessary which are capable of acting upon a small quantity of matter, yet sufficient for all the changes which fire can produce from simple digestion to the most perfect vitrification. For the others, those are to be chosen which can produce the same changes upon very large quantities of matter, that as much may be done at once as possible.

To avoid the trouble and expense of a number of portable furnaces, a portable one hath long been a desideratum among those chemists who are fond of making experiments. One of the best of these, if not the very best, that has yet appeared, is that described in Shaw's edition of Boerhaave's chemistry, and represented fig. 1. Plate CXXXIV. This furnace is made of earth; and, as the workmanship of a furnace requires none of the neatness or elegance which is required in making potters' vessels, any person may easily make a furnace of this kind for himself, who has time and patience for doing it. With regard to the most proper materials, all that we have said concerning crucibles and retorts must be applicable to the materials for constructing a furnace; only here we need not care so much for the porosity, or disposition to crumble, as when crucibles or other diluting vessels are to be made.

Plate iron is commonly directed for the outside of portable furnaces; but we cannot help thinking this is a very needless expense, seeing the coating which it necessarily requires on the inside may be supposed to harden to such a degree as soon to support itself, without any assistance from the plate-iron. This will be the less necessary, if we consider, that, for the thickness of the walls of any furnace where a considerable heat is wanted, two or three inches are by no means sufficient. When the inside of a furnace is heated, the walls, if very thin, are soon penetrated by the heat, and great part of it by this means dissipated in the air. If they are of a sufficient thickness, the heat cannot penetrate so easily; and thus the inner part of the furnace preserves the heat of the fuel, and communicates it to the contained vessel. In the construction of a portable furnace, therefore, it will be convenient to have all parts of it six inches thick at least. This will also give it a sufficient degree of strength; and, as it is formed of several different pieces, no inconvenience can follow from the weight of each of them taken separately.

In Boerhaave's chemistry, this furnace is represented as narrower at the bottom than at the top; but we cannot suppose any good reason for such a form, seeing a cylindrical one must answer every purpose much better, as allowing a larger quantity of air to pass through the fuel, and likewise not being so apt to be overturned as it necessarily must be when the upper part is considerably heavier than the lower. We have, therefore, given a representation of it as of a cylindrical form.

The furnace consists of five or more parts. C, represents the dome, or top of the furnace, with a short earthen funnel E for transmitting the smoke. B, B, B, are moveable cylinders of earth, each provided with a door D, D, D. In Boerhaave's chemistry these doors are represented as having iron hinges and latches; but they may be formed to more advantage, by fastening pieces of earth, having two holes in the middle, by which they may be occasionally taken out, by introducing an iron fork. In like manner, the domes and cylinders,
Chemical cylinders, in Boyle's chemistry, are represented with iron handles; but they may be almost as easily taken off by the cheaper contrivance of having four holes in each, two directly opposite one another, into which two short forks may be introduced when the parts are to be separated.

In the lowermost cylinder is to be placed an iron grate, a little below the door, for supporting the fire. In the under part is a small hole, big enough for introducing the pipe of a pair of good perpetual bellows when the fire is to be violently excited. Dr Lewis prefers the organ-bellows to any other kind.

When the bellows is used, the whole must stand upon a close cylinder A, that the air may be confined, and made to pass through the fuel. By having more bellows, the fire may be excited to a most intense degree. In this case, the pipe of every one of them must enter the cylinder B.

Each of the cylinders should have, in its upper part, a round hole, opposite to its door, for carrying off the smoke, by means of a pipe inserted into it, when the furnace is used for distillation by the sand-bath. Each cylinder ought likewise to have a semicircular cut in the opposite sides, both above and below, that when the under cut of the upper cylinder is brought directly above the upper cut of the lower one, a perfect circle may be formed. These are for giving a passage to the necks of retorts, when distillation by the retort is to be performed. The holes may be occasionally filled with stopples made of the same materials with the body of the furnace.

The most convenient situation for a furnace of this kind would be under a chimney, the vent of which might be easily flopped up by a broad plate of iron, in which a hole ought to be cut for the reception of the earthen tube of the dome. By this means the use of a long tube, which at any rate must be very troublesome, might be easily avoided, and a very strong blast of air would pass through the fuel. If it is found convenient to place the furnace at some distance from the chimney, a plate-iron pipe must be procured to fit the earthen pipe of the dome, and carry the smoke into the chimney. This pipe will also be of use, when the furnace is used for distillation by the sand-bath; it must then be inserted into the hole opposite to the door of any of the cylinders, and will convey away the smoke, while the mouth of the cylinder is totally covered with a sand-pot.

For portable furnaces, Dr Lewis greatly recommends the large black crucibles, marked n° 60, on account of their resisting a violent heat, and being very easily cut by a knife or saw, so that doors, &c. may be formed in them at pleasure. The bottom of one of these large ones being cut out, a grate is to be put into the narrow part of it. For grates, the doctor recommends cast iron-rings, having each three knobs around them. These knobs go into corresponding cavities of the outer rings, and the knobs of the outermost rest on the crucible, which is to be indented a little to receive them, that so the grate may rest the more firmly, and the furnace not be endangered from the swelling of the iron by heat. When this is to be made use of as a melting-furnace, and a violent heat to be excited, another crucible must be inverted on that which contains the fuel, which serves instead of the dome of the last mentioned furnace; and chemical matters must give very considerable weight to any thing he advances; and the warmth with which he recommends the furnaces must convince us, that he has found them abundantly answer the purposes of experiments. We cannot help thinking, however, that where a very great and lasting heat is to be given, the thicknefs, and even the form, of these crucibles, is some objection to their use. It is certain that such a permanent, or, as the workmen call it, a fixed heat, can never be given where the walls of a furnace are thin, as when they are of sufficient thicknefs. They are also very apt to burst with great heat; and, for this reason, Dr Lewis desires his furnace to be strengthened with copper hoops. This disposition to burst proceeds from the inner parts which are more intensely heated than the outer, expanding more than these do, and consequently bursting them. Hence the doctor desires his furnace to be strengthened also by putting it within another crucible of a larger size, and the intermediate space to be filled up with a mixture of sifted ashes and water. For most chemical processes, where only a small degree of heat is requisite, these furnaces answer beyond any thing that has hitherto been attempted. The whole is to be supported by an iron ring with three feet.

Dr Black has contrived a furnace in which all these inconveniences are avoided. Two thick iron plates, above and below, are joined by a thinner plate, forming the body of the furnace, which is of an oval form. The upper part is perforated with two holes; the one A, pretty large, which is the mouth of the furnace, and which is of a circular form; the other behind it, B, of an oval form, and designed for fastening the end of the vent which is screwed down upon it. The undermost thick plate has only the large circular opening G near to the middle, but not altogether fo, being nearer to one side of the ellipse than the other, where the round hole in the top is placed; so that a line passing this circular hole has a little obliquity forwards. The ash-pit C E is likewise made of a nolliptical form, and a very small matter widened; so that the bottom of the furnace is received within the ellipse. A little below, there is a border D that receives the bottom of the furnace; and except the holes of the damping-plate E, the parts are all closed by means of soft lute, upon which the body of the furnace is pressed down; by means of which the joining of the two parts, and all the different pieces, are made quite tight; for the body, fire place, ash-pit, vent, and grate, are all separable from one another. As the furnace comes from the workman, the grate is made to apply to the outside of the lower part. It consists of a ring laid on its edge, and then bars likewise laid on their edges; and from the outer ring proceed four pieces of iron, by means of which it may be ferewed down; so it is kept out of the cavity of the furnace, and preferred from the extremity of the heat. Thus it lasts much longer, and indeed hardly liable to any decay; for being exposed to the cool air, it is kept so cool, that it
Chemical Furnaces.

603 How adapted to the various operations of化学, we may observe, that for a melting furnace it is very convenient; we need only provide a cover for the opening above, which is made the door; and which being immediately over the grate, is convenient for introducing the substances to be acted upon, and for allowing us to look into the vessel and take it out. This cover may be a piece of tile, or two bricks rendered flat and square. Dr Black commonly uses a kind of lid with a rim containing a quantity of close metal. To preserve the substance from the contact of the fuel, they cut off about a third part of the length of a brick, and then put it on one end on the middle of the grate. They choose their fuel of large pieces, that the air may have free passage through it, and open a little of the door, which occasions a stream of air to flow in; and this strikes upon the substance and produces the effect desired; so that it may be used in the calculation of lead to convert it into litharge. It also answers very well in operations for producing vapour.

If we desire to employ it in distillations which require an intense heat, the earthen retort is to be suspended by means of an iron ring having three branches standing up from it, and which hangs down about half a foot from the hole; so that the bottom of the retort rests upon the ring, and is immediately hung over the fuel; and the opening between the mouth of the furnace and retort is filled up with broken crucibles and pottersclay, which are covered over with ashes. This transmission of heat is very slow; so it answers well for distillations performed with the naked fire. Dr Black has sometimes cauied them to be provided with a hole in the side, from which the neck of the retort may be made to come out; and in this way has distilled the phosphorus of urine, which requires a very strong heat. For distillations with retorts performed with the sand-bath, there is an iron pot fitted for the opening of the furnace, which is set on and employed as a sand-pot. The vent of the furnace then becomes the door; and it answers very well for that purpose; and is more easily kept tight than if it were in the side, and may be kept close with a lid of charcoal and clay. In like manner it answers well for the common still, which may be adapted to it; part of it being made to enter the open part of the furnace, and hang over the fire, as in Plate CXXXIII. fig. 8. and 9. that the bottom part of that still may be made to enter; and the vent becomes the door, by which fresh fuel may be added. Indeed it is seldom necessary to add fresh fuel during any operation. In the ordinary distillations it is never necessary; and even in distilling mercury, phosphorus, &c. it generally contains enough to finish the operation; so effectively is the heat preferred from loss or dissipation, and so very slow is the consumption of the fuel.

Theory.

For luting this and other furnaces, the doctor finds nothing preferable to a simple mixture of sand and clay. The proportions for luting the violence of fire are four parts of sand to one of clay; but when designed for the lining of furnaces, he uses six or seven parts of sand to one of clay, the more effectually to prevent the contraction of the latter; for it is known from experiments, that clay, when exposed to a strong heat, contracts the more in proportion to its purity. The sand settles into the lusks when wet, and does not contract by heat, which it also resists as well as the clay itself.

Besides this outside luting next the fire, Dr Black uses another to be laid on next the iron of the furnace; and this consists of clay mixed with a large portion of charcoal dust. It is more firm for containing the heat, and is put next to the iron, to the thickness of an inch and a half. That it may be pretty dry when first put in, he takes three parts by weight of Method of charcoal dust, and one of the common clay, which applying must be mixed together when in dry powder, otherwise it is very difficult to mix them perfectly. As much water is added as will form the matter into balls; and these are beat very firm and compact by means of a hammer upon the inside of the furnace. The other lute is then spread over it to the thickness of about half an inch, and this is also beat solid by hammering; after which it is allowed to dry slowly, that all cracks and fissures may be avoided; and after the body of the furnace is thus lined, the vent is screwed on and lined in the same manner. It must then be allowed to dry for a long time; after which a fire may be kindled, and the furnace gradually heated for a day or two. The fire is then to be raised to the greatest intensity; and thus the luting acquires a hardnefs equal to that of free-stone, and is afterwards as lasting as any part of the furnace.

When furnaces are used in the large way, they are Melting always built of brick, and each particular operation has furnace. a furnace allotted for itself. The melting-furnace, where very large quantities of matter are not to be melted at once, requires only to be built of brick in such a form as we have already described; but where very large quantities of matter are to be melted, it is necessary to procure a dome of the proper figure, the forepart of which is to be left entirely open for the admission of distillation vessels. The opening may be closed up with bricks and earth during the operation. There is no necessity for having the inside of a circular form; a square one will answer the purpose equally well. According to the author of the Chemical Dictionary, when the internal diameter of a furnace is 12 or 15 inches, the diameter of the tube of the furnace is 8 or 9 inches, and its thickness 18 or 20 feet, and when the figure be well supplied with fuel, and extreme heat is produced; in less than an hour the furnace will be white, and dazzling like the sun; its heat will be equal to the strongest glass-house furnace; and in less than two hours will be melted whatever is fusible in furnaces. The hottest part is at H F, 4 or 6 inches above the grate. A plate-iron tube may be advantageously supplied by a short chimney of bricks, built under a pretty high vent, so as the whole may easily be stopped, except that passage which transmits the smoke of the furnace. By this means a very strong current of air will be made to pass through the fuel.

On this subject Dr Black informs us, that Mr Pott of the melting Pott of Berlin employs one almost similar to the above furnace de- for friable.

Chemical Furnaces. for making the fire-place of a roundish form.

The ellipse too may be employed for driving air into fuel. The effect of this has been considered as a proof that air acts by its elasticity in animating fuel, as an elastic fluid vapour from the ellipse produces, the Chemical fame effect. But when we contrive to send flame.

2. That the vent should be made about one-half the grate. A small portable furnace of this kind is very convenient for ordinary crucibles; the largest of which are only about four or five inches high; the widest part of the furnace may be about an inch and a half in diameter, and when made of thin plate iron, and lined within, are very convenient, and may be heated at very little expense of fuel. But for heating much larger vessels, it is proper to construct them of brick, when they have prettily the same form; only it is necessary to make them square, and round on the inside with a luting of sand and clay. The top is generally made flat, and covered over with two or three bricks; the vent goes a little backwards, and then is raised to a proper height. Where the vessel to be heated is very large, it is common to leave the front open for putting in the vessel; and then to build it up with bricks, clay, and sand; which can be easily pulled down again when the operation is over.

There are some cafes in which it is necessary to have a rapidity of inflammation even beyond what this furnace can give; and in these we have recourse to belows of various constrictions, by which the air can be compressed and made to enter the fuel with great velocity. These again are sometimes wrought by water; but there is another machine which produces a greater effect, viz. the water-blown described by Lewis in his Commercial Philosph. Technical.

The ellipse too may be employed for driving air into fuel. The effect of this has been considered as a proof that air acts by its elasticity in animating fuel,
The under part of the vent. A much better method is to build the back part of the furnace entirely close, and make the fire come out through a long narrow opening before, after which it passes out through a hole in the back and upper part of the furnace into the chimney. The convenience of this form is, that the vent must either be very wide, or it is apt to choke up with foot, which is a very troublesome circumstance. If the vent is made very wide, a prodigous draught of air rushes through the fuel, and increases the heat to such a degree as to calcine the metal of which the still is made; and, on the other hand, nothing can be more disagreeable than to have the vent of a furnace stopped up with foot. These inconveniences, however, are totally avoided by making two small vents, one on each side of the distilling vessel, which may communicate with a chimney by means of two tubes either of plate-iron or formed with clay or bricks, which may be occasionally taken off if they happen to be choked up. The vessel is to be suspended by three trunnions, so that the whole surface may be exposed to the fire, excepting a ring the thickness of a brick all round; so that a very strong heat will be communicated although the furnace draws but little. The two small vents on each side will draw the flame equally; and by this means the most equal heat can be preferred, and may be pulled so far as to make the whole bottom and sides of the vessel intense red. Such a construction as this is more especially useful for sand-pots, and those which are used for the distillation of alkaline spirits from bones.

In the use of the furnaces hitherto described, the attendance of the operator is necessary, both for inspecting the process, and for supplying and animating the fuel. There are some operations, of a slower kind, that require a gentle heat to be continued for a length of time; which demand little attendance in regard to the operations themselves, and in which, of consequence, it is extremely convenient to have the attendance in regard to the fire as much as possible dispensed with. This end has been answered by the furnace called athanor; but the use of it has been found attended with some inconveniences, and it is now generally laid aside.

Sundry attempts have been made for keeping up a continued heat, with as little trouble as in the athanor, by the flame of a lamp; but the common lamp-furnaces have not answered so well as could be wished. The lamps require frequent filling, and smoke much; and the foot accumulated on the bottom of the vessel placed over them, is apt, at times, to fall down and stop the flame. The largeness of the wick, the irregular supply of oil from the reservoir by jets, and the oil being suffered to sink considerably in the lamp, so that the upper part of the wick burns to a coal, appeared to be the principal causes of these inconveniences, which accordingly were found to be in great measure remedied by the following contrivance.

The lamp consists of a brass pipe 10 or 12 inches long, and about a quarter of an inch wide, infected at one end into the reservoir of the oil, and turned up at the other to an elbow, like the hole of a tobacco-pipe, the aperture of which is extended to the width of near two inches. On this aperture is fitted a round plate, having 5, 6, or 7 small holes, at equal distances, round its outer part, into which are inserted as many pipes of cotton, all together not exceeding what is in the common lamps form one wick: by this division of the wick, the flame exposes a larger surface to the action of the air, the fum of the fish is confirmed and carried off, and the lamp burns clear and vivid.

The reservoir is a cylindrical vessel, eight or ten inches wide, composed of three parts, with a cover on the top. The middle partition communicates, by the lateral pipe, with the wicks; and has an upright open pipe folded into its bottom, whose top reaches as high as the level of the wick; so that, when this part is charged with oil, till the oil rises up to the wicks in the other end of the lamp, any further addition of oil will run down through the upright pipe into the lower division of the reservoir. The upper division is designed for supplying oil to the middle one; and, for that purpose, is furnished with a cock in the bottom, which is turned more or less, by a key on the outside, that the oil may drop fast enough to supply the consumption, or rather faster, for the overplus is of no inconvenience, being carried off by the upright pipe; so that the oil is always, by this means, kept exactly at the same height in the lamp. For common uses, the middle division alone may be made to suffice; for, on account of its width, the sinking of the oil will not be considerable in several hours burning. In either case, however, it is expedient to renew the wicks every two or three days; oftener or seldom according as the oil is more or less foul; for its impure matter, gradually left in the wicks, occasions the flame to become more and more dull. For the more convenient renewing of them, there should be two of the perforated plates; that when one is removed, another, with wicks fitted to it, may be ready to supply its place.

One of the black-lead pots, recommended by Dr Lewis for his portable furnace, makes a proper furnace for the lamp. If one is to be fitted up on purpose for this use, it requires no other aperture than one in the bottom for admitting air, and one in the side for the introduction of the elbow of the lamp. The reservoir stands on any convenient support without the furnace. The stopper of the side aperture consists of two pieces, that it may be conveniently put in after the lamp is introduced; and has a round hole at its bottom fitting the pipe of the lamp. By these means, the furnace being set upon a trevet or open foot, the air enters only underneath, and spreads equally all around, without coming in streams, whence the flame burns steady. It is not advisable to attempt raising the heat higher than about the 150th degree of Fahrenheit's thermometer; a heat somewhat more than sufficient for keeping tin in perfect fusion. Some have proposed giving a much greater degree of heat in lamp-furnaces, by using a number of large wicks; but when the furnace is so heated the oil emits copious fumes, and its whole quantity takes fire. The balnezum or other vessel including the subject-matters, is supported over the flame by an iron ring, as already described in the sand-bath and still; a bath is here particularly necessary, as the subject would otherwise be very unequally heated, only a small part of the vessel being exposed to the flame. Since the new invention of Argand's lamps, which perfectly consume the oil, attempts have been made to construct...
The vitriolic acid is never found pure, but always united with some proportion, either of phlogiston or metallic and earthy substances. Indeed there is scarce any kind of earth which does not contain some portion of this acid, and from which it may always some way or other be separable. When pure, the vitriolic acid appears in the form of a transparent colourless liquor. By distilling in a glass retort, the aqueous part arises, and the liquor which is left becomes gradually more and more acid. This operation is generally called the rectification, or dephlegmation, of the acid. After the distillation has gone on for some time, the water adheres more strongly to what remains in the retort, and cannot be forced over without elevating part of the acid along with it. The remaining acid, being also exceedingly concentrated, begins to lose its fluidity, and puts on the appearance of a clear oil. This is the state in which it is usually sold, and then goes by the name of oil of vitriol. If the distillation is still farther continued, with a heat below 600° of Fahrenheit's thermometer, the acid gradually loses more and more of its fluidity, till at last it congeals in the cold, and becomes like ice. In this state it is called the icy oil of vitriol. Such exceedingly great concentration, however, is only practised on this acid for curiosity. If the heat be suddenly raised to 600°, the whole of the acid fuses, and generally cracks the receiver. Clear oil of vitriol is immediately turned black by an admixture of the smallest portion of inflammable matter.

The icy oil of vitriol, and even that commonly sold, attracts the moisture of the air with very great force. Newmann relates, that having exposed an ounce of this acid to the air, from September 1736 to September 1737, at the end of the twelvemonth it weighed seven ounces and two drachms; and thus had attracted from the air above fix times its own weight of moisture. This quantity, however, seems extraordinary; and it is probable, that in so long a time some water had been accidentally mixed with it; for Dr Gould, professor at Oxford, who seems to have tried this matter fully, relates, that three drachms of oil of vitriol acquired, in 57 days, an increase only of six drachms and an half. The acid was exposed in a glass of three inches diameter; the increase of weight the first day was upwards of one drachm; in the following days less and less, till, on the fifty-sixth, it scarce amounted to half a grain. The liquor, when saturated with humidity, retained or lost part of its acquired weight according as the atmosphere was in a moist or dry state; and this difference was so sensible as to afford an accurate hygrometer. Hoffman having exposed an ounce and two scruples in an open glass-dish, it gained fifteen drachms and a scruple in 14 days.

This acid, when mixed with a large quantity of productive water, makes the temperature something colder than that of cold water; but if the acid bears any considerable proportion to the water, a great heat is produced, so as to make the vessel insupportable to the hand; and therefore

612

Never found pure.

The vitriolic acid is never found pure, but always united with some proportion, either of phlogiston or metallic and earthy substances. Indeed there is scarce any kind of earth which does not contain some portion of this acid, and from which it may always some way or other be separable. When pure, the vitriolic acid appears in the form of a transparent colourless liquor. By distilling in a glass retort, the aqueous part arises, and the liquor which is left becomes gradually more and more acid. This operation is generally called the rectification, or dephlegmation, of the acid. After the distillation has gone on for some time, the water adheres more strongly to what remains in the retort, and cannot be forced over without elevating part of the acid along with it. The remaining acid, being also exceedingly concentrated, begins to lose its fluidity, and puts on the appearance of a clear oil. This is the state in which it is usually sold, and then goes by the name of oil of vitriol. If the distillation is still farther continued, with a heat below 600° of Fahrenheit's thermometer, the acid gradually loses more and more of its fluidity, till at last it congeals in the cold, and becomes like ice. In this state it is called the icy oil of vitriol. Such exceedingly great concentration, however, is only practised on this acid for curiosity. If the heat be suddenly raised to 600°, the whole of the acid fuses, and generally cracks the receiver. Clear oil of vitriol is immediately turned black by an admixture of the smallest portion of inflammable matter.

613

Rectification.

614

---

The icy oil of vitriol, and even that commonly sold, attracts the moisture of the air with very great force. Newmann relates, that having exposed an ounce of this acid to the air, from September 1736 to September 1737, at the end of the twelvemonth it weighed seven ounces and two drachms; and thus had attracted from the air above fix times its own weight of moisture. This quantity, however, seems extraordinary; and it is probable, that in so long a time some water had been accidentally mixed with it; for Dr Gould, professor at Oxford, who seems to have tried this matter fully, relates, that three drachms of oil of vitriol acquired, in 57 days, an increase only of six drachms and an half. The acid was exposed in a glass of three inches diameter; the increase of weight the first day was upwards of one drachm; in the following days less and less, till, on the fifty-sixth, it scarce amounted to half a grain. The liquor, when saturated with humidity, retained or lost part of its acquired weight according as the atmosphere was in a moist or dry state; and this difference was so sensible as to afford an accurate hygrometer. Hoffman having exposed an ounce and two scruples in an open glass-dish, it gained fifteen drachms and a scruple in 14 days.

This acid, when mixed with a large quantity of productive water, makes the temperature something colder than that of cold water; but if the acid bears any considerable proportion to the water, a great heat is produced, so as to make the vessel insupportable to the hand; and therefore
Vitriolic acid and its combinations.

The vitriolic acid unites itself very strongly with alkalis, both fixed and volatile, it does not fuse near so much of the latter as of the former. A pound of oil of vitriol will fuse two of the common fixed alkali, but scarce one of volatile alkali. The specific gravity of good oil of vitriol is to water as 17 to 8.

If the concentrated acid is applied slightly and superficially to the skin of a living animal, it raises a violent burning heat and pain; but a larger quantity prefied on, so as to prevent the ingress of aerial moisture, occasions little pain or erection. If diluted with a little water, it proves corrosive in either case. Largely diluted with water, this acid is employed for checking putrefaction, abating heat, and quenching thirst; in debilities of the stomatch, and heart-burn. To persons of weak and unfound lungs, to women who give suck, to hydropic or emaciated persons, it is injurious. Some recommend it as a collyrium for fo eyes; but as it coagulates the animal plasmas, and is not at all, to be made in glass vessels, but in the common stone-bottles, or leaden vessels, which are not apt to be corroded by this acid. The greatest heat is produced by equal parts of acid and water.

The vitriolic acid unites itself very strongly with alkalis, both fixed and volatile, it does not fuse near so much of the latter as of the former. A pound of oil of vitriol will fuse two of the common fixed alkali, but scarce one of volatile alkali. The specific gravity of good oil of vitriol is to water as 17 to 8.

The greatest heat is produced by equal parts of acid and water.

The difficulty of procuring it itself.

The vitriolic acid is so much used in different arts and manufactures, that the making of it has become a trade by itself; and the procuring it in plenty, and at a cheap rate, would be a very advantageous piece of knowledge to any person who could put it in practice. This, however, is very far from being easily done; for though it exists in almost every mineral substance, the attraction betwixt this acid and the bases with which it unites, is found to be so strong, that we can only decompose such combinations by prefening another substance to the acid, to which it has a greater attraction than that one with which it is joined. Thus the first combination is indeed dissolved, but we have another from which it is equally difficult to extricate the acid by itself. Thus, if we want to difegenate the vitriolic acid from any metallic substance, suppoce iron, this may be easily done by throwing a calcareous earth into a solution of green vitriol. We have now a compound of vitriolic acid with the calcareous earth, which is known by the name of gypsum or selenites. If we want to decompose this we must apply a volatile or a fixed alkali; and the result of this will certainly be a new combination, which we are as unable to decompose, and indeed more so, than the firft. There are two general methods which have been in use for procuring the vitriolic acid in such quantity as to supply the demands of trade. The one is from pyrites, and the other from sulphur.

I. From Pyrites, with the making of Copperas, and obtaining the pure Oil of Vitriol from it.

Pyrites are found in large quantity in the coal-mines of England, where most of the copperas is made. They are very hard and heavy substances, having a kind of braffy appearance, as if they contained that metal; and hence they are called brafier by the workmen. A very large quantity of these is collected, and vitriolic acid spread out upon a bed of stiff clay to the depth of three feet. After being some time exposed to the air, the uppermost ones lose their metallic appearance, split, and fall to powder. The heaps are then turned, the under part uppermost, so as to expose fresh pyrites to the air. When they are all reduced to powder, which generally requires three years, the liquor, which is formed by the rain-water running from such a large mass, becomes very acid, and has likewise a fhyptic vitriolic taste. It is now conveyed into large cisterns lined with clay, whence it is pumped into a very large flat vessel made of lead. This vessel, which contains about 15 or 20 tons of liquor, is supported by cast-iron plates about an inch thick, between which and the lead a bed of clay is interposed. The whole rests upon narrow arches of brick, under which the fire is placed. Along with the liquor, about half a ton or more of old iron is put into the evaporating vessel. The liquor, which is very far from being saturated with acid, acts upon the iron, and, by repeated filling up as it evaporates, dissolves the whole quantity. By the time this quantity is dissolved, a pellicle is formed on the surface. The fire is then put out; and as such a prodigious quantity of liquor does not admit of filtration, it is left to settle for a whole day, and then is let off by a cock placed a little above the bottom of the evaporating vessel, so as to allow the impurities to remain behind. It is conveyed by wooden spouts to a large leaden cistern, five or six feet deep, sunk in the ground, and which is capable of containing the whole quantity of liquor. Here the copperas crystallizes on the sides, and on sticks put into the liquor. The crystallization usually takes up three weeks. The liquor is then pumped back into the evaporating vessel; more iron, and freth liquor from the pyrites, are added; and a new solution takes place.

Copperas is used, in dyeing, for procuring a black colour; and is an ingredient in making common ink. It is also used in medicine as a corroboration, under the name of salt of vitriol; but before it is used with this intention, it is redissolved in water, and crystallized with the addition of a little pure oil of vitriol. Whether it is at all mended by this suppos'd purification, either in appearance or quality, is very doubtful.

This process furnishes us with the vitriolic acid, which could not be applied to any useful purpose; afterwards with an imperfect neutral salt, called green vitriol, which is applicable to several purposes where the pure acid itself could not be used; but still the acid by itself is not to be had without a very troublesome operation.

Though this acid adheres very strongly to iron, it is capable of being expelled from it by fire; yet not of vitriolic acid without a very violent and long-continued one. If acid from copperas we attempt to distil green vitriol in a retort, it swells and boils in such a manner by the great quantity of water contained in its crystals, that the retort will almost certainly crack; and though it should not, the salt would be changed into an hard stony mass, which the fire could never sufficiently penetrate so as to extricate the acid. It must therefore be calcined previous to the distillation. This is best done in flat iron-pan's, set over a moderate fire. The salt undergoes the water
Vitriolic acid and its combinations.

**Practice.**

Vitriolic acid, (See Fusion) after which it becomes opaque and white. By a continuance of the fire, it becomes brown, yellow, and at last red. For the purposes of distillation, it may be taken out as soon as it has recovered its solidity.

The dry vitriol, being now reduced to powder, is to be put into an earthen retort, or rather long neck (a kind of retort where the neck lies laterally, that the vapours may have little way to ascend), which it may nearly fill. This retort must be placed in a furnace capable of giving a very strong heat, such as the melting furnace we have already described. A large receiver is to be fitted on; and a small fire made in the furnace to heat the vessels gradually. White fumes will soon come over into the receiver, which will make the upper part warm. The fire is to be kept at an equal degree of strength, till the fumes begin to disappear, and the receiver grows cool. It then is to be increased by degrees; and the acid will become gradually more and more difficult to be raised, till at last it requires an extreme red, or even white, heat. When nothing more will come over the fire must be suffered to go out, the receiver be unstoppered, and its contents poured into a bottle fixed with a glass stopper. A sulphurous and suffocating fume will come from the liquor, which must be carefully avoided. In the retort, a fine red powder will remain, which is used in painting, and is called coloet of vitriol. It is useful on account of its durability; and, when mixed with tar, has been employed as a preservative of wood from rotting; but Dr Lewis prefers finely powdered pit-coal. As a preservative for masts of ships, he recommends a mixture of tar and lamp-black; concerning which he relates the following anecdote.

"I have been favoured by a gentleman on board of a vessel in the East-Indies, with an account of a violent thunder-storm, by which the main-mast was greatly damaged, and whose effects on the different parts of the mast were pretty remarkable. All the parts which were greased or covered with turpentine were burnt in pieces; those above, between, and below the greased pieces, as also the yard-arms, the round-top or scaffold, coated with tar and lamp-black, remained unburnt."

Oil of vitriol, when distilled in this manner, is always of a dark colour, and must therefore be rectified by distillation in a glass retort. When the acid has attained a proper degree of strength, the blackness either flies off, or separates and falls to the bottom, and the liquor becomes clear. The distillation is then to be discontinued, and the clear part which is left in the retort is vitriol.

This was the first method by which the vitriolic acid was obtained; and from its being distilled from vitriol has ever since retained the name of oil of vitriol. Green vitriol is the only substance from which it is practicable to draw this acid by distillation; when combined with calcareous earths, or even copper (though to this last it has a weaker attraction than to iron), it refits the fire most obstinately. When distillation from vitriol was practised, large furnaces were erected for that purpose, capable of containing an hundred long necks at once; but as it has been discovered to be more easily procurable from sulphur, this method has been laid aside, and it is now needless to describe these furnaces.

**CHEMISTRY.**

II. To procure the Vitriolic Acid from Sulphur.

This substance contains the vitriolic acid in such plenty, that every pound of sulphur, according to Mr Kirwan's calculation, contains more than one-half of acid in sulphur; which being in a flat perfectly dry, is consequently of a strength far beyond that of the most highly rectified oil of vitriol. Common oil of vitriol requires to be distilled to one-fourth of its quantity before it will coagulate when cold; and even in this state it undoubtedly contains some water. No method, however, has as yet been upon to condense all the fumes of burning sulphur, at least in the large way, nor is any other profitable way of accomplishing quantity produced from it.

Method of obtaining it, though to this last it has a weaker difficulty. When nothing more will come over, the receiver be unluted, and the liquor becomes clear, the distillation will be suffered to go on, the receiver be unluted, and its contents poured into a bottle fixed with a glass stopper. A sulphurous and suffocating fume will come from the liquor, which must be carefully avoided. In the retort, a fine red powder will remain, which is used in painting, and is called coloet of vitriol. It is useful on account of its durability; and, when mixed with tar, has been employed as a preservative of wood from rotting; but Dr Lewis prefers finely powdered pit-coal. As a preservative for masts of ships, he recommends a mixture of tar and lamp-black; concerning which he relates the following anecdote.

"I have been favoured by a gentleman on board of a vessel in the East-Indies, with an account of a violent thunder-storm, by which the main-mast was greatly damaged, and whose effects on the different parts of the mast were pretty remarkable. All the parts which were greased or covered with turpentine were burnt in pieces; those above, between, and below the greased pieces, as also the yard-arms, the round-top or scaffold, coated with tar and lamp-black, remained unburnt."

Oil of vitriol, when distilled in this manner, is always of a dark colour, and must therefore be rectified by distillation in a glass retort. When the acid has attained a proper degree of strength, the blackness either flies off, or separates and falls to the bottom, and the liquor becomes clear. The distillation is then to be discontinued, and the clear part which is left in the retort is vitriol.

This was the first method by which the vitriolic acid was obtained; and from its being distilled from vitriol has ever since retained the name of oil of vitriol. Green vitriol is the only substance from which it is practicable to draw this acid by distillation; when combined with calcareous earths, or even copper (though to this last it has a weaker attraction than to iron), it refists the fire most obstinately. When distillation from vitriol was practised, large furnaces were erected for that purpose, capable of containing an hundred long necks at once; but as it has been discovered to be more easily procurable from sulphur, this method has been laid aside, and it is now needless to describe these furnaces.

**Method of**

This substance contains the vitriolic acid in such

plenty, that every pound of sulphur, according to Mr Kirwan's calculation, contains more than one-half of acid in sulphur; which being in a flat perfectly dry, is consequently of a strength far beyond that of the most highly rectified oil of vitriol. Common oil of vitriol requires to be distilled to one-fourth of its quantity before it will coagulate when cold; and even in this state it undoubtedly contains some water. No method, however, has as yet been upon to condense all the fumes of burning sulphur, at least in the large way, nor is any other profitable way of accomplishing quantity produced from it.

The difficulties here are, that sulphur cannot be burnt but in an open vessel; and the stream of air, which is admitted to make it burn, also carries off the acid which is emitted in the form of fume. To avoid this, a method was contrived of burning sulphur in large glass globes, capable of containing an hog-head or more. The fume of the burning sulphur was then allowed to circulate till it condensed into an acid liquor. A greater difficulty, however, occurs here; for though the sulphur burns very well, its steam will never condense. It has been said, that the condensation is promoted by keeping some warm water continually smoking in the bottom of the globe; and even Dr Lewis has asserted this: but the steam of warm water immediately extinguishes sulphur, as we have often experienced; neither does the fume of burning sulphur seem at all inclined to join with water, even when forced into contact with it. As it arises from the sulphur, it contains a quantity of phlogiston, which in a great measure keeps it from uniting with water; and the deidentarum is not something to make the sulphur burn freely, but to deprive the fumes of the phlogiston they contain, and render them miscible with water. For this purpose nitre has been advantageously used. This conforms a very large quantity of the phlogiston contained in sulphur, and renders the acid easily condensable: but it is plain that few of the fumes, comparatively speaking, are thus deprived of the inflammable principle; for the vessel in which the sulphur and nitre are burnt, remains filled with a volatile and most suffocating fume, which extinguishes flame, and lies in such quantity as to render it highly dangerous to stay near the place. It has been thought that nitre contributes to the burning of the sulphur in clove vessels; but this too is a mistake. More sulphur may be burnt in an oil of vitriol globe without nitre than with it, as we have often experienced; for the acid of the sulphur unites with the alkaline basis of the nitre, and forms wither with an inflammable compound, which soon extinguishes the flame, and even prevents a part of the sulphur from being burnt either at that time or any other.

In the condenstation of the fumes of sulphur by means of nitre, a remarkable experience happens, which naturally leads us to think that the condensation is produced by some struggle between the vitriolic and nitrous oxides.
A very great improvement in the apparatus for its kindling, after which they change their colour to white. How the nitrous acid should exist in the liquid, indeed, does not appear; for this acid is totally destructible by deagglutination with charcoal: but it does not follow, that because the nitrous acid is destroyed when deagglutinated with charcoal, it must likewise be so if deagglutinated with sulphur. Indeed it certainly is not; for the clysis of nitre made with charcoal is very different from that made with charcoal.

The proportions of nitre to the sulphur, used in the large oil of vitriol works, are not known, every thing being kept as secret as possible by the proprietors. Dr Lewis reckons about six pounds of nitre to an hundred weight of sulphur; but from such experiments as we have made, this appears by far inadmissible. An ounce and a half, or two ounces, may be advantageously used to a pound of sulphur. In greater proportions, nitre seems prejudicial.

A very great improvement in the apparatus for making oil of vitriol, lies in the using lead vellums instead of glafs globes. The globes are so apt to be broken by accident, or by the action of the acid upon them, that common prudence would suggest the use of lead to those who intend to prepare any quantity of vitriolic acid, as it is known to have so little affinity with sulphur; indeed it does not appear, that the acid and alkali are not very much diluted, the salt will be precipitated in powder, during the time of saturation.—It is very difficult of fusion, requiring a strong red heat; but, notwithstanding its fixedness in a violent fire, it arises with the steam of boiling water in such a manner as to be almost totally diffipated along with it by strong boiling.—This salt has been used in making glafs; but with little success, as the glafs wherein it is an ingredient always proves very brittle and apt to crack of itself.

If, instead of the vegetable fixed alkali, the vitriolic Glauber's salt is saturated with the fomile one called the salt of falt. Soda, a kind of neutral salt will be produced, having very different properties from the vitriolated tartar. This compound is called Glauber's salt. It dissolves easily in water, fothers into long and beautiful crystals, which contain a large quantity of water, in consequence of which they undergo the aqueous fusion when exposed to heat. They are also more easily fusible than vitriolated tartar.—This kind of salt was formerly much recommended as a purgative, and from its manifold virtues was instilled by its inventor falt mirabile. It is, however, found to possess no virtue different from that of other purgative salts: and its use is, in many places, entirely superseded by a salt prepared from the bitterm, or liquor which remains after the crystallization of sea-fals, which shall be afterwards described.

II. With volatile alkali. Take any quantity of volatile alkali, that prepared with quicklime secret salt ammoniac.

Vitriolic Acid combined,

With Fixed Alkali. Dilute a pound of oil of vitriol with ten times its quantity of water; diluive also two pounds of fixed alkali falt in ten pounds of water, and filter the solution. Drop the alkali into the acid as long as any effervescence arises; managing matters so that the acid may prevail. The liquor will now be a solution of the neutral salt, called vitriolated tartar, which may be procured in a dry form, either by evaporation or crystallization. In case the latter method is made use of, some more alkali must be added vitriolic when it is set to evaporate, for this salt crystallizes best in an alkaline liquor.

Other methods, besides that above described, have been recommended for preparing vitriolated tartar; particularly that of using green vitriol instead of the pure vitriolic acid. In this case the vitriol is decomposed by the fixed alkali: but as the alkali itself dissolves the calx of iron after it is precipitated, it is next to impossible to procure a pure salt by such a process; neither is there occasion to be particular about the preparation of this salt by itself, as the materials for it are left in greater quantity than will ever be demanded, after the distillation of spirit of nitre.

Vitriolated tartar is employed in medicine as a purgative; but is not at all superior to other farts which are more easily prepared in a crystalline form. Its very difficultly fusible in water, from which proceeds the difficulty of crystallizing it: for if the acid and alkali are not very much diluted, the salt will be precipitated in powder, during the time of saturation.—It is very difficult of fusion, requiring a strong red heat; but, notwithstanding its fixedness in a violent fire, it arises with the steam of boiling water in such a manner as to be almost totally diffipated along with it by strong boiling.—This salt has been used in making glafs; but with little success, as the glafs wherein it is an ingredient always proves very brittle and apt to crack of itself.
Practice.

Vitriolic acid and its combinations.

Vegetate, or arise in emolences upon the fishes of the glass. It easily melts in the fire; penetrates the common crucibles; and if diluted in glads vessels, which requires a very considerable heat, it always becomes acid, however exactly the saturation was performed.

This salt has been dignified with the names of Glau-ber's salt, sal ammoniaci, or philosophical salt, from the high opinion with which some chemists have entertained of its activity upon metals: but from Mr Potter's experiments, it appears, that its effects have been greatly exaggerated. It dissolves or corrodes in some degree all those metals which oil of vitriol dissolves, but has no effect upon those on which that acid does not act by itself.

Gold is not touched in the least, either by the salt in fusion, or by a solution of it: the salt added to a solution of gold in aqua-regia occasions no precipitation or change of colour. On melting the salts with inflammable matters, it forms a sulphurous compound, which dissolves gold in fusion, in the same manner as compositions of sulphur and fixed alkaline salt. Melted with silver, it corrodes it into a white clay, which partially dissolves in water: it likewise precipitates silver from its solution in aquafortis. It acts more powerfully on copper; elevates a part of the metal in sublimation, so as to acquire a bluish colour on the surface; and renders the greatest part of the residue soluble in water. This solution appears colourless, so that it could not be supposed to hold any copper; but readily discovers that it abounds with that metal, by the blue colour it acquires on an addition of volatilised alkali, and the green calx which fixed alkalies precipitate. In evaporation it becomes green without addition. Iron is corroded by this salt in fusion, and dissolved by boiling in a solution of it. Zinc dissolves more freely and more plentifully. Lead unites with it, but does not become soluble in water. Tin is corroded, and a part of the calx is soluble in boiling water. Of regulus of antimony also a small portion is made soluble. Alkalies precipitate from the solution a bluish powder. Calcined bismuth-ore treated with its equal weight of the salt, partly dissolved in water into a pale red liquor, which became green from heat, in the same manner as tinctures made from that ore by aqua-regia. The undiluted part yielded still, with frit, a blue glas. On treating manganese in the same manner, aluminous crystals were obtained: the undiluted part of the manganese gave still a violet colour to glads.

III. With Calciferous Earth. This combination may be made by saturating diluted oil of vitriol with chalk in fine powder. The mixture ought to be made in a glas; the chalk must be mixed with a pretty large quantity of water, and the acid dropped into it. The glas must be well shaken after every addition, and the mixture ought rather to be over saturated with acid; because the superfluous quantity may afterwards be washed off: the solution, as it is called, or gypsum, having very little solubility in water.

This combination of vitriolic acid with chalk or calciferous earth, is found naturally in such plenty, that it is seldom or never made, unless for experiment's sake, or by accident. Mr Potter indeed says, that he found some slight differences between the natural and artificial gypsum, but that the former had all the essential properties of the latter.

The natural gypsums are found in hard, semitransparent masses, commonly called alabaster, or piolifer of Paris. (See Alabaster, Gypsum, and Plaster.) By exposure to a moderate heat, they become opaque, and very friable. If they are now reduced to fine powder, and mixed with water, they may be cast into moulds of any shape: they very soon harden without shrinking; and are the materials whereof the common white images are made. This property belongs likewise to the artificial gypsum, if moderately calcined.

Mr Beaumé has observed, that gypsum may be dissolved in some measure by acids; but is afterwards separable by crystallization in the same state in which it was before solution, without retaining any part of the acids. This compound, if long exposed to a pretty strong heat, loses great part of its acid, and is converted into quicklime. In glas vessels it gives over no acid with the most violent fire. It may be fused by suddenly applying a very intense heat. With clay it soon melts, as we have observed when speaking of the materials for making crucibles. A like fusion takes place when pure calciferous earth is mixed with clay; but gypsum bubbles and swells much more in fusion with clay than with calciferous earth.

From natural gypsum we see that vitriolated tartar may be made, in a manner similar to its preparation from green vitriol. If fixed alkaline salt is boiled with any quantity of gypsum, the earth of the latter will be precipitated, and the acid united with the alkali. If a mild volatile alkali is poured on gypsum contained in a glas, and the mixture frequently shaken, the gypsum will in like manner be decomposed, and a philosophical salt ammoniaci will be formed. With the caustic volatile alkali, or that made with quicklime, no decomposition ensues.

IV. With Argillaceous Earth. The produce of Alum of this combination is the astringent salt called alm, which was much used in dyeing and other arts. It has a different name from the Latin word alumen called from our semiaque. The Greeks; though by those words the ancients expressed a flataeish substance containing very little alum, and that entirely enveloped in a vitriolic matter. The alum used at present was first discovered in the oriental parts of the world; though we know not when, or on what occasion. One of the most ancient alum-works of which we have any account was the name of that of Rococco, now Edessa, a city of Syria: and from rock alum this city was derived the appellation of Rock-alum; an expression soleilte understood by the generality, that it has been supposed to signify rock-alum. From this, and some works in the neighbourhood of Constaninopole, as well as at Phocaea Nova, now Foyra Nova, near Smyrna, the Italians were supplied till the middle of the 15th century, when they began to set up works of a similar kind in their own country. The first Italian alum-works was established about 1459 by Bartholomew Perrix, or Permiss, a Genoese merchant, who had discovered the proper matter, or ore of alum, in the island of Iclia. Soon after the same material was discovered at Tolfa by John de Castri, who had visited the alum manufactories at Constaninopole.
The component principles of this fault were long unknown; but at last Meffrs. Boulauce and Geoffroy discovered, that it consisted of argillaceous earth superabundantly vitriolic acid. This is confirmed by the experiments of other chemists. It is found to reden the tin dioxide and paper of vitriolic acid; and on taking away the superabundant acid, it leaves its solubility and all the other properties of alum. Mr Morveau, indeed, will not admit of a superabundance of acid in alum, which he thinks would necessarily be separated by edulcoration and crystallization; and he is of opinion with Mr Kirwan, that the turning vegetable juices red is not any unequivocal sign of the presence of an acid. In the present cafe, however, we certainly know that there is a superabundance of acid, and that a certain portion of the vitriolic acid adheres to the clay less tenaciously than the remainder. If we put a piece of it into a solution of alum, it will attract this portion of acid; and the vitriolated clay when deprived of the superfluosity, will fall down to the bottom in an infusible powder.

Alum in its ordinary state contains a considerable quantity of water, and crystallizes by proper management into ochrecoloured and perfectly transparent and colourless crystals. When exposed to a moderate fire, it melts, bubbles, and swells up; being gradually changed into a light, spongy, white mass, called burnt alum. This, with the addition of some vitriolic acid, may be crystallized as before. The principles it contains, therefore, are water, vitriolic acid, and argilla­ceous earth. The proportions may be ascertained in the following manner. 1. The water and superfluos vitriolic acid may be distilled by evaporation, or rather distillation; and the loss of weight sustained by the salt, as well as the quantity of liquid which comes over into the receiver, shows the quantity of aqueous phlegm and uninfusurate acid. 2. By combining this with as much caustic fixed alkali as is sufficient to saturate the acid which comes over, we know its proportion to the water; and by redistilling this new compound, we have the water by itself. 3. The earth may be obtained by precipitation with an alkali in its caustic state, either fixed or volatile: but this part of the process is attended with considerable difficulty; for the alkalies first absorb the superfluos acid, after which the earth combined to saturation with the acid falls to the bottom, and the digestion with the alkaline must be continued for a very considerable time before the acid is totally separated. By analysing alum in this manner, Mr Bergman determined the principles of alum to be 38 parts of vitriolic acid, 18 of clay, and Vitriolic acid and 44 of water, to 100 of the crystallized salt.

It has been a question among chemists, whether the earth of alum is to be considered as a pure clay or not. The fault was extracted from common clay by Meffrs. Hellot and Geoffroy. The experiment was repeated Propos with success by Mr Pott; but he seemed to consider it rather as the production of a new substance during the operation, than a combination of any principle already existing with the vitriolic acid. Margrauf, however, man­ from some very accurate experiments, demonstrated, that all kinds of clay consist of two principles mecha­ nically mixed: one of which constantly is the pure earth of alum. This opinion is expounded by Bergman; who concludes, that since an equal quantity of it may or not, be extracted from clay by all the acids, it can only be mixed with these clays; for if it was generated by Compounds during the operation, it must be procured in parts different quantities, if not of different qualities also, ac­ cording to the difference of the solvents made use of. Notwithstanding this, the matter seems to be rendered somewhat obscure by an experiment of Dr Lewis. Powdered tobacco-pipe clay (says he) being boiled in Lewis’s a considerable quantity of oil of vitriol, and the boiling experiment continued to dryness, the matter when cold discovers very little tafe, or only a slight acidulous one. Ex­ posing to the air for a few days, the greatest part of clay under which it was changed into laugnious effu­ rences tainting exactly like alum. The remainder, treated with fresh change in oil of vitriol, in the same manner exhibits the same being accompanied phenomena till nearly the whole of the clay is converted into an astringent salt.” Hence he concludes, that the clay is in some degree changed before the alumi­ nous salt is produced. Without this supposition, in­ deed, it is difficult to see why the salt should not be produced immediately by the combination of the two principles. An hundred parts of crystallized alum requires, according to Mr Bergman, in a mean heat of alum in 1412 parts of distilled water, but in a boiling heat warm and in cold water.

The ores from which alum is prepared for sale, according to Mr Bergman, are of two kinds: one containing the account of alum already formed, the other its principles united by the swedische roasting method of finding the ingredients and their proportions.

Difficultly in obtaining the pure earth of alum.
by lixiviating this schist before calcination, thought Mr Bergman thinks nothing more is necessary for the production of the salt but the presence of a pyrites. This, he tells us, is generally dispersed through the masses in form of very minute particles, though it sometimes appears in small nuclei. The goodness of the ore, therefore, depends on the proper proportion of the pyrites to the clay, and its equal distribution through the whole. The most dense and ponderous is most esteemed, while that which contains so much pyrites as to be visible is rejected as having too much iron. The ore which produces less than four pounds of alum from 100 of the ore does not pay the expense of manufacturing in Sweden. Sometimes this kind of ore produces salts without the application of fire; but this must be attributed to a kind of spontaneous calcination.

That species of ore which contains the principles already united into alum, according to Mr Bergman, is to be met with only in volcanic countries; and of this kind are the principal Italian ores of alum, particularly that employed at Tolfa near Cencelles, for boiling the Roman alum. Mr Monnet, however, is of opinion, that even this ore does not contain alum perfectly formed, but a combination of nearly equal parts of clay and sulphur, which by exposure to air during calcination, is converted into alum. He found a little earthy material also contained in it, to which he ascribes the reddish colour of that alum. The alumino ore at Solfatara in Italy consists of old lava whitened by the phlogocitic vitriolic acid. The clay thus becomes a component part of the alumina salt, and the masses effloresce in the same manner, and for the same reason, as the mass left after boiling tobacco-clay in all of vitriol mentioned by Dr Lewis. Mr Bergman, who examined this ore, found that 100 pounds of it contained eight of pure alum, besides four of pure clay; and that the remainder was sialicious. This proportion, however, must be very variable, according to the quantity of rain which falls upon the ore.

A variety of aluminous ores are to be met with in different parts of the world. In Hailia and Bohemia, this salt is obtained from wood impregnated with bitumen. At Hellingsborg in Scania, a turf is found consisting of the roots of vegetables mixed with nuts, straw, and leaves, often covered with a thin pyrites crust, while the remaining part was alum. Even the lightest, vitriolic pyrites is generally mixed with an argillaceous matter, which may be separated by menstruation. In some places, phylite, vitriol, and alum are extracted from the same material. The sulphur riffs by distillation; the residuum is exposed to the air till it effloresces, after which a green vitriol is obtained by lixiviation, and alum from the same liquor, after no more vitriol will crystallize. The alum flat, from which the salt is made near York in England, contains a considerable quantity of sulphur; and therefore produces alum on the principles already mentioned.

Mr. Bergman has given various particular directions for the preparation of this salt, from its ores, and minutely describes the several operations which they must undergo. These are.

1. **Roasting**. This is absolutely necessary in order to destroy the pyrites; for on this the formation of the alum entirely depends; as the sulphur of the pyrites will not part with its phlogiston without a burning heat in the open air. By long exposure to the air, indeed, the same effect will follow; but unless the ore be of a particular kind, and loose in texture, so that the air can freely pervade it, the process we speak of cannot take place. The hard ores, therefore, cannot be treated in this manner; and the earthy ores are not only unfit for spontaneous calcination, but for roasting also, as they will not allow the air to pervade them and extinguish the fire. Such as are capable of spontaneous calcination, should be supplied with some quantity of water, and laid on a hard clay bottom, as directed for making green vitriol. The roasting is performed in Sweden in the following manner. Small pieces of the ore are strewn upon a layer of burning ficks to the thickness of half a foot. When the ficks are consumed, these are covered, nearly to the same thickness, with pieces burned before and four times lixiviated: Thus the ficks are alternately laid of such thickness, and at such intervals of time, that the fire may continue, and the whole mass grows hot and smoky, but not break out into flame. The upper ficks, however, may sometimes be increased to a double thickness on account of the long continuance of the fire. When eight ficks are laid, another row is placed contiguous to the former; when this is finished, a third; and so on until the heap be of a proper size, which rarely requires more than three rows. When the ore is once roasted, it still contains so much phlogiston that water acts but little upon it; but after the operation is two or three times repeated, the ore yields its principles more freely: the roasting may even be repeated to advantage till the whole be reduced to powder. The bottom keeps up the fire; for which reason alternate layers of the crude ore are used; and in rainy weather these layers of unburnt ore should be thicker. An heap, 20 feet broad at the base, two feet at the top, and consisting of 26 rows, is finished in three weeks, but requires two or three months to be well burned, and three weeks to cool. The greater pyrites nuclei explode like bombs. In this process the sulphur of the pyrites is slowly consumed, and the phlogocitic acid penetrating the mass, is fixed; after which the remaining phlogiston is gradually dissipated. The chief art consists in moderating the heat in such a manner as to avoid with safety the two extremes; for too small a heat would not be capable of forming the mass, while a heat too strong would destroy it by melting the ore. The scoria is insoluble in water, and therefore thrown away as useless. They are produced by violent winds, or by a strong heat too much closed up; for it is necessary to make holes in the red ficks, that the fire may reach the back stratum which is to be laid on. Another method of burning was invented by the celebrated Rinman, and is practiced at a place called Garphytan in Sweden. There the ore itself is set on fire; and after burning is boiled, and yields alum in the same manner as the former. The heaps are formed in the following manner: First the schist, burning from the furnace, is laid to the depth of four feet; if the fire be then wood is added; after that a thin stratum of elixiated schist; the third stratum of schist not burned; and the fourth of elixiated schist a foot and a half thick, after that the burning schist, and so on. This method, however, is attended with some inconveniences. The vitriolic acid is partly dissipated by the fire, and thus
CHEMISTRY.

Vitriolic acid and its combinations.

671 Method of burning the hard ores at Tofla in Italy.

672 Singular circumstance by which the alum may be destroyed.

673 Of the proper strength of the lixivium before boiling.

674 Contraction of the evaporating vessecl.

675 Of the first evaporation, where it is allowed to rest for about an hour to free it from the greater sediment; after which it is put into wooden or stone receptacles to crystallize. In eight or ten days the remaining liquor, commonly called mother ley, or magindar water, is let off into another vessecl. A great number of crystals, generally small and impure, adhere to the bottom and sides of the vessel, which are afterwards collected and washed in cold water.

676 Depuration of the crystals.

677 Vitrile acid and its combinations.

678 Bergman's remarks on the proper form of the coolers.

The quantity of alum is diminished: so much schift also is requisite in this method that it cannot all be elixated; and thus the heat must be perpetually increasing. The hard ores containing bitumen, such as those of Tofla, are burned upon wood for some hours like lime-furnes, until they become pervious to water, and effulce. The fire is extinguished as soon as the flame becomes white, and the smol of sulphurous acid begins to be perceived. When the ore cools, those particles which were nearest to the fire are placed outermost, and those which had been outermost within, the fire being again lighted. The ore is sufficiently burned when it can be broken with the hands. It is then heaped up near certain trenches, and watered five times a-day, particularly when the sun shines clear; the operation being destroyed by a continued rain and cloudy sky. In some places the ore is first burned and afterwards elixated; neither is there any way of knowing the proper methods of managing it but by experiment.

Elixation. This is performed in some places with hot, and at others with cold, water. At Garphytan in Sweden, where the latter method is choosen, the receptacles, in the year 1772, were of iron stone, having their joints united by some cement capable of resisting the liquors. Every fet consisted of four square receptacles dippofed round a fifth, which was deeper than the rest. The first receptacle is filled with roasted schift, and the ore lies in water for 24 hours; the water is then drawn off by a pipe into the fifth; from thence into the second, containing schift not yet washed; from that in like manner, after 24 hours, through the fifth into the third, and so into the fourth. The lixivium is then conveyed to the fifth, and allowed to stand in it; and lastly is drawn off into a vessel appropriated for its reception. In other places the water passes over the schift that has been washed three times for six hours, then that which has been twice washed, next what has been once washed, and lastly, the ore which has been newly roasted. Those who superintend the alum manufactories are of opinion that the alum is destroyed by passing the water first over the newly burnt ore, and then over that which has been previously elixated.

The lixivium, before boiling, ought to be as richly impregnated with alum as possible, in order to fave fuel, though this is frequently neglected. In some places the tafte is used as the only criterion; but in others the weight of water which fills a small glass bottle is divided into 64 equal parts, each of which is called in Sweden a pannings; and the quantity by which the same bottle, full of lixivium, exceeds it when filled with water, is supposed to indicate the quantity of salt dissolved. This method may undoubtedly be reckoned sufficiently accurate for work conducted on a large scale: and though Mr Bergman gives formulae by which the matter may be determined to a frupus exactness, it does not appear that such accuracy is either necessary or indeed practicable in works conducted in a great way.

Those who manage the alum manufactories assert, that the cold lixivium ought to be made no richer than when the weight of the bottle filled with lixivium exceeds it when filled with water by 41 pannings, which shows the water to be loaded with one half of its weight of alum. If the overplus amounts to two pannings, which indicates its containing 4½ of salt, crystals are then deposited. Congelation is of no use to concentrate the aluminous lixivium; for water saturated with alum freezes almost as readily as pure water.

2. Boiling the ley for crystallization.

The ley being now brought from the pits through channels made for the purpose, is put into a leaden boiler, at the back of which is a retort, out of which the felsuftrated by evaporation is constantly supplied, so that the surface of that in the boiler continues always nearly at the same height. Variousings are used by different manufacturers to know when the ley is properly evaporated: some determining the matter by the floating of a new laid egg; others by dropping a small quantity on a plate, and observing whether it crystallizes on cooling; and lastly, others weigh the lixivium in the bottle abovementioned. The boiling is supposed to be finished when the increase of weight is equal to 10 pannings; that is, if the water be loaded with half of its own weight. It might, however, take up above one half of its weight, or nearly 27 pannings; but as it has to be depurated by standing quiet before the crystals are formed, the liquor must not be fully saturated with salt.

The lixivium, when sufficiently concentrated by the first evaporation, flows through proper channels into coolers, where it is allowed to rest for about an hour to free it from the greater sediment; after which it is put into wooden or stone receptacles to crystallize. In eight or ten days the remaining liquor, commonly called mother ley, or magindar water, is let off into another vessel. A great number of crystals, generally small and impure, adhere to the bottom and sides of the vessel, which are afterwards collected and washed in cold water.

When a sufficient quantity of the small crystals are collected, thy must then be put into the boiler for depuration. They are now dissolved in as small a quantity of water as possible; after which the lixivium is poured into a great tub containing as much as the boiler itself. In 61 or 8t days the hoops of the tub are holed, and the aluminous mass bound with an iron ring; and in 28 days more the residuum of the solution is let out through a hole, and collected in a trench; after which the saline mafs, which at Garphytan in Sweden amounts to 26 tons, is dried and fold as depurated alum. The boiler emptied for the first crystallization is next filled two-thirds full with the magindar lixivium; and as soon as the liquor arrives at the boiling point, the other third is filled with crude lixivium, with which the evaporation is also constantly supplied. A certain quantity of the aluminous impurities left by washing the fels of the first crystallization in water is then added, and the above described processes repeated. Only the first boiling in the spring is performed with the crude lixivium alone, the rest are all done as juft now related. Mr Bergman remarks, that the time required for crystallization may undoubtedly be shortened. The retrovers used in Sweden for this purpose (he says), are deep and narrow at the top; on which account they are not only long
long in cooling, but the evaporation, which is absolutely necessary for the crystallization, goes on very slowly, especially in extremely warm weather, at the same time that the doors and windows are disposed in such a manner as to direct a current of air along the surface. In Italy he tells us that conical reveriers are used with the wide part uppermost.

It is remarkable, that pure alum cannot be obtained in very considerable quantity by merely evaporating and cooling the ley. The reason of this is, that the lixivium sometimes acquires such a confluence, that it both crystallizes with difficulty, and produces impure crystall. The cause was unknown till the time of Mr Bergman, who has shown that it proceeds from an excess of vitriolic acid. Hence also we may see the reason why alkaline farts, volatile alkali in its pure state, or even purerized urine, when added to this thick solution, produce good crystals of alum when they cannot be obtained otherwise... It is remarkable that this impediment to crystallization is not removed by mineral alkali, though it may be vegetable and volatile alkalis, which is a phenomenon hitherto unexplained. According to our author, however, an addition of pure clay, to absorb the superabundant acid, is preferable to any other; and indeed it is reasonable to think so, as the union of vitriolic acid and pure clay forms the salt desired, which is not the case with any of the alkalis. To ascertain this, he made the following experiments.

1. He dissolved 215 grains of pure alum in distilled water, in a small cucurbit, and evaporated it over the fire till the surface of the liquor floor at two marks, which indicated, in a former evaporation, that it was fit for crystallization. 2. Having poured out this into a proper glass vessel, he dissolved other 215 grains, and added to the solution 241 grains of concentrated vitriolic acid. 3. This solution being likewise poured out, the experiment was repeated a third time, with the addition of 53 grains of vitriolic acid, and the glases being at last let in a proper place for crystallization, the first yielded 1551, the second 1709, and the third 1200 grains of alum.

This shows that an excess of vitriolic acid impedes the crystallization of the alum; but to determine how far this could be remedied by the addition of clay, farther experiments were necessary. Having therefore employed a magistral residuum, in which the excess of acid was nearly in the proportion already related, he added two drachmas of clay in fine powder to a kanne, or Swedish canthus, of the liquor; he boiled the mixture for ten minutes; and on separating the clay that remained, he found that 25 grains were dissolved, which indicates an increase of 141 grains of alum. On gently boiling the liquor for half an hour, 75 grains of the clay were dissolved, which indicated an increase of 416 grains of alum.

The addition of clay must therefore be much preferable to that of alkaline farts, but also as there is no danger of adding too much; for we have already shown, that when the liquor is entirely deprived of its superabundant acid, the neutralized clay is insoluble in water.

The earth itself, however, dissolves so slowly, that there is not the least danger of the acid being oversaturated by simply boiling them together.

Alum, as commonly made, though depurated by a second crystallization, yet is almost always found contaminated by dephlogisticated vitriol; whence it grows yellow, and deposits an ochre in solution when old. This is equally useful in some arts with the purest kind, and is even so in dyeing where dark colours are required; but where the more lively colours are wanted, every vitriol must be avoided. This is done by the addition of pure clay, which precipitates the ole.

This defect to the laws of chemical attraction; for though iron is remedied dissolved by a solution of alum, and the earthy base of the clay precipitated, and though in a solution of vitriol and alum the white earth falls first on an addition of alkali, and then the ochre; this happens only in consequence of employing phlogisticated metallic iron, or such as is but very little dephlogisticated; for the inflammable principle be any further diminished, the attraction is thereby so much weakened, that the clay has a greater attraction for the vitriolic acid than the iron. The truth of this may be proved in many different ways. Thus, let a portion of alum be dissolved in a solution of highly dephlogisticated vitriol, and an alkali then added, the ochre of the vitriol will be first deposited and then the clay; and provided there be a sufficient quantity of the latter, the iron will all be precipitated; and hence we see that an aluminous solution mixed only with one of dephlogisticated vitriol may readily be freed from it.

But a solution of alum containing perfect vitriol cannot be freed from it effectually either by clay or alkali; for the former effects no decomposition, and the latter, although it can destroy the vitriol, will undoubtedly decompose the alum in the first place. As long, therefore, as the solution is rich in alum, it may be employed in the common manner; but when the vitriolic salt begins to predominate, it must either be crystallized in its proper form, or be destroyed in such a manner as to produce alum, which may be accomplished in the following manner.

Let the lixivium be reduced to a tenacious mass with clay, phlogisticated and formed into cakes, which must be exposed in an hause to the open air. Thus the phlogiston, which is powerfully attracted by the dephlogisticated part of the atmosphere, by degrees separates from the iron, while the clay is taken up by its superior attraction for the acid. The calcination is accelerated by fire; but it must be cautiously employed, lest the acid should be expelled.

In the alum manufactories in Sweden, a considerable quantity of vitriolated magnesia, or Ephom salt, may be mixed with the alum. Mr Bergman directs this to be separated by means of an uncalked calcareous earth, which entirely destroys both the alum and vitriol; falling down to the bottom with the acid in form of a felsenitic matter. This must be added to the boiling liquor gradually, left the effervescence should cause the mass to swell and run over the top of the vessel. A just proportion destroys both the alumino and vitriolic salt, on being properly agitated and heated; neither is there any danger of the Ephom salt.
CHEMISTRY.

Vitriolic acid and its combination.

689 Superfluous acid might be advantageously distilled.

falt being decomposed in this process, the uncalcined earth being unable to separate the magnesia from the acid. Were this method followed in the Swedish manufactories, he is of opinion, that as much Epom falt might be produced from them as would supply the confumpt of that kingdom.

With regard to the quantity of superfluous acid found in the magisterial lixivium, Mr Bergman informs us, that it amounted to five ounces in onenullable; so that in a single boiler there is nearly 250 lb. But vitriol, when well dephlogisticated, retains its acid do loosely that it may easily be separated by fire. He has no doubt, therefore, that if the surface of such a lixivium were first increased in order to let the phlogiston evaporate, the liquor might afterwards be advantageously committed to distillation for the sake of its acid.

From what has been above delivered the necessity will be sufficiently apparent of not continuing the coction even with pure clay to perfect saturation of the liquor; and this is further confirmed by M. Beernaé, who relates, that having boiled four ounces of earth of alum with two ounces of the falt, in a sufficient quantity of water, the acid became saturated to such a degree with earth, that the liquor loft its aluminous taff entirely, and assumed that of hard spring water. After filtration and evaporation, only a few micaceous crysals, very difficult of solution, were formed by letting the liquor stand for some months.—Dr Sieffert informs us, that by boiling half an ounce of alum with half a drachm of flaked lime, cubical crysals of alum may be obtained.

V. With Magnesia. The earthy substance called magnesia alba is never found by itself, and consequently this combination cannot originally take place by art. The vitriolic acid, however, is found combined with magnesia in great plenty in the bitter liquor which remains after the crystallization of common falt; from whence the magnesia is procured by precipitating with a fixed alkali. If this liquor, which, when the common falt is extracted, appears like clean oil of vitriol, is set by for some time in a leaden vessel, a large quantity of falt shoots, very much resembling Glauher’s falt mirabile. This falt is in many places sold instead of the true Glauher’s falt; and is preferred to it, because the true sal mirabile calcines in dry air, which the spurious kind does not. If after the first crystallization of the bittren, the remainder is gently evaporated further, a fresh quantity of Glauher’s falt will shoot; and if the liquor is then hastily evaporated, a falt will still be crystallized; but instead of large regular crysals, it will concrete into very small ones, having something of the appearance of snow when taken out of the liquid. These fals are essentially the fame, and are all used in medicine as purgatives. The falt shot into small crysals is termed Epom falt, from its being first produced from the purging waters at Epom in England. The bittren affording this kind of falt in such great plenty, these waters were soon neglected, as they yielded it but very sparingly, and the quantity prepared from them was insufficient for the demand. Neumann says, that having infilpated two quarts of Epom water, he scarce obtained half an ounce of fa-

Practice.

Vitriolic acid and its Combination.

692 Epom falt.

VI. With Silver. Oil of vitriol boiled on half its weight of silver-filings, corrodes th'm into a salina mafs. ver. This substance is not used in medicine nor in the arts. The only remarkable property of it is, that it has a very strong attraction for mercury; coagulating and hardening as much quicker as the acid weighed at first. If the hard concrete be diluted with fresh acid, it melts easily in the fire, and does not part with the mercury in the greatest heat that glass vessels can endure. The vitriolic acid, by itself, strongly retains mercury, but not near so much as when combined with silver.

Silver thus corroded by the vitriolic acid, or precipitated by it from the nitrous, may in great part be dissolved, by cautiously applying a very little water at a time; and more effectually by boiling in fresh oil of vitriol.

VII. With Copper. With this metal the vitriolic acid of copper cannot be combined, unless in its concentrated state, and strongly heated. If pure oil of vitriol is boiled on copper filings, or small pieces of the metal, it dissolves it into a liquor of a deep blue colour, which easily crystallizes. The crysals are of a beautiful blue colour, and are sold under the name of blue vitriol, or Roman vitriol.

Where sulphur is found in great plenty, however, blue vitriol Roman vitriol is made by straining thin plates of copper, how with sulphur; and upon slowly burning the sulphur, made its acid corrodes the copper. The metal is then to be boiled in water, that the salina part may be dissolved. The operation is to be repeated till all the copper is consumed; and all the salina liquors are to be evaporated together to the crystallizing point. By this method, however, a great part of the acid is lost; and in Britain, where the sulphur must be imported, we should think the pure acid preferable for those who prepare blue vitriol.

This falt, on being exposed to the fire, first turns Phosphene, white, then of a yellowish red colour. On urging it on with a strong fire, the acid finely exalhes, and a dark red calx of copper remains. The whole of the vitriolic acid cannot be expelled from copper by heat: as much of it still remains as to render a part of the metal soluble in water. After this soluble part has been extracted, a little acid is still retained amounting to about 1/3 of the calx.

Vitriol of copper is employed in medicine as a cathartic, in which respect it is very useful; but when used internally, is dangerous, as indeed all the preparations of copper are found to be. It has, nevertheless,
Practice.

VI. With Iron. The vitriolic acid does not act on this metal till considerably diluted. Common oil of vitriol requires to be mixed with ten or twelve times its quantity of water before it will act briskly on the metal. In this state it offervences violently with iron filings, or small bits of the metal, and a great quantity of inflammable vapour is discharged (see Air). The liquor assumes a fine green colour; and by evaporation and flow coolings, very beautiful rhomboidal crystals are formed. These are named salt of steel, and are used in medicine; but for the salt made of the pure acid and iron, the common copperas, made with the impure acid extracted from pyrites, is commonly substituted. This is generally esteemed a venial fraud, and the acid and iron, the common copperas, made with the impure acid extracted from pyrites, is commonly substituted. This is generally esteemed a venial fraud, and the acid of nitre, being left at liberty to act upon the remaining part of the litharge, begins anew to dissolve it with effervescence. When it is again saturated, more oil of vitriol is to be dropped in, and a white precipitate is again thrown down. If any of the litharge is still undissolved, the nitrous acid, being left at liberty a second time, attacks it at first; and by continuing to add oil of vitriol, the whole of the litharge may be converted into a most beautiful and durable white. Unfortunately this colour cannot be used in oil, though in water it seems superior to any. If the process is well managed, an ounce of spirit of nitre may be made to convert several pounds of litharge into a white of this kind.

XI. With Quicksilver. The distillation of quicksilver Quicksilver in vitriolic acid cannot be performed but by a concentrated oil and strong boiling heat. The metal is first corroded into a white calx, which may afterwards be easily dissolved by an addition of fresh acid. Every time it is dissolved, the mercury becomes more and more fixed and more difficult to dry. If the exsiccation and distillation has been repeated several times, the matter becomes as fixed as to be of the greatest degree of red heat. This combination is the basis of a medicine formerly of some repute, under the name of turbit mineral. The procès for making turbit mineral is given by the author of the Chemical Dictionary as follows.

"Some mercury is poured into a glass retort, and turbit mineral, or more, according to the strength of the acid. These matters are to be diffilied together, in the heat of a sand-bath, till nothing remains in the retort but a dry saline mass, which is a combination of the vitriolic acid and mercury. The acid which passes into the receiver is very suffocating and fulphurous; which qualities it receives from the phlogiston of the mercury. The white saline mass which is left at the bottom of the retort is to be put into a large vessel; and upon it are to be poured large quantities of hot water at several different times. The water weakens the acid, and takes it from the mercury; which is then precipitated towards the bottom of the vessel, in form of a very shining yellow powder. The water with which
which it is washed contains the acid that was united with the mercury, and likewise a little mercury rendered soluble by means of the very large quantity of acid.

Most chemists have believed, that a portion of vitriolic acid remains united with the turbith mineral, only too little to render it soluble in water. But Mr Beaumé, having examined this matter, affirms, that turbith mineral contains no acid, when it has been sufficiently washed; and that, by frequently boiling this preparation in a large quantity of distilled water, not a vestige of acid will adhere to it."

Dr Lewis, who is of opinion that the whole of this mercurial calx is soluble in a very large quantity of water, desires the water with which it is washed to be impregnated with some alkaline salt; which makes the yield of turbith greater than when pure water is used. The author of the Chemical Dictionary also observes, that the precipitate remains white till well freed from the acid; and the more perfectly it is washed, the deeper yellow colour it acquires.

The product of this combination is white vitriol, which is used in medicine as an ophthalmic, and in painting for making oil-colours dry quickly: what is used for this purpose, however, is not made in Britain, but comes from Germany. It is made at Gollar by the following process. An ore containing lead and silver, having been previously roasted for the obtaining of sulphur, is lixiviated with water, and afterwards evaporated in leaden boilers, as for the preparation of green vitriol: but the bottom; but, on standing for some days, was taken up, and dissolved in the liquor, nothing being left but a little yellowish dust scarcely worth mentioning. Six parts of oil of vitriol, dissolved with an equal quantity of water, dissolves one part of zinc.

The product of this combination is white vitriol; which is used in medicine as an ophthalmic, and in painting for making oil-colours dry quickly: what is used for this purpose, however, is not made in Britain, but comes from Germany. It is made at Gollar by the following process. An ore containing lead and silver, having been previously roasted for the obtaining of sulphur, is lixiviated with water, and afterwards evaporated in leaden boilers, as for the preparation of green vitriol: but the bottom; but, on standing for some days, was taken up, and dissolved in the liquor, nothing being left but a little yellowish dust scarcely worth mentioning. Six parts of oil of vitriol, dissolved with an equal quantity of water, dissolves one part of zinc.

XII. With Zinc. This femimetal is not acted upon by the vitriolic acid in its concentrated state; but, when diluted, is dissolved by it with effervescence, and with the extraction of an inflammable vapour in the same manner as iron. Neumann observes, that, during the distillation, a grey and blackish fpongy matter fell to the bottom; but, on standing for some days, was taken up, and dissolved in the liquor, nothing being left but a little yellowish dust scarcely worth mentioning. Six parts of oil of vitriol, dissolved with an equal quantity of water, dissolves one part of zinc.

XIII. With Regulus of Antimony. To combine vitriolic acid with regulus of antimony, the same method must be used as before, except that quicksilver, for making turbith mineral, sib. to employ a very concentrated acid, and to distil in close vessels. The same phenomena also occur in this case as in making turbith mineral; a very suffocating sulphureous acid arises; and, as Mr Grégoire observes, a true sulphur sublimes into the neck of the retort; a white, soapy, tumeled mass remains in the vessel; and when the vessels are unluted, a white fume issues, as in the smoking spirit of libavius. See Combinations of marine acid with tin, infra.

XIV. With Regulus of Cobalt. From a combination of Regulus of the vitriolic acid with cobalt, a red salt may be obtained, cobalt.

To procure it, one part of cobalt, reduced to a very fine powder, may be mixed with two or three of concentrated acid, diluting the liquor after it has been digested for 24 hours, and then filtering and evaporating it.

XV. With arsenic. Neumann relates, that powdered white arsenic being distilled in a retort with oil of vitriol, a transparent sublimate like glass arose, which in a few days lost its transparency, and became opaque like the arsenic itself. The arsenic remaining in the retort sustained an open fire without any sensible alteration. The author of the Chemical Dictionary says, that if a concentrated vitriolic acid is distilled from arsenic, the acid which comes over smells exactly like marine acid. When the solution is distilled till no more acid arises, the retort is then almost red-hot, and no arsenic is sublimed; but remains fused at the bottom of the retort; and, when cold, is found to be an heavy, compact mass, brittle and transparent as crystal-glass. This kind of arsienical glass, exposed to the air, soon loses its transparency from the moisture it attracts, which dissolves and partly detepliates it. This deliquium is extremely acid—by digesting one part of arsenic with two of concentrated oil of vitriol, diluting the solution with water, and then filtering and evaporating, we obtain a yellowish salt which shines into pyramidal, transparent, and shining crystals. None of the three last mentioned combinations have been found applicable to any useful purpose.

XVI. With Oil. The product of this combination is a thick black substance, very much resembling balsam of sulphur in colour and consistence; to which it is sometimes sublimated. If this substance is distilled with a gentle heat, great part of the acid becomes volatile, and evaporates in white fumes, having a pungent smell resembling that of burning sulphur. This goes by the name of volatile or sulphureous vitriolic acid; and a salt Volatile was formerly prepared from it by furation with fixed sulphure-alkali, which was thought to poise great virtues. From its invention it was called the sulphureous salt of Stahl. The most singular property of this volatile acid is, that though the vitriolic in its fixed state is capable of expelling any other acid from its basis, the volatile one is expelled by every acid, even that of vinegar. It is very difficult condensible, as we have already taken notice; and, when mixed with water, seems scarcely at all acid, but rather to have a bitternis taste.

Several methods have been proposed for procuring this acid from burning sulphur, which yields it in its greatest degree of volatility, as well as concentration; but the produce is so exceedingly small, that none of them are worth mentioning. Dr Priestley has given some very good directions for obtaining the volatile vitriolic acid in the form of air. His method was, to pour, on
Vitriolic acid and its combinations.

some oil of vitriol contained in a phial, a very small quantity of oil of olive; as much as was sufficient to cover it. He then applied the proper apparatus for the reception of the air in quicksilver (see Air); and, holding a candle to the phial, the volatile vitriolic acid rushed out in great quantity. Had he received this air in water, instead of quicksilver, the confluence would have been, that some part of it, at least, would have been absorbed by the water, and a sulphurous acid liquor produced. This seems indeed almost the only method of procuring the fulphureous vitriolic acid of any aborbed by the water, and a fulphurous acid liquor produced. This seems indeed almost the only method of a liquor, except for experimental purposes. The acid is, that it is remarkably destructive of colours of all kinds; and hence the fumes of sulphur are employed to whiten wool, &c.

Charcoal.

Vitriolic acid and charcoal. If charcoal is mixed with concentrated vitriolic acid, and the mixture distilled, the same kind of acid is at first obtained, which comes over when oil is used; and towards the end, when the matter begins to grow dry, a true sulphur sub- limes. The best way, however, of producing sulphur from the vitriolic acid is by combining it, when in a perfectly dry state, with the phlogiston. By this means sulphur may very readily be made at any time. The procefs is generally directed to be performed in the following manner:

Reduce to fine powder any quantity of vitriolated tartar. Mingle it carefully with a tenth part of its weight of charcoal-dust. Put the whole into a covered crucible set in a melting furnace. Give a heat sufficient to melt the falt; and when thoroughly melted, pour it out on a flat stone. The vitriolated tartar and charcoal will now be converted into a sulphurous maf, similar to a combination of alkaline salts with sulphur. See Alkaline Salts, below.

Sulphur prepared from vitriolated tartar.

Spirit of wine.

XVII. With Phlogiston of charcoal. If charcoal is mixed with concentrated vitriolic acid, and the mixture distilled, the same kind of acid is at first obtained, which comes over when oil is used; and towards the end, when the matter begins to grow dry, a true sulphur sub- limes. The best way, however, of producing sulphur from the vitriolic acid is by combining it, when in a perfectly dry state, with the phlogiston. By this means sulphur may very readily be made at any time. The procefs is generally directed to be performed in the following manner:

Reduce to fine powder any quantity of vitriolated tartar. Mingle it carefully with a tenth part of its weight of charcoal-dust. Put the whole into a covered crucible set in a melting furnace. Give a heat sufficient to melt the falt; and when thoroughly melted, pour it out on a flat stone. The vitriolated tartar and charcoal will now be converted into a sulphurous maf, similar to a combination of alkaline salts with sulphur. See Alkaline Salts, below.

Sulphur prepared from vitriolated tartar.

XVIII. With Spirit of wine. The result of this combination is one of the most extraordinary phenomena in chemistry; being that fluid, which, for its extreme degree of volatility, was first distinguished by the name of ether; and now, since a liquor of the like kind is discoverèd to be preparable from spirit of wine by means of other acids, this species is distinguished by the name of vitriolic ether. The method of preparing this subtile liquor recommended by M. Beaumé, seems to be the best of any hitherto discovered.

Ether.

Mix together equal parts by weight, of highly rectified spirit of wine and concentrated oil of vitriol, or somewhat more than two measures of spirit of wine with one of the acid. The mixture is to be made in a flint glafs retort, the bottom and sides of which are very thin, so that the spirit may be directed against the side of the glafs; in which case it will not exert much of its force on the spirit, but will lie quietly below at the bottom. The retort is now to be very gently shaken, that the acid may mingle with it by little and little. When the mixture is completed, very little more heat will be necessary to make the liquor boil.

This mixture is to be distilled with as brisk and quick a heat as possible; for which reason, immediately after the acid and spirit are mixed, the retort should be put into a sand furnace heated as much as the mixture is. The distillation should be continued only till about one-third of the liquor is come over; if it is continued farther, part of the vitriolic acid rises in a sulphurous flate. In the retort a thick, black, acid matter remains, which is similar to a combination of oil of vitriol with any inflammable matter, and from which a little sulphur may be obtained. Along with the sulphurous acid, a greemish oil, called oleum vitri- oli dulcis, arises, which has a smell compounded of that of the ether and sulphurous acid; and Mr Beaumé has shown that it is compounded of these two; for if after being recomposed with an alkali, to attract the acid, it is changed into ether. If, after the distillation of the ether, some water be poured into the retort, the liquor by distillation may be brought back to the state of a pure vitriolic acid.

As the fumes of the ethereal liquor are exceedingly volatile, and at the same time a quick fire is necessary to the success of the operation, the receiver must be carefully kept cool with very cold water or with snow. Care must also be taken to prevent any of the sulphurous acid fumes from coming over; but as it is impossible to prevent this totally, the liquor requires rectification. This is the more necessary, as a part of the spirit of wine always rises unchanged. From this acid the liquor is easily set free, by adding a small quantity of alkaline salt, and redistilling with a very gentle heat; but as spirit of wine is likewise very volatile, the distillation must be performed in a very tall glafs. Dr Black recommends a matras, or bolt-head, with a tin-pipe adapted to the head, so as to convey the fumes at a right angle, to be condensed in the receiver. When this fluid is to be prepared in great quantities, the ether, by proper management, may be made to equal half the weight of the spirit of wine employed. Mr Dollfus has made many important experiments on this subject; of which the following is an abstract: 1. Two pounds of vitriolic acid were mixed with one of spirit of wine, and the mixture distilled with a very gentle fire. The first ten ounces that came over consisted of a liquor strongly impregnated with ether, and of an agreeable odour. This was put in itself and marked A. It was followed by a stronger ethereal liquor, of which a small quantity only would mix with water. Of this there were 12 ounces, which were also put by themselves, and marked B. By continuing the proccs two ounces more were obtained, which smelled of sulphur, and were marked C. The distillation was now continued with a view to concentrate the vitriolic acid, when three drachms of a thicker kind of ether were found swimming on a weak sulphurous acid. This thick liquid was not in the least volatile, and in confidence resembled an expressed oil. 2. Twenty-four ounces of spirit of wine were now added to the residuum of the former distillation, and the proccs recommenced. The first seven ounces that came over were poured to the dulified spirit marked A. Next passed over ten ounces of a tolerably pure ether, which was mixed with the contents of B; besides two ounces that had a sulphurous smell, which were mixed with C. By a repeated dephlegmation of what remained in the retort were obtained five ounces of a weak sulphurous acid; and
the remainder being again mixed with 20 ounces of spirit of wine, yielded first six ounces of the liquor marked A; then four ounces of pure ether marked B; and after that another ounce marked C. By continuing the distillation four ounces of weak sulphurous acid were obtained, on which floated a little oil of wine. 2. The remainder, which was very thick, and covered with a flight pellicle, was mixed with 20 ounces of spirit of wine, and yielded five ounces of dulcified spirit marked A; eight ounces of pure ether marked B; and at last one ounce of the same, which had rather a sulphurous smell. This was followed by a few drops of acid; but the remainder frothed up with such violence, that an end was put to the operation, in order to prevent its pouring over into the receiver.

By these four distillations there were obtained from six pounds of spirit of wine and two of oil of vitriol, 28 ounces of dulcified spirit of vitriol and 38 of ether; which last, when rectified by distillation over manganese, yielded 28 ounces of the best ether. At the end of this distillation were produced 13 ounces of weak acetic acid; and the liquor of the last running marked C, afforded, by rectification, four ounces of good ether. The sulphurous acid liquor yielded four ounces of weak acetic acid, and three drachms of naphtha resembling a distilled oil in consistency. By these processes the vitriolic acid was rendered quite thick and black; its weight being reduced to 24 ounces. The blackness was found to be owing to a powder which floated in the liquid, and could neither be separated by subiding to the bottom nor rising to the top. The liquor was therefore diluted with eight ounces of water, and filtered through powdered glas; by which means the black fulphate was collected, partly in powder, and partly in grains of different sizes. It felt very soft between the fingers, and left a black stain upon paper like Indian ink; but though washed with 24 ounces of water, still tasted of naphtha.

The above experiment made by Wallerius, induced him and others to think, that the vitriolic acid was convertible into the nitrous acid, in favour of the transmutation of vitriolic into nitrous acid.

Some felt of tartar (says he) being mixed with the dulcified spirit of vitriol, or perhaps with the acetic acid (for the author expresses himself a little ambiguous), the full bottle flopped a cork, tied over with bladder, and laid on its side; on standing for four months, the greatest part of the spirit was found to have escaped, and the felt was that into hexagonal prismatic crystals resembling nitre. It tasted strongly ff the spirit, but had no other particular taste. Laid on a burning coal, it crackled, exploded with a bright flash, and flew into the air. He afterwards found, that by adding to the spirit a drop or two of any acid, the felt crystallizes the sooner; that in this case it has a fourth taste, but in other respects is the same with that made without acid. This felt-petre (says the author) promisses, from the violence of its explosion, to make the strongest gun-powder in the world, but a very dear one. Though the experiment should not be applicable to any use in this way, it will probably contribute to illustrate the generation of nitre: as it palpably shows nitre, that is, the acid or characteristic part of nitre, produced from the vitriolic acid and phlogiston.

We cannot here help again regretting that chemists of superior abilities should sometimes leave very important discoveries only half finished, so that chemists of an inferior rank knew not what to make of them. Had Wallerius,
Practice.

Wallerius, who seems more than once to have been in possession of this fact, only poured on it a few drops of oil of vitriol, the peculiar colour and smell of its fumes must have been a much more convincing proof of the reality of the transmutation than that of mere deflagration; because the latter can be otherwise accounted for.

It is certain, that many substances, water itself not excepted, when exploded with great violence if suddenly heated beyond their great heat of combustion, will explode with great violence if suddenly applied to the containing vessel, their great heat will be suddenly communicated to the air itself, and this happens, not from any substance are inflammable, the explosion will be attended with a flash if any flame is near. In like manner ether, on the approach of a candle, takes fire, and goes off in a flash like lightning; but this happens, not from any thing nitrous, but from its great volatility and inflammability. If therefore the vapours of the etheral liquors are confined, and heat is applied suddenly to the containing vessel, their great volatility will cause them make an instantaneous effort against the sides of it, which increasing with a swiftness, and in like manner a violent explosion, will make a much quicker as well as a much stronger explosion than either of them; and if a flammable substance is near, the explosion will be attended with a bright flash like that of the ether itself.

In the experiment now before us, the salt raised strongly of the spirit, or ether, from which it was made. The spirit was therefore confined in the crystals of salt; and this volatile liquor, which, even under the pressure of the atmosphere, boils with the heat of 100° of Fahrenheit, was, in a confined state, subjected to the heat of a burning coal; that is, to more than ten times the degree of heat necessary to convert it into vapour. The consequence of this could be no other, than that the particles of salt, or perhaps the air itself, not being capable of giving way from enough to the forcible expansion of the ether, a violent explosion would happen, and the salt be thrown about, which accordingly came to pafs, and might very reasonably be expected, without any thing nitrous contained in the salt.

Mr Cavallo describes an easy and expeditious method of purifying ether, though a very expensive one; as out of a pound of the common kind scarce three or four ounces will remain of that which is purified. The method of purifying it, he says, was communicated to him by Mr Winch chemist in London, and is to be performed in the following manner. "Fill about a quarter of a strong bottle with common ether, and pour upon it twice as much water; then stop the bottle and give it a shake, so as to mix the ether for some time with the water. This done, keep the bottle for some time without motion, and the mouth of it downwards, till the ether be separated from the water, and swins above it; which it will do in three or four minutes. Then opening the bottle with the mouth full inverted, let the greatest part of the water run out very gently; after this, turn the bottle with the mouth upwards; pour more water upon the ether, shaking and separating the water as before. Repeat this operation three or four times; after which the ether will be exceedingly pure, and capable of dissolving elastic gum, though it could not do so before."

As great part of the ether undoubtedly remains nitrous with the water after this process, our author remarks, that it might be worth while to put the water into a retort, and distil the ether from it, which will come sufficiently pure for common use. He observes also, that "it is commonly believed that water combines with the purest part of the ether when the two fluids are kept together; though the contrary seems to be established by this process. According to Mr Walthurn, we may obtain from the residue of vitriolic ether a reain containing vitriolic acid, vinegar, Glauber's salt, sebene, calcareous earth, filax, iron, and phosphoric acid."

§ 2. Of the NITROUS Acid and its Combinations.

This acid is far from being so plentiful as the vitriolic. It has been thought to exist in the air; and the experiments of Mr Cavendish have shown, that it may be artificially composed, by taking the electric spark in a mixture of dephlogisticated and phlogisticated air. See ARKNOLOGY, No. 77.

With regard to the preparation of nitre, Dr Black observes, that it is made in great plenty in the more southern parts of Europe; likewise in the southern part of Perla, in China, the East Indies, and in North America. We have had no accounts of the manner in which it is prepared in the East Indies, no person on the spot having taken particular notice of the manufacture. The general account is, that it is obtained from the soil of certain districts which are called faltpetre grounds; where the soil is very cold, barren, and unhealthy. The falt is there ready formed by nature. It is only necessary to gather large quantities of the earth, and to put it into a cavity through which the water runs into an adjacent pit, out of which it is lifted in order to be evaporated and obtained in the form of cryflas. This account, however, has been thought unsatisfactory; because there is hardly any part of Europe in which it is found in this manner. It is discovered indeed in some very large districts in Poland, particularly in Podelia, where the country is flat and torrid, and had been once very populous, but is now in a great measure defverted. It is there obtained from tumuli or hillocks, which are the remains of former habitations; but these are the only places in which it is found in any considerable quantity. In Spain, it is said that the inhabitants extract it from the soil after a crop of corn. It has been found in America in lime-flone grounds, in the shores of pigeon-houses, tobacco-houses, or the ruins of old stables, where a number of purifying vegetables were once collected. In general, however, it is extracted from artificial compounds or accidental mixtures, where animal and vegetable substances have been fully purified by being exposed to the air with any spongy or loose earth, especially of the calcareous kind, and open to the north or north-east wind, and more or less covered from the heat or rains. This last particular is absolutely necessary to its formation in any quantity; for the heat, by evaporating the moisture too much, prevents it from being produced, and the rains wash it away after it is already made. Cramer, an author of the greatest credit, informs us in his Deoimagistics, that he made a little but exposed to the fresh air, and the country, nitre.
Nitrous acid and its combinations.

How prepared in Hanover.

In other parts of Germany.

In France.

Dr Black's conclusions concerning the nature of saltpetre.

C H E M I S T R Y.

Practice.

Nitrous acid and its combinations.

In this country, with windows to admit the winds. In this he put a mixture of garden mold, the rubbish of lime, and putrid animal and vegetable substances. This he frequently moistened with urine; and in a month or two found his composition very rich in nitre, yielding at least one-eighth part of its weight.

It is manufactured in Europe by making artificial compounds with less trouble. In Hanover it is got by collecting the raking of the streets, which are built up into mud-walls that are allowed to remain a certain time, when the surface is found covered with a white saline efflorescence. A person is employed to scrape this off; and putting it into a vessel, it is washed with water to dissolve the nitre, and the remaining earthy matter is again plastered on the mud-walls, and fresh matter brought from the streets to renew them occasionally: and by this simple method a considerable quantity is obtained. In Germany the peasants are directed by law to build mud-walls of this kind with the dung and urine of animals, and some straw. After they have flooded for some time, the vegetable and animal substances are rotten, they afford a considerable quantity of nitre. In France it is obtained from accidental collections of this kind, as where loofe earth has been long exposed to the contact of animal substances, as the rains of old stables, pigeon-houses, &c. Sometimes from the mould upon the ground where dunghills have been lying. A particular act of people go about in search of these materials; and when, by making a small effay, they find that they will turn to account, they put the materials into a large tub with a perforated bottom, and another which is water-proof put below it. Some straw is interposed between the two; and on pouring water upon the materials, it soaks through them, undergoes a kind of filtration in pouring through the draw, and is then drawn off by a cock placed in the under-tub, and boiled to a proper consistence for crystalization. The crystals are at first brown and very impure, but by repeated distillation and crystalization become pure and white.

From these particulars relating to the history of saltpetre, Dr Black concludes, that it is not properly a foil, being produced at the surface of the ground. Margraaff discovered a small quantity of it in the analysis of some of the waters about Berlin, and others have found it in the wells about some great cities: but no true nitre has ever been found in springs; so that this nitrous salt may be supposed to have derived its origin from the quantity of putrid matters with which all cities abound. All rich and fertile soils are found to contain it; and in the hot countries, where the products of nature are numerous, and putrefaction carried on very fast, they are often very rich in nitre. This may happen in some places from the conflux of waters; which remaining for some time on the surface, and afterwards exhalting, left the saline particles behind.

On the whole, Dr Black concludes, that neither nitre nor its acid does exist in the air, because it might easily be detected there; though many have embraced this opinion from its being usually found at the surface of the ground. He is of opinion, that it is the effect of the last stage of putrefaction of animal and vegetable substances; and it is never to be found except where these or their effluvia are present, and never till the putrefaction is complete. It has been a matter of dispute, whether it existed in those matters before the process of putrefaction, or was produced by it. But it is pretty certain, says the Doctor, that it originated in them; for the sun-flower, tobacco, and other plants, are found to contain it before putrefaction; and some have even asserted, that plants placed in the earth, deprived of all its saline substances, will yield it. The compositions recommended by Cramer are the finest for producing a complete degree of putrefaction; provided they contain a moderate degree of humidity, and that the quantity exposed to the air be defended from too great a heat by the sun, which would dry up its moisture; and likewise from too great a degree of cold, which likewise checks fermentation. The importance of the calcareous earth in such a composition would likewise favour the conclusions just now drawn; for the most remarkable effect of this earth is to promote and perfect the putrefaction of these substances. It would seem, therefore, that the true secret of the production of nitre is to mix properly together animal and vegetable substances with earth, particularly the calcareous kind; exposing them to the air with a moderate degree of humidity, sufficient to promote their putrefaction in the most effectual manner; and when the putrefaction is carried to the utmost height, we may then expect that nitre will be produced.

The distinguishing characteristic of the nitrous acid is its great disposition to unite with the phlogiston; and, when so united, to become exceedingly volatile, and at last be diffipated in a very white bright flame: this is called its detonation or deflagration. In the strongest state in which this acid is procurable in a liquid form, it is of a reddish yellow colour, and continually exahles its noxious fumes; and in this state it is called smokning, or, from its inventor, Clauiter's, spirit of nitre.

1. To extract the Nitrous Acid by means of the Vitriolic.

Into a glass retort put two pounds of good salt spirit of nitre, and pour upon it 18 ounces of concentrated oil of vitriol; set the retort in a sand-heat, and lute on a large receiver with the composition already recommended, for redistilling acid fumes; the mixture will grow very warm, and the retort and receiver will be filled with red vapours. A small fire is then to be kindled, and cautiously raised till no more drops will fall from the nofe of the retort. What comes over will be a very strong and smokning spirit of nitre.

In this process, the nitrous acid is generally mixed with part of the vitriolic which comes over along with it, and from which it must be freed if designed for nice purposes. This is most effectually done by distilling in it a small quantity of nitre, and redistilling the mixture. The vitriolic acid which came over in the first distillation is kept back by the nitre in the second, combining with its alkaline baits, and expelling a proportionable quantity of the nitrous acid.

We have here directed the pure vitriolic acid to be different used, in order to expel the nitrous one; but for this method of purpose any combination of the vitriolic acid with a metallic or earthy basis may be used, though not with equal advantage. If calcined vitriole is made use of,
its exceedingly volatile, so that great part of it is lost. If calcined alum, or felenite, is made use of, the vir- tuous acid in these substances immediately leaves the earth with which it was combined, in order to unite with the alkaline bases of the nitre, and expels its acid: but the moment the nitrous acid is expelled from the alkali, it combines with the earth which the vir- tious acid had left; from which it cannot be driven without a violent fire; and part of it remains obsti- nately fixed, so as not to be expelled by any degree of heat. Hence the produce of spirit, when nitre is distilled with such substances, always turns out consid- erably less than when the pure vivriolic acid is used. Alum is preferable to felenite, for the purposes of distilling spirit of nitre; because the acid does not ad- here so strongly to argillaceous as to calcareous earth.

According to Weigleb, the nitrous acid may be expelled not only by clay, gypflun, and other substances containing the virtuous acid, but even by various kinds of vitrifiable earth. Clay, pebbles, quartz in the form of sand, pieces of broken china and stone ware, powdered glafs, etc. mixed with nitre in the proportion of six to one, always expel the acid, though imperfectly. In France the acid is always extracted by means of clay.

The reason of these decompositions is, that the alk- aline bases of the nitre attract the flicile earth, whose fixed nits in a vehement fire gives it an advan- tage over the volatile nitrous acid, in the same manner that the weak acid of phosphorus or arsenic will also expel it by reason of their fixed nits in the fire.

Even spirit of salts, according to Margraaff's experi- ments, may be used for distilling the spirit of nitre. That celebrated chemist informs us, that on distilling nitre with eight or nine times its quantity of strong marine acid, a spirit comes over which consists chiefly of the nitrous acid, but has also some portion of that of fes-falt. The reason of this is shown in Mr. Kir- want's experiments on chemical atractiones in the present cafe, however, the decomposition may be facili- tated by the strong attraction of the nitrous acid for phlogifon; for it is well known, that on mixing the nitrous and marine acids together, the latter is always déphlogififed. It seems therefore that in this cafe a double decomposition takes place, the nitrous acid uniting itself to the phlogifon of the marine, and the latter attaching itself to the alkali of the nitre.

Spirit of nitre is very useful in the arts of dyeing and refining, where it is known by the name of aquafor- tis; and therefore an easy and cheap method of procuring it is a valuable piece of knowledge. Many difficulties, however, occur in this process, as well as that for the vivriolic acid. Oil of vitriol, indeed, al- ways expels the nitrous acid with certainty; and on distilling the mixture, a spirit of nitre arises; but if a glafs retort is used for the purpose of distilling this acid, the quantity of residuum left in distillation is so great, and so inoluble in water, being no other than vitriolated tartar, that the retort must always be broken in order to get it out; and the produce of spirit will scarce afford the breaking a retort. If earthen ret- torts are made use of, they must certainly be of that kind called stone-ware, and the price of them will be

very little if at all inferior to that of glafs. Iron pots are said to be made use of in the distillation of common acids and aquafortis in large quantities; but they have the great inconvenience of making a quantity of the acid fo vo- latile, that it not only will not condense, but spreads its suffocating vapours all round in such a manner as to prove very dangerous to those who are near it. If an iron vessel, therefore, is thought of for the purpose of distilling aquafortis, it will be proper at least to at- tempt luting over the inside with a mixture of gyp- seous earth and sand, to prevent as much as possible the acid from attracting the metal.

Déphlogififed spirit of nitre is obtained by distil- ling the smoking kind with a gentle heat, until what remains is as colourless as water. It is distilled with emitting white and not red fumes like the other kind, when set in a warm place. It must be kept con- stantly in the dark, otherwise it will again become phlogififed, and emit red vapours by the action of the light; the same thing will also take place if it be heated with too violent a fire.

II. To procure the Nitrous Acid by means of Arsenic.

Pulverife equal quantities of dried nitre and white blue aquafor- tis arsenic; mix them well together, and distill fortis, in a glafs-retort with a fire very cautiously applied; for the arsenic sets on the nitre with such a violence, and the fumes are so fific that volatile, that unless great care is taken, a moft dangerous explosion will almost certainly happen. As in this cafe, the nitrous fumes arise in a perfectly dry state, some water must be put into the receiver, with which they may unite and conden- se. The aquafortis so produced will have a blue colour, owing to the inflammable principle separated from the arsenic, by which its extreme volatility is likewise occasioned. If this blue aquafortis is ex- posed to the air, its colour soon flies off. If instead of the white arsenic we employ the pure arsenic acid, the distilled liquor will have no blue colour.

Nitrous Acid combined.

I. With Vegetable fixed Alkali. This salt, combined Sulphate.

with the nitrous acid to the point of saturation, regener- rates nitre. It is observable, however, according to Neumann, that there is always some diffimilarity between the original and regenerated nitre, unlefs quick- lime is added. The regenerated salt, he says, always corrodes tin, which the original nitre does not; owing probably to a quantity of phlogififed acid remaining in it. Boiling with quicklime deprives it of this quality, and makes it exactly the same with original nitre.

II. With Fossil alkali. The neutral salt arising from Cubic- a combination of the nitrous acid and fossil alkali is nitre, somewhat different from common nitre; being more difficult to crystallize, inclining to deliquate in the air, and flowing into crystals of a cubical form, whence it gets the name of cubic nitre. Its qualities are found somewhat inferior to the common nitre; and therefore it is never made, unless by accident, or for exper- iments.

Nitre is one of the most fusible salts. It is liquefied in a heat much less than what is necessary to melt red; and thus remain in tranquil fusion, without fus- ting. If nitre thus melted be left to cool and fix, whe-
CHEMISTRY.

Practice.

whether it has been made red-hot or not in the fusion, it coagulates into a white, semi-transparent, solid mass, called mineral crys\(\text{t}\)al, having all the properties of nitre itself. By this fusion, Mr Beaumo observes that nitre leaves very little, if any, of the water contained in its crys\(\text{t}\)als, since the weight of mineral crys\(\text{t}\)al is nearly the same with that of the nitre employed.

When nitre is kept in fusion with a moderate heat, and at the same time does not touch any inflammable matter, nor even flame, it remains in that state without suffering any very sensible alteration; but if it is long kept in fusion with a strong fire, part of the acid is destroyed by the phlogiston which penetrates the cooler; but very often fits uneasily on the considerable antiseptic power; whence its use in the resemblance of the

Nitrous III. utts. 743

its effect on itself. By this means a sediment falls to the bottom, which carries with it any impurities that may have been in the nitre, and leaves the fluid salt clear and transparent as water. This precipitate is probably no other than a vitriolated tartar formed by the union of the sulphurous acid and alkali of the nitre, which being less fusible than the nitre, sublimes in a solid form and clarifies it.

IV. With Calcareous Earths. These the nitrous acid Calcareous dissolves into a transparent colourless liquid; but for this nitre purpose it must be very much diluted, or the solution will have a gelatinous consistence. This compound is not applicable to any useful purpose. It has a very acrid taste; and, if inspissated, attracts moisture from the air. If it is totally dried, it then resembles an earthy matter, which deflagrates very weakly. By distillation in a retort, almost all the acid may be expelled, and what little remains flies off in an open fire.

Mr Pott, who has particularly examined the combination of nitrous acid with quicklime, says that the acid decomposes and is converted into a white precipitate. By these experiments he obtained a salt more easily fusible than the quicklime, and repeated coagulations upon it. By these experiments it would seem, that nitrous acid, by this treatment with quicklime, was capable of being entirely decomposed.

If a solution of chalk in the nitrous acid be evaporated to dryness, and then gently calcined, it acquires the property of fuming in the dark, after having been exposed to the sun’s rays, or even to the light of a candle. This substance, from its inventor, is called Baldwin’s phosphorus; or, from its being necessary to Phosphorus keep it in a glass hermetically sealed, phosphorus hermeticus. (See EARTHS.)

V. With Argillaceous Earths and Magnesia. All that is known concerning the combinations of nitrous acid with these earths is, that the first produce alriment, and the second purgative compounds, similar to alum and Epsom salt, and which are not fusible in crystallization.

VI. With Gold.—Till very lately it has been the opinion of chemists, that the nitrous acid by itself was incapable of acting upon this metal. Dr Brandt, however, produced before the Swedish academy of sciences, a solution of gold in the nitrous acid, obtained in parting, by that acid, a mixture of gold and silver.

The mixed metal was boiled with aquafortis in a glass body fitted with a head and receiver, the liquor poured off, and the coction repeated with fresh parcels of stronger and stronger nitrous spirit, till all the silver was judged to be extracted. The last parcel was boiled down till the matter at the bottom looked like a dry salt; on boiling this in fresh aquafortis in close vessels, as before, a part of the gold was dissolved, and the liquor tinged yellow. But though gold is by this means truly soluble in the nitrous acid, the union is extremely slight; the gold being not only precipitated on the addition of silver, but likewise spontaneously on exposure to the air.—Dr Lewis very justly observes, that this solution may have been often made unknown.

NITROUS aci\(d\)d and its combination.

745

Nitrous ammoliac. 745
unknown to the chemist who did so; and probably occasioned the mistakes which some have fallen into, who thought that they were in position of aquafortis capable of transmuting silver into gold. Notwithstanding these authorities, Mr. Kirwan is of opinion that the nitrous acid is in no case able to dissolve gold; the metal being only intimately mixed or diffused through it.

II. With Silver.—Pure spirit of nitre will dissolve its own weight of silver; and shoots with it into fine white crystals of a triangular form, consisting of very thin plates joined closely one upon another. These crystals are somewhat deliquescent; of an extremely bitter, pungent, and nauseous taste; and, if taken internally, are highly corrosive and poisonous. They melt in a small heat, and, on cooling, a dark-coloured mass still more corrosive, called lunar caustic, or lapis infernalis. They readily dissolve in water; and, by the affinity of warmth, in spirit of wine. In the Æte Natura Curiosorum, tom. vi. there is a remarkable history of silver being volatilized by its combination with the nitrous acid. Four ounces of silver being dissolved in aquafortis, and the solution let to distil in an earthen retort, a white transparent butter rose into the neck, and nothing remaining behind; by degrees the butter liquefied, and piled down into the phlegm in the receiver. The whole being now poured back into the retort, the silver arose again along with the acid. The volatilization being attributed to the liquor having stood in a laboratory where charcoal was burning in, the experiment was repeated with a fresh solution of silver, and a little powdered charcoal, with the same event.

Solution of silver in the nitrous acid stains hair, bones, and other solid parts of animals, and different kinds of wood, of all the intermediate shades from a light brown to a deep and lasting black. The liquors commonly used for staining hair brown or black, are no other than solutions of silver in aquafortis, so far diluted in water as not sensibly to corrode the hair.

It gives a permanent stain likewise to sandy stones; not only to those of the softer kind, as marble, but to some of considerable hardness, as agates and jaspers.

The solution for this purpose should be fully saturated with the metal; and the stone, after the liquor has been applied, exposed for some time to the sun. M. du Fay observes (in a paper on this subject in the French memoirs for 1728), that if the solution be repeatedly applied, it will penetrate into the whitish agate, or chalcedony, about one-twelfth of an inch: that the tinctorium does not prove uniform, on account of the veins in the stone: that the colours, thus communicated by art, are readily distinguished from the natural, by disapppearing on laying the stone for a night in aquafortis: that, on exposing it to the sun afterwards for some days, the colour returns: that the solution gave somewhat different tinctures to different stones; to oriental agate, a deeper black than to the common chalcedony; to an agate spotted with yellow, a purple; to the jade stone, a pale brownish; to the common emerald, an opaque black; to common granite, a violet unequally deep; to serpentine stone, an olive; to marble, a reddish, which changed to purple, and fixed in a brown; that on plates, tales, and amianthus, it had no effect.

If a solution of silver be diluted with pure water, a considerable quantity of pure mercury added, and the whole set by in a cold place; there will form by degrees a precipitation and crystallization resembling a little tree, with its root, trunk and branches, called arbor Diana, or the philosophic silver tree. Another kind of artificial vegetation may be produced by spreading a few drops of solution of silver upon a glass plate, and placing in the middle a small bit of any of the metals that precipitate silver, particularly iron. The silver quickly concretes into curious ramifications all over the plate.

Like other metallic solutions, this combination of solution of the nitrous acid with silver is decomposed by fixed and volatile alkalies, calcareous earths, and several metals, (see the Table of Affinities); but with several peculiar circumstances attending the precipitation. With metals, the silver is readily and copiously thrown down at first, but slowly and difficulty towards the end. The menstruum generally retains some portion of the silver, as the silver almost always does of the metal which precipitated it. For recovering the silver from aquafortis after paring, the refiners employ copper. The solution, diluted with water, is put into a copper vessel, or into a glass one with thin plates of copper, and let into a gentle warmth. The silver begins immediately to separate from the liquor in form of fine grey scales, or powder; a part of the copper being dissolved in its place, so as to tinge the fluid more or less of a bluish green colour. The plates are now and then shaken, that such part of the silver as is deposited upon them may fall off, and settle to the bottom. The digestion is continued till a fresh bright plate, kept for some time in the warm liquor, is no longer observed to contract any powdery matter on the surface; when the liquor is poured off, and the precipitate washed with fresh parcels of boiling water. It is observable, that though the acid in this process separates itself with the copper, in proportion as it lets go the silver, yet the quantity of copper which it takes up is not near so great as that of silver which it depots. One dram of copper will precipitate three of silver, and saturate all the acid that held the three drachms dissolved.

Calcereous earths, as chalk or quicklime, throw Characters down a part of the silver, but leave a very confiderecurably part suspended in the liquor. If the earth be marked on moiltened with the solution into the conftitution of a pale, and exposed to the sun, it changes its white by means colour to a dark purplish black; different characters of the sun's may be exhibited on the matter, by intercepting a light. part of the sun's light by threads, flit paper, &c. placed on the outside of the glass. Culinary fire does not afiect its colour; after the mass has been exploded by this, it changes as before, on exposure to the sun.

Mild volatile alkaline spirits, added to a solution of silver, precipitate but little, and caustic volatile alkalies none. Pure fixed alkalies, and alkalies rendered caustic by quicklime, throw down the whole. Fixed alkalies impregnated with inflammable matter by calcination with animal coals, occasion at first a considerable precipitation; but if added to a larger quantity, take up a great part of the metal again. Mr. Mar- graaf relates, that edulcorated calces of silver totally dissolve, both in a lixivium of these alkalies and in vo-
In this case had been contained in the aquafortis; for nitrous pure lead dissolved in pure aquafortis gives no such precipitate.

The crystals of lead in the nitrous acid, when thrown into the fire, do not disengage as other combinations of this acid with metallic or saline bases; but crackle violently, and fly round, with great danger to the by-standers. If they are rubbed into very fine powder, they may then be melted without any danger. By repeated dissolutions in fresh aquafortis, they at last form a thick fluid like oil, which cannot be dried without great difficulty. This composition is not adapted to any particular use, and is a violent poison.

Nitrous acid and its combinations.

Copper.

The nitrous acid very readily dissolves this metal into a green-colored and very caustic liquor. The solution, if properly evaporated, will crystallize; but the crystals are deliquescent, and therefore difficult to be prepared. The only use of this combination is for the preparation of the pigment called verditer. Of this there are two kinds, the blue and green. The blue is by far the brightest colour, and consequently the most valuable. It has been said that this is obtained by precipitating a solution of copper by any calcareous earth; and therefore is sold by the refiners who have large quantities of solution of copper accidentally made. The solution is said to be precipitated by chalk, or whiting; and that the precipitate is the beautiful blue colour called verditer. By this method, however, only the green kind can be obtained. The blue we have found to be of a quite different nature, and formed by precipitation with a gentle heat from a solution of copper in volatile alkali. See the article Colour-making.

Iron.

This metal is very abundantly precipitated in the nitrous acid, and is then dissolved in the aquafortis; for nitrous dioxide of such a degree of strength as to take up half its weight of silver, dissolves with ease above equal its weight of mercury into a limpid liquor, intensely corrosive and poisonous, which spontaneously shoots into white crystals. These crystals, or the solution exsiccated, and moderately calcined, assume a sparkling red colour; and are used in medicine as an escharotic, under the name of red lead precipitate. The precipitate has sometimes been given internally, it is said, in very large quantities; even a whole drachm at one dose. But this would seem incredible; and the present practice does not contemplate the taking of red precipitate inwardly. This solution seems to have been what gave the efficacy to Ward's white drop.

When red precipitate is prepared in quantity, it is proper to dilute the mercurial solution; because most of the aquafortis may then be saved. It is exceedingly pure, if by purity we mean its being free of any admixture of vitriolic or marine acid; but is considerably tainted with the inflammable principle of the mercury extracted during the distillation. In consequence of this, it is very volatile and smoking; which has generally, though improperly, been taken as a sign of strength in the nitrous acid.

Bismuth.

This semi-metal is very readily dissolved in the nitrous acid. The nitrous acid dissolves about half its weight of bismuth. If the metal was formerly added, the solution proves of a greenish colour; if otherwise, it is colourless and transparent. Unless the acid was diluted with about an equal quantity of water, a part of the bismuth crystallizes almost as fast as it dissolves. The metal is totally precipitated both by fixed and volatile alkalis. The lead, added in greater quantities than are sufficient for precipitation, takes it up again. The liquor generally appears greenish; by alternate additions of the alkaline spirit and solution, it becomes bluish or purple. Fixed alcalies calcined with inflammable matter likewise dissolve the bismuth after they have precipitated it.

The only use of this compound is for the precipitate, which is used as a cosmetical, under the name of bismuth.

In the memoirs of the French academy for 1733, there is a particular account of an experiment, in which mercury is said to have been extracted from lead by dissolving in it the nitrous acid. During the distillation, there fell a precipitate which is plainly proved to be mercury, and was looked upon to be one of the constituent parts of the lead separated by this simple process: it seems probable, however, that the mercury spirit
CHEMISTRY.

Nitrous acid and its combinations.

IX. With Zinc. Upon this sublimate the nitrous acid acts with greater violence than any other, and will forswear any other metallic sublimation for it. The whole is very soon dissolved into a transparent colourless liquor. The cals of flowers of zinc are likewise soluble in the nitrous acid; but neither the solution of the flowers, nor of the metal itself, have been yet found applicable to any useful purpose. Neumann remarks, that on extracting the nitrous acid, the soluble parts of calamine, which is an ore of zinc, the solution, infuriated to dryness, left a reddish brown mass, which on digestion with spirit of wine exploded and burst the vessel.

X. With Regulus of Antimony. The nitrous acid rather corrodes than dissolves this femimetal. The corroded powder forms a medicine formerly used under the name of bezoar mineral, but now disfregaded.

XI. With Regulus of Cobalt. This femimetal dissolves readily in the nitrous acid, both in its metallic form and when reduced to a calx. The solution is of a red colour. Hence the nitrous acid furnishes means of discerning this femimetal in ores after long calcination; very few other cals being soluble in the nitrous acid, and those that are not influencing the colour.

XII. With Nickel. This femimetal is easily dissolved by the nitrous acid into a deep green liquor; but neither this solution, nor indeed the femimetal of which it is made, has hitherto been found of any use.

XIII. With Arsenic. This sublimation is readily dissolved by the nitrous acid; which abstracts the phlogiston, and leaves the pure arsenical acid behind. See below.

Acid of Arsenic.

XIV. With Expressed Oils. These, as well as all other fatty or unctuous substances, are considerably thickened and hardened by their union with the nitrous acid. There is only one preparation where this combination is applied to any use. It is the breguentum citrinum of the shops. This is made by adding to some quantity of melted hog-plaster a solution of quicksilver in the nitrous acid. The acid, though in a diluted state, and combined with mercury, nevertheless acts with such force on the lard, as to render the ointment almost of the consistence of tallow.

XV. With Vinous Spirits. If highly rectified spirit of wine and strong spirit of nitre are suddenly mixed to-gether, the acid instantly becomes volatile, and is dissipated with great heat and effervescence in highly noxious red flames. If the acid is cautiously poured into the spirit, in the proportion of five, six, or even ten parts of spirit to one of acid, and the mixture distilled in a glass retort set in a water-bath, an exceedingly fragrant and volatile spirit comes over, used in medicine as a diuretic and cooler, under the name of spiritus nitri dulcis. This liquor is not acid; nor has spiritus nitri dulcis any of the characterisitics of tri duleis, of nitrous acid, which seems to be entirely decomposed in this process. (See the following article.)

With the nitrous acid and spirit of wine, may also Nitrous ether be made an exceedingly volatile liquor, called nitrous ether, to distinguish it from the vitriolic abovementioned. The proportions of nitrous acid and spirit of wine to each other for nitrous ether, are two of the acid by weight to three of the spirit. Dr Black's process for making it is as follows. Take four ounces of strong phlogilicated nitrous acid; and having cooled it by putting it into a mixture of salt and snow, or into water cooled very near the freezing point, by putting pieces of ice into it, he puts it into a phial, and pours upon it an equal quantity of water, likewise cooled very low, in such a manner that the water may float as much as possible on the surface of the spirit. Six ounces of strong spirit of wine are then put in, so as to float in like manner on the surface of the water; the phial is placed in a vessel containing cold water; and so great is the power of cold in restraining the action of bodies, that if the mixture was too cold, no ether would be produced; but at the temperature just mentioned, the ether begins to form in a few hours, with some little effervescence, and an expulsion of a small quantity of nitrous air. We must provide for the escape of this elastic fluid, by having a hole in the cork, or the vessel would be broken. The whole of the ether will be formed in a few days, and may be separated from the rest of the liquor by means of a funnel, shaped as in Pl. CXXXIV. fig. 9.

To procure the nitrous ether in large quantities, Mr Woulfe recommends the following process. Put four ounces of nitre into a retort four pounds of nitre, then mix together four pounds of vitriolic acid, and three pounds five ounces of spirit of wine. These are poured on the nitre by adding only two ounces at a time; the vitriolic acid acting on the nitre, produces a sufficient degree of heat; and the acid of the nitre uniting with 302 the
Chemistry.

Practice.

Marine acid and its combinations.

Mr Potter has given an analysis of the oleaginous residue from the distillation. Distilled by a stronger fire, it gave over a yellow, slightly empyreumatic spirit, which being saturated with fixed alkali, the liquor evaporated, and the dry neutral fuel laid on burning coals, did not deflagrate. After this spirit arose a red empyreumatic oil; and in the bottom of the retort it left a shining black mass like a foot, which, burnt in a crucible, left a white fixed earth, convertible by a vehement fire into gla.s. Another parcel of the above residuum was evaporated to the consistence of pitch. In this state it gave a yellow tincture to spirits of wine, flame vividly and quietly on burning coals, and at last swelled up like bitumen. Another portion was saturated with alkaline ley, with which it immediately evaporated, and then evaporated as the former. It gave, as before, a yellow tincture to rectified spirit of wine, and a much deeper yellow to dulcified spirit of nitre; and in the fire discovered no footstep of detonation. M. Marquer supposes this acid to have been not the nitrous, but the acetous, which enters into the composition of the spirit of wine; and his conjecture is now confirmed by late experiments.

§ 3. Of the Marine Acid and its Combinations.

This acid is never, at least very rarely, found but Marine acid in a state of mixture with the mineral alkali; in said which case it forms the common salt used in food. Almost the only exception to this is human urine, and perhaps that of some other animals; for there the marine acid is found saturated, not with the mineral, but the common vegetable, fixed alkali. From being found in such plenty in the waters of the ocean, it has the name of marine acid.

It is commonly thought that this acid is no other than the vitriolic, somehow or other disguised by the inflammable principle; to which some have added another, called by them a mercurial earth. The reasons given for this supposition, however, are but very slight, consisting chiefly in the resemblance between the volatile vitriolic acid and the marine, both in the white colour of their vapours, and likewise the great volatility of both. As to the existence of that principle called a mercurial earth, it hath never been proved; and till that time, can never be allowed to be an ingredient in the composition of any substance whatever. As we do not remember to have read of any experiments where the marine acid was directly produced from that of vitriolic, we shall content ourselves with relating one very remarkable fact which happened to fall under our own observation.

As vitriolized tartar, or Glauber's salt, when fused with charcoal dust, is converted into an hepar sulphuris, attempts have been made on this principle to separate the pure alkali from the residuum of Glauber's spirit of nitre and spirit of salt. In an attempt of this kind, which, by the bye, proved unsuccessful, as all others of the same kind must do, 30 or 40 pounds

Nitrous acid and its combinations.

Inquiry into the nature of ether.

Marine spirit, forms a nitrous ether, which flies off from the mixture, and is condensed in a number of vessels placed in cold water. To obtain good nitrous ether readily, and at one distillation, Mr Dollfué advises to divide four parts of nitre of manganese, four of vitriolic acid, and eight parts of spirit of wine.

M. Macquér supposes ether to be the most oily part or quintessence of spirit of wine. But it cannot be proved that ether contains any oil. And, besides, if this were the case, those acids which have the strongest attraction for water would produce the greatest quantity of ether; which is found not to be the case: and it is most probable that ether is produced by a combination of some part of the acid with a portion, particularly the inflammable part, of the spirit of wine; and it has been shown by chemical experiments, that every kind of ether contains a part of the acid employed. Dr Black himself has formed ether without any spirit at all, by expelling nitrous acid highly phlogosticated for some months to the light of the sun. This was owing to the attraction of the principle of inflammability; which it is well known that light has the power of affording to bodies that attract it with force.

Nitrous Acid Decomposed.

I. By Essential Oils. If equal quantities of strong nitrous acid and oil of cloves are poured into the same vessel, the mixture instantly takes fire; both acid and oil burning with great fury till only a light fumption coal remains. Dr Lewis observes, that this experiment does not always succeed, and that there are but few oils which can be fired with certainty, without attending to a particular circumstance first discovered by M. Roselle, and communicated in the French Mémoirs for the year 1747. "On letting fall into the oil equal its quantity of acid, the mixture effervesces, swells, and a light fungous coal arises: a little more of the acid poured upon this coal lets it instantly on fire. By this method almost all the distilled oils may be fired by spirit of vitriolic moderate strength. Expressed oils also may be set on fire by a mixture of the nitrous acid and oil of vitriolic; the use of which last seems to be to absorb the aqueous humidity of the spirit of nitre.

II. By Charcoal. By this substance the nitrous acid cannot be conveniently decomposed, unless it is combined with an alkaline or metallic base. For the purpose of decomposing the acid, common saltpetre is most convenient. The proportions recommended by Dr Lewis for alkaliating nitre, are four ounces of the salt to five drachms of powdered charcoal. If these are carefully mixed, and injected by little and little into a tubulated retort made red hot, and fitted with a large receiver and a number of adopters, a violent deflagration will ensue on every addition, attended with a great quantity of air, and some vapours which will circulate for some time, and then condense in the vessels. This liquor is called Clyfus of nitre. If sulphur is used instead of nitre, the clfyfus is of a different kind, consisting of a mixture of the nitrous and vitriolic acids. The residuum, when charcoal issued, is a very strong and pure alkali; with sulphur it is vitriolated tartar. To prevent the loss occasioned by the violent deflagration, when this operation is performed in open vessels, Dr Black recommends to have the materials somewhat moist.

III. By Vincis Spirits. In the process already mentioned for making spiritus nitri dulcis, a total decomposition of the acid seems to take place: for neither the dulcedified spirit itself, nor the acid matter left in the retort, show any signs of deflagration with inflammable matters, which is the peculiar characteristic of nitrous acid.
The yellow colour of the marine acid is sometimes Marine owing to iron, which may be precipitated from it by acid means of an alkali. In certain cases, however, it is observed to have a much darker and nearly a brown colour, without containing the smallest particle of this metal.—Mr Duflos is of opinion, that the yellow colour of the marine acid is owing to a portion of depoliticized air which it generally contains. A pretty strong proof that it emits this kind of air indeed is, that a candle will burn longer in a bottle containing some marine acid, than it will in an equal quantity of common air.

I. To procure the Marine Acid by means of the Vitriolic.

Put any quantity of sea-salt into a tubulated glass retort, to which a large receiver is firmly luted, having a quantity of water in it, more or less as you want your spirit of salt to be more or less strong. Having placed your retort in a sand-bath, take of concentrated oil of vitriol half as much as you put salt into the retort. Through the aperture in the upper part of the retort, pour a small quantity of the vitriolic acid; a violent effervescence will immediately arise, and white vapours will ascend, and come over into the receiver. These vapours are the marine acid in its most concentrated state; and, as they are very greedy of moisture, they will unite with the water in a very short time, unless too much oil of vitriol is put in at once; in which case, part of them will be diffipated through the small hole in the receiver. When you perceive the first fumes condensed, add a little more oil of vitriol, taking care to stop the aperture of the retort as soon as you drop in the vitriolic acid, that the marine acid may not escape. Continue this by intervals, till your acid is all put in; and then make a very gentle fire, that the retort may be no warmer than the hand can bear. This degree of heat must be continued a long time, otherwise very much of the acid will be lost. To perform this operation perfectly, no more acid should be forced over, than what the water in the receiver can take up; and by this means the operator’s patience will be rewarded with a vastly larger produce of acid than can be procured by hasty distillation. When the vapours become a little more fixed, a greater heat is necessary, but nothing equal to what the nitrous acid requires. For distilling spirit of salt, Mr Wiegleb recommends four pounds of oil of vitriol to six of common salt.—It may also be obtained from the bittern remaining after the crystallization of common salt, by adding one pound of oil of vitriol to five of bittern. It may even be obtained from this liquid by simple distillation without any additional acid; but a violent fire will then be necessary, and it is almost impossible to prevent the liquor from swelling and running over the neck of the retort in the beginning of the process.

The marine acid cannot be procured by means of Why distillation of sea-salt with cop per passes does not succeed. combinations of the vitriolic acid with metallic and earthy bases, as the nitrous is: for though, by means of calcined vitriol, for instance, the marine acid is effectually expelled from its alkaline basis, yet it immediately combines with the calx of iron left by the vitriolic acid, and not only adheres obstinately, but even sublimes the metal; so that what little spirit can be ob-
obtained, is never pure. This inconvenience is not
so great when uncalci ned copperas is made use of:
for the marine acid has a very strong attraction to
water; which partly dissolves its union with the me-
tanine salt. If gypsum is used, instead of calcined
vitriol, not a drop of spirit will be obtained. Alum
and sal cathericus amans answer better.

II. To procure the Marine Acid by means of the
Nitrous.

Aqua-regis.
Take equal quantities of sea-faIt and Glauber's spi-
rit of nitre; put the salt into a retort, and pour on it
the nitrous acid; let them stand for 10 or 12 hours;
then distil with a gentle heat; an acid liquor will come
over, which is a compound of the nitrous and marine
acids, called aqua-regis. When the distillation is fi-
nished, and the vessels cooled, pour back the distilled
liquor on the mash which is left in the retort, and
distil again; the second produce will be more of the
nature of spirit of sea-faIt than the former. Continue
to do this, pouring the distilled liquor either on the
mash left in the retort, or upon fresh sea-faIt, till you
observe that no nitrous acid arises. No experiments
have been made on this spirit of salt, by which we can
judge whether it is different from that procured by the
vitrilic acid or not.

III. To procure the Marine Acid, by distilling Salt
per se.
Put into a retort any quantity of common salt which
has not been dried, and distil in a sand-heat till noth-
ing more will come over. In the receiver you will
have a liquor considerably more acid than vinegar, in
weight about the fourth part of the salt employed.
On the dry salt left in the retort, pour some water,
somewhat less in quantity than the liquor which came
over. Let it stand till the salt has thoroughly imbi-
ced the moisture, and then distil again. You will again
have an acid, but weaker than the former. Repeat
this process four or five times, after which you will obtain
no more marine acid in this way. It has been thought
that sea-faIt was capable of total decomposition by
means of moisture alone; but that is found to be a
mistake. The reason of any acid being procured in
this way, is the impurity of the common salt, which is
always mixed with a quantity of sal cathericus am-
arus, and of marine acid combined with magnesia, from
which it is separable by moisture. If a pure salt be
formed by combining marine acid with salt of soda,
no spirit will be obtained.

IV. To dephlogisticate the Marine Acid.

The marine acid, when mixed either with that of
nitre or with manganese, loses that peculiar smell by
which it is usually distinguis hed, and acquires one much
more volatile and suffocating. When mixed with the
former, the compound is called aqua-regis; when sub-
mitted to the action of manganese, the product is called
dephlogisticated spirit of salt. The method of procuring
this acid recommended by Mr. Scheele is as follows:
Mix common muriatic acid in any quantity with levit-
gated manganese in a glass retort; to which lute on
with blotting paper a receiver capable of containing
about 12 ounces of water. Put about two draehms of
liquid into it; and in about a quarter of an hour, or
somewhat more, a quantity of elastic fluid, which is the
true dephlogisticated spirit of salt, will pass over, and Marine
communicate a yellow colour to the air in the receiver; acid and
water will be separated from the retort. If the paper has been closely applied, a quantity of
the air will now null out with some violence; a con-
stant reat must therefore instantly be put into it, and another
receiver applied, having in like manner two draehms of
water in it, which will also be filled in a short time;
and thus mayveral phials full of this aerial acid be
procured in a short time. Care should be taken, that
the retort be placed in such a manner as that any drops
of liquid which chance to arise may fall down again in-
to it. The water put into the receivers seems to den-
si f y the vapours of the marine acid; and it is most
proper to use small receivers, on account of the great
quantity of vapour which is lost at every operation.

The effects of this dephlogisticated marine acid, which can scarcely be condensed into a liquid, are:
The lute is corroded in distillation, and the corks be-
come yellow, as from aquafortis. 2. Paper coloured
by lacmus becomes nearly white; as well as all vege-
table red, blue, and yellow flowers; and the same
change is likewise produced upon the green colour of
vegetables; nor can any of these colours be recovered
by either alkalies or acids. 3. Expressed oils and an-
imal fats, exposed to the vapour, become as tenacious
as turpentine. 4. Cinnabar grew white on the sur-
f ace; and when it was washed, a pure solution of corro
sive sublimate was obtained; but the sublimate did not
change. 5. Green vitriol became red and delique-
cent, but white and blue vitriol remained unchanged.
6. Iron filings were dissolved; and on evaporating the
solution to dryness, common muriatic acid was ob-
ained by distillation with marine acid. 7. In like man-
ner all the metals, even gold itself, were dissolved;
and by precipitation with volatile alkali, the solution of
gold yielded aurum pulvis. 8. The caustic volatile
alkali produced a white cloud, and emitted a number
of air-bubbles, which on burning discharged an elastic
vapour. 9. Fixed alkali was changed into common
faIt, which decomp sed in the fire. 10. Arsenic be-
came deliquec dent, infects died, and fire was infanta-
iously extinguished in the v.pour.

These phenomena proceed from the strong attrac-
tion of dephlogisticated marine acid for the phlogis-
to have lost; and which is one of the es sential parts of it,
without which it cannot scarce be condensed into a
liquid. "Perhaps (says Mr. Scheele) Stable obtained
such a dephlogisticated muriatic acid by means of iron;
and from the yellow colour of the cork was led to sup-
pose that the muriatic acid had been changed into the
nitrous. If you make a mixture of manganese, muri-
atic acid, or distilled vitriolic acid, and alcohol; and af-
after some days digestion distil it by a gentle fire, no ef-
rence ensues; but the spirit of wine goes over;
and, what is very remarkable, has a strong smell of
nitrus ether.

A new salt has been produced by Mr. Berthollet from New salt
the union of dephlogisticated spirit of salt with vege-
table alkali. This appears to be the nitrous kind, nitre by
as having a coal taste and devastating strongly in the tho-
let. The compound was in very small quantity, and
seemed to require more pure air for its composition than
an equal bulk of acid. The greatest part of this salt
produced was the common salt of Sylvius, or digestive
salt, formed by a combination of the phlogisticated ma-
}H
When the fixed alkali is employed, marine rine acid with alkali. Six parts of the dephlogiticated acid are required to give their air to one of the salt. When the fixed alkali is employed, some of the dephlogiticated acid escapes with the pure air; and in general, when not exposed to a bright heat, the salt we speak of is formed. Some of the dephlogiticated acid remains in its proper form after the salt is made, and may be separated by the volatile alkali. It is to be observed, that if the caustic alkali be employed, and the solution much concentrated, even though not under the influence of a bright light (for it is the light which produces the extraction of the dephlogiticated air*), the other properties of this salt as yet discovered are, that it fothers into rhomboidal crystals; it does not precipitate mercury, silver, or lead, from their solutions in nitrous acid; and it gives out its air again in such a pure state as scarcely to be paralleled in any other substance.

With the mineral alkali the dephlogiticated acid forms a deliquescence salt, soluble in spirit of wine; and which, even in a fluid state, detoanates with burning charcoal. With lime, when so far quenched that the air in its interstices is separated, the dephlogiticated acid unites but weakly. It may be recovered from the lime, however, provided the light be obscure, with very little loss, and almost unchanged.

Marine acid and its combinations.

Sal ammoniac is usually sold in large semi-transparent cakes, which are again capable of being sublimed into masses of the like kind. If they are dissolved in water, the salt very easily shoots into small crystals like feathers. Expoused to a moist air, it deliquates. It is one of the salts which produces the most cold by its solution; so as to sink the thermometer 18 or 20 degrees, or more, according to the temperature of the atmosphere. According to Mr Gellert, a solution of salt ammoniac has the property of dissolving resins. According to Neumann, the volatility of salt ammoniac is so much diminished by repeated sublimations, that at last it remains half fluid in the bottom of the sublimate vessel. In its natural state, it sublimes with a degree of heat necessary to melt lead. Pott says, that a small quantity of salt ammoniac may be produced by distilling sea-salt with charcoal, or with alum, or by distilling marine acid with Armenian balsam. The same author affirms, that the inflammability of sulphur is destroyed by subliming it with twice its quantity of salt ammoniac.

The method of making this salt was long unknown; and it was imported from Egypt, where it was said to be prepared by sublimation from foot alone, or from a mixture of sea-salt, urine, and foot. That it should be produced from foot alone is very improbable; and the other method, from the known principles of chemistry, is absolutely impossible. The composition of this salt, however, being once known, there remained no other desideratum than a method of procuring those competent parts of salt ammoniac sufficiently cheap, so as to afford salt ammoniac made in Britain at a price equal to what was imported. The volatile alkali is to be procured in plenty from animal substances or from foot; and the low price of the vitriolic acid made from sulphur affords an easy method of decomposing sea-salt, and obtaining its acid at a low rate. A salt ammoniac work has, accordingly, been established for several years past in Edinburgh; the principal material made choice of for procuring the volatile alkali is foot; and though no persons are admitted to see the work, the large quantities of oil of vitriol brought into it, and the quantities of genuine salt mirabilis which are there made, evidence that the process for making salt ammoniac also produces Glauber's salt, by the decomposition of common salt by means of vitriolic acid. The method of conducting the process is unknown; but it is plain that there can be no other difficulty than what arises from the volatility of the vapours of the alkali and of the marine acid. In the common way of distilling these substances, a great part of both is lost; and if it is attempted to make salt ammoniac by combining these two when distilled by the common apparatus, the product...
duc will not pay the cost; a little ingenuity, however, will easily suggest different forms and materials for distilling-vessels, by which the marine acid and volatile alkali may be united without losing a particle of either.

If a solution of vitriolic or Glauber's secret sal ammoniac is mixed with sea-salt, the vitriolic acid feizes the alkaline balls of the sea-salt, and expels the marine acid, which immediately unites with the volatile alkali left by the vitriolic acid, and forms a true sal ammoniac. If this solution is now evaporated to dryness, and the saline masses sublimed, the sal ammoniac rifies, and leaves a combination of vitriolic acid and mineral alkali at the bottom. This fixed mafs being dissolved, filtered, and evaporated, affords Glauber's salts. This has sometimes been thought a preferable method of making sal ammoniac, as the trouble of distilling the marine acid was thereby prevented; but it is found vastly inconvenient on another account, namely, that when sal ammoniac is mixed with any fixed salts, it is always more difficult of sublimation, and a part of it even remains entirely undissolved; but if the mctal is melted in a crucible and cooled, it appears luminous when struck, and has been called phosphorus fluens. See Earths.

V. With Gold. The marine acid has no action on gold in its metallic state; in whatever manner the acid be applied; but if the metal is previously attenuated, or reduced to a calx, either by precipitation from aqua-regia or by calcination in mixture with calcinable metals, this acid will then perfectly dissolve, and keep it permanently suspended. Gold, precipitated from aqua-regia by fixed alkalis, and evaporated by repeated ablations, may be dissolved even in a very weak spirit of salt by moderate digestion. This solution appears of the same yellow colour as that made in aqua-regia; gives the purple stain to the skin, feathers, bones, and other solid parts of animals; the same violet stain to marble; and strikes the same red colour with tin. Even when common aqua-regia is made use of for the menstruum, it seems to be chiefly by the marine acid in that compound liquor that the gold is held in solution. In distillation the nitrous acid arises, and the marine acid remains combined with the gold in a blood-red mafs, soluble, like most of the combinations of metallic bodies with this acid, in spirit of wine. If, towards the end of the distillation, the fire is hastily raised, part of the gold dills in a high faffron-coloured liquor; and part sublimes into the neck of the retort in clusters of long slender crystals of a deep red colour, fusible in a small heat, deliquating in the air, and easily soluble in water. By repetitions of this process the whole of the gold may be elevated, except a small quantity of white powder whose nature is not known. Marine -This red sublimate of gold is said to be easily fusible acid and with the heat of one's hand, and to be thrown by the combinations Papiffs for the blood of St. Januarius; the sublimate contained in a phial, being warmed by the hands of the priests who hold it, constitutes the miracle of that blood of St. Januarius.

VI. With Silver. Strong spirit of salt corrodes leaf-silver into a white powder, but has no effect on filings or larger masses of the metal. If applied in the form of vapour to masses of silver, and strongly heated at the same time, it readily corrodes them. Thus, if filings, grains, or plates, of silver are mixed with about twice their weight of mercury sublimate, and exposed to a moderate fire, in a retort, or other distilling vessel, a part of the marine acid in the sublimate will be separated and unite with the silver, leaving the mercury to arize in the form of mercurius dulcis. Marine acid is commonly supposed to be incapable of dissolving silver into a liquid state; but Hencelk relates, that if red silver ore, which consists of silver intimately mixed with red arsenic, be digested in spirit of salt, the silver will be extracted and kept permanently dissolved.

The combination of marine acid with silver is called Luna cornea. The most ready way of preparing it is by means of dissolving silver in the nitrous acid, and then adding spirit of salt, or a solution of sea-salt, when a precipitation instantly ensues; the marine acid expels the nitrous, and unites with the silver, falls to the bottom in form of a white powder. The same precipitation would take place, if a solution of silver was made in the vitriolic acid.

Luna cornea weighs one-fourth more than the silver it is employed; yet, when perfectly washed, it is quite in- tin-sipid to the taste. It does not dissolve in water, spirit of wine, aqua-fortis, or aqua-regia; but is in some small degree acted upon by the vitriolic acid. It melts in the fire as soon as it grows red-hot; and, on cooling, forms a ponderous brownish mafs, which being cast into thin plates, becomes semitransparent, and somewhat flexible, like horn; whence its name Luna cornea. A stronger fire does not expel the acid from the metal, the whole concrete either fusilming entire, or fusiling through the crucible. It totally dissolves in volatile alkali spirits without any separation of the metal. Exposed to the fire in a clofe copper vessel, it penetrates the copper, and tinges it throughout of a silver colour. Kuncelk observes, that when carefully prepared, melted in a glafs vessel, and suffered to cool slowly, to prevent its cracking, it proves clear and transparent; and may be turned into a lafe and formed into elegant figures. He supposes this to be the preparation which gave rise to the notion of maleable glafs.

VII. With Copper. In the marine acid, copper dissolves but slowly. The solution, if made without heat, appears at first brown; but, on standing for some time, deposits a white sediment, and becomes green. On adding fresh copper, it becomes brown again, and now recovers its greenness more slowly than before. The white sediment, on being barely melted, proves pure and perfect copper of the same colour as at first. Copper calcined by fire communicates a reddish colour to this acid.

VIII. With Iron. The marine acid acts upon iron-
PRACTICE.

Marine acid and its combinations.

Maries very much than the nitrous, and does not dissolve so much; nevertheless, it attacks the metal briskly, so as to raise considerable heat and effervescence, and distils off a yellow liquor. During the solution, an inflammable vapour arises as in the solution of this metal by vitriolic acid. This solution of iron does not crystallize. If it is evaporated, it leaves a greenish saline mass, which is soluble in spirit of wine, and runs in the air into a astringent yellow liquor. On distillation, some of the acid separates, and towards the end of the operation the spirit becomes yellow. This is followed by a yellowish, or deep reddish sublimate, which glitters like the scales of fishes; leaving behind a substance which consists of thin, glossy plates, like talc.

Iron volatileized.

The solution of iron in spirit of salt, with the addition of some spirit of wine, is used in medicine as a corrosorant, under the name of tincture a maris. The sublimate of iron is also used for the fame purpose, and called enervis, or florae maritales. It is commonly directed to be prepared by subliming iron filings and salt ammoniac together. In the process, the salt ammoniac is partly decomposed, and a caustic alkaline liquor diffuses. Then the undecomposed salt ammoniac, and the marial sublimate abovementioned, arise together. The sublimate has a deeper or lighter yellow colour, according as it contains more or less iron. The name enervis is improper. It was given by Mr. Boyle, who discovered this medicine. He imagined it to be a preparation of copper, having made use of a colocho of vitriol containing both iron and copper. A medicine of this kind was lately sold with great reputation on the Continent, under the name of Belutschef's nervous tincture. It was introduced by M. Belutschef Field Marshal in the Russian service: but not long after it came into vogue in Prussia and other northern kingdoms of Europe: it made its appearance also in France, under the name of General de la Motte's golden drops. This happened through the infidelity of Belutschef's operator, who, for a sum of money, violated the oath of secrecy he had taken to Belutschef, and discovered the secret to de la Motte. To the latter it proved a very valuable acquisition; for he not only procured a patent for it from the king of France in 1750, with the exclusive privilege of selling it, but had a handsome pension allotted upon it; selling his medicine besides a half a Louis d'or per phial.

The attention of the public was particularly drawn to these drops, by their remarkable property of losing their yellow colour in the sun, and regaining it in the shade, which induced many to believe that they contained gold; and in which opinion they were encouraged by de la Motte. Even chemists of no little reputation were deceived by this appearance; and M. Beaumé, imagining he had discovered the secret, published a preparation to the world as the true arcanum of de la Motte's drops. It consisted of a calx of gold precipitated from aqua-regia by means of fixed alkali, and redissolved in nitrous acid, to which was added a large quantity of spirit of wine. Others, however, who could find nothing but iron by an analysis of the drops, refuted their ailment; and at length, in 1750, M. Beaumé's mistake was made evident by the publication of the process at the desire of the empress of Russia, who gave 5000 rubles for the receipt. The original receipt is perplexed, tedious, and expensive; but when deprived of its superfluous parts, is nearly as follows. Six pounds of common pyrites and twelve pounds of corrosive sublimate are to be triturated together, and then sublimed fix or eight times till all the mercury is expelled. The residuum is to be boiled three times with thrice its quantity of water, and as often filtered, and lastly, distilled to dryness. By increasing the fire, a martial salt is at last sublimed into the neck of the retort; to three drachms of which are to be added 12 ounces of highly rectified spirit of wine. The whole exposed to the rays of the sun. This is the yellow tincture; but there was also a white one, which, however, seems to be but of little value. It is made by pouring on the residuum of the last sublimation twelve pounds of highly rectified spirit of wine, and drawing it off by a gentle distillation after a few days digestion.—Mr. Klaproth imagines, from the following experiment, that Belutschef's tincture absorbs phlogiston from the rays of the sun. He poured a phlogiston few drops of a solution of tartar into two ounces of distilled water, and divided this into two parts. Into one glass having poured a few drops of the tincture that had not been exposed to the sun, the iron was precipitated in the usual form of a yellow ochre; but on treating in the same manner a portion of the tincture that had been exposed to the solar rays, the precipitate fell of a bluish green colour.

and is capable of fully dissolving much tin in the ordinary way. From this imperfect saturation, together with its concentration, proceeds partly its property of smoking so considerably: nevertheless, some other cause probably concurs to give it this property; for though it smokes infinitely more than the most concentrated spirit of salt, its vapours are, notwithstanding, much less elastic. It has all the other properties of concentrated marine acid when imperfectly saturated with tin. If it is diluted with much water, most of the metal separates in light white flocks. In drying, it produces the same effects as solution of tin made in the common way. If the distillation is continued after the smoking liquor of Libavius has come over, the mercury of the corrosive sublimate will then arise in its proper form.

X. With Lead. Marine acid, whether in its concentrated or diluted state, has little effect upon lead, unless affixed by heat. If spirit of salt is poured on filings of lead, and the heat is increased so as to make the liquor boil and distil, a part of the acid will be retained by the metal, which will be corroded into a feline mass; and this, by a repetition of the process, may be dissolved into a limpid liquor. If lead is dissolved in aquafortis, and spirit of sea-salt, or sea-salt itself, added to the precipitation of the metal entire, but if some aqua-regia is added, the precipitate is redissolved.

The combination of lead with marine acid, has, when melted, some degree of transparency and flexibility like horn; whence, and from its resemblance to which he says, some precautions are necessary, and which those constantly employed here-in are belch acquainted with. The principal are, the due mixture of the ingredients, which in some places is performed in the same manner as that of the ingredients for gun-powder: that a head and receiver be adapted to the subliming glas, to sáye some spirit of nitre which will come over. (Here a bent tube of glas will answer the purpose, as already mentioned). The fire must not be rased too hastily. When the sublimate begins to form, the ashes must be removed a little from the sides of the glas, or the glas cautiously raised up a little from the ashes. (This last, we think, is highly imprudent.) Lastly, the laboratory must have a good chimney, capable of carrying off the noxious fumes. The above-mentioned quantities commonly yield 360 pounds of sublimate; the 280 pounds of quicksilver gaining 80 from the 200 pounds of sea-salt. The makers of sublimate...
Marine acid and its combinations.

817. Observations on the different methods.

The above processes, particularly the last, are unexceptionable as to the production of a sublimate perfectly corrosive; but the operation, it is evident, must be attended with considerable difficulty, by reason of the large quantity of matter put into the glass at once. We must remember, that always on mixing a volatile salt with a quantity of fixed matter, the sublimation of it becomes more difficult than it would have been had no such matter been mixed with it. This is of considerable consequence, therefore, in all sublimations, to make the quantity of matter put into the glasses as little as possible. It would seem more proper, instead of the calcined vitriol used in the processes last mentioned, to dissolve the mercury in the vitriolic acid, as directed in turbit mineral, and sublimate the dry mafs mixed with nitre and peaf-fall.

819. Subpoled adulteration with arsenic.

It has been said, that corrosive sublimate mercury was frequently adulterated with arsentic; and means have even been pointed out for detecting this supposed adulteration. These means are, to dissolve a little of the suspected salt in water, and add an alkaline lixivium to precipitate the mercury. If the precipitate was of a black colour, it was said to be a certain sign of arsentic. This, however, shows nothing at all, but that either the alkali contains some inflammable matter, which, joining with the precipitate, makes it appear black; or that the sublimate is not perfectly corrosive; for if a volatile alkali is poured on leigeated mercurius dulce, the place it touches is instantly turned black.

Mercurius dulcis, or calomel, is prepared by mixing equal parts, or at least three of quicksilver with four of sublimate; after being thoroughly ground together in a glass or stone mortar, they are to be poured through a long funnel into a bolt-head, and then sublimed. The medicine has been thought to be improved by repeated sublimations, but this is found to be a mistake. Mr. Beanné has found that mercurius dulcis cannot be united with corrosive sublimate in the way of sublimation; the former, by reason of its superior volatility, always rides to the top of the vessel.

XII. Zinc volatilized.

This femimetal dissolves readily in the marine acid into a transparent colourless liquor. It is volatilized, as well as most other metallic substan­ces by this combination, as appears from the following process delivered by Neumann.

"Equal parts of filings of zinc and powdered sal amnoniac being mixed together, and urged with a gradual fire in a retort, at first ardent, in a very gentle heat, an excessively penetrating volatile spirit, so strong as to strike a man down who should inadvertently receive its vapour freely into the nose. This came over in subtile vapours, and was followed by a spirit of falt in dense white fumes. In an open fire, white flowers succeeded; and at length a reddish and a black butter. In the bottom of the retort was found a portion of the zinc in its metallic form, with a little ponderous and fixed butyrous matter which liquefied in the air. The lump was far more brittle than zinc ordinarily is; of a reddish colour on the outside, and blackish within. The bottom of the retort was variegated with yellow and red colours, and looked extremely beautiful. The remaining zinc was mixed with earth with equal its weight of sal ammoniac, and the process repeated. A volatile alkaline spirit and marine acid were obtained as at first; and in the retort was found only a little black matter. When the zinc was taken at first in twice the quantity of the sal ammoniac, the part that preferred its metallic form proved less brittle than in the foregoing experiment, and the retort appeared variegated in the same manner. On endeavouring to rectify the butter, the retort parted in two by the time that one half had distilled." The nature of this combination is unknown.

831. With Regulus of Antimony. This semimetal can. Butter of not be united with the marine acid unleas the latter is antimony, in its most concentrated state. The produce is an exceedingly caustic thick liquid, called butter of antimony. The process for obtaining this butter is similar to that for distilling the smoking spirit of Libavius. Either crude antimony, or its regulus, may be used: for the spirit of falt will attack the regulus part of this mineral without touching the sulphurous. Three parts of corrosive sublimate are to be mixed with one of crude antimony; the mixture to be digested in a retort set in a sand-heat; the marine acid in the sublimate will unite with the regulus part of the antimony. Upon increasing the fire, the regulus arises, dissolved in the concentrated acid, not into a liquid form, but that of a thick unctuous substance like butter, from whence it takes its name. This substance liquefies by heat, and requires the cautious application of a live coal to melt it down from the neck of the retort. By rectification, or exposure to the air, it becomes fluid like oil but still retains the name of butter. If water is added to butter of antimony, either when in a butyrous form, or when become fluid by rectification, the antimony is precipitated in a white powder called powder of algaroth, and improperly mercurius vitreus. This powder is a violent and very un­safe emetic. The butter itself was formerly used as a caustic; but it was totally neglected in the present practice, until lately that it has been recommended as the most proper material for preparing emetic tartar. (See below.) Mr. Dollfus recommends the following method as the best for making butter of antimony; viz. two ounces and a quarter of the grey calc of antimony, eight ounces of common salt, and six of acid of vitriol. By distilling this mixture, ten ounces of the antimonial caustic were obtained; and in order to determine the quantity of metal contained in it, he mixed two ounces of the caustic with four ounces of water; but such a strong coagu­lum was formed, that he was not able to pour off any of the water even after standing 24 hours. The precipitate, when carefully dried, weighed 50 grains. The result was much the same when glass of antimony was used, only that the precipitate was much more confederable, half an ounce of the caustic then yielding 60 grains, and at another time only 50 grains were obtained. In the re­

**S**ympathetic ink.

**XV. With Regulus of Cobalt.** Pure spirit of salt dissolves this semimetal into a phosphoric spirit, which immediately becomes green from a very gentle warmth. On saturating the solution with urinous spirits, the precipitate appears at first white, but afterwards becomes blue, and at length yellow. If the nitrous acid is added to solutions of regulus, they assume a deep emerald green when moderately heated, and on cooling become red as at first. Duly evaporated, they yield rose-coloured crystals, which change their colour by heat in the same manner. This solution makes a curious sympathetic ink, the invention of which is commonly ascribed to M. Helvetius, though he himself acknowledges that he received the first hint of it from a German chemist in 1736. Any thing wrote with this solution is invisible when dry and cold; but assimilates a fine green colour when warm, and will again disappear on being cooled; but if the heat has been too violent, the writing still appears. M. Helvetius observes, that if nitre or borax be added to the nitrous solution, the characters wrote with it become rose-coloured when heated; and if tea-salt is afterwards puffed over them, they become blue; that with alkali sufficient to saturate the acid, they change purple and red with heat. — A blue sympathetic ink may be made from cobalt in the following manner. Take of an earthenware of cobalt, as free from iron as possible, one ounce. Brui[e it, but not to too fine a powder. Then put it into a cylindrical glass, with 16 ounces of distilled vinegar, and set the mixture in hot sand for the space of six days, stirring it frequently; or else boil it directly till there remain but four ounces. Filter and evaporate it to one half. If your solution be of a rose-colour, you may be certain that your cobalt is of the right sort. A red brown colour is a sign of the solution containing iron; in which case the process fails. To two ounces of the solution thus reduced, add two drachms of common salt. — Set the whole in a warm place to dissolve, and the ink is made.

**XV. With Regulus of Arsenic.** This substance is soluble in all acids; but the nature of the compounds formed by such an union is little known. If half a pound of regulus is distilled with one pound of corrosive sublimate, a thin smoking liquid and a brownish gummy substance will be obtained, as in making the smoking liquor of Libavius. By repeated rectifications, this butter may be almost all converted into spirit. If equal parts of the arsenic and sublimate are used, a pungent black oil comes over along with the spirit, which cannot be mixed with it. By rectification in a clean retort they will become clear, but still will not incorporate. If they are now returned upon the red mass remaining in the first retort, and again distilled, a much more pungent oil than the former will be obtained.

**Marine oil.**

**XVI. With Inflammable Substances.** The acid of sea-

falt is very little disposed to contract any union with the phlogiston, while in a liquid state; and much less so, even in its most concentrated state, than either the vitriolic or nitrous. Mr Beaumé, however, has found, that a small quantity of ether, similar to that prepared with the vitriolic and nitrous acids, may be obtained by cauling the fumes of the marine acid unite with those of spirit of wine. Others, and particularly some German Chemists, attempted to make this liquor, by employing a marine acid previously combined with metallic substances, such as butter of antimony. The smoking liquor of Libavius succeeds best. If equal parts of this liquor and highly rectified spirit of wine are distilled together, a considerable quantity of true ether is produced; but which, like the vitriolic and nitrous ether, must be rectified in order to its greater purity. The thin contained in the smoking liquor is separated and precipitated in white powder. In this process, the acid is probably more disposed to unite with the spirit of wine, than having already begun to combine with the inflammable principle of the metal. — For marine ether, Mr Dollfuss recommends to put into a retort four ounces of digestive salt previously well dried and powdered, and two ounces of manganese; pouring upon this mixture of five ounces of spirit of wine and two of oil of vitriol; the first five ounces and a half of the distilled liquor being poured back on the residuum, and the whole afterwards drawn off by a gentle heat. The spirit of salt thus obtained had a very penetrating agreeable odour, somewhat like that of nitrous ether; and at first swam upon the top of water; but at length mixed with it on being agitated for a long time. Towards the end of the distillation a little oil was obtained, which did not mix with the water; and by the addition of four ounces more of spirit of wine, more of the dulced acid was obtained. With regard to this kind of ether, however, Mr Weftromb denies that it can be made by any method hitherto known; and inflets, that all the liquids as yet produced under the name of marine ether are in reality dulced spirit of salt, and not true ether, which will boil upon the top of water.

Dr Priestley has observed, that the pure marine acid, attrac-
ted when reduced to an invisible aerial state, has a strong phlogistic affinity with phlogiston; so that it decomposes many substances that contain it, and forms with them an air permanently inflammable. By giving it more time, it will extract phlogiston from dry wood, crusts of bread not burnt, dry flesh; and, what is still more extraordinary, from flints. From what has been above related, it appears that the dephlogisticated spirit of salt has a very strong attraction for phlogiston.

Essential oil of mint absorbed the marine acid air pretty well, and pretty became one of a deep brown colour. When taken out of this air, it was of the consti-
tituents of treacle, and funk in water, smelling differently from what it did before; but still the smell of the mint was predominant. Oil of turpentine was also much thickened; and became of a deep brown colour, by being saturated with acid air. Ether absorbed the air very fast; and became first of a turbid white, and then of a yellow and brown colour. In one night a considerable quantity of strongly inflammable air was produced.

Having once saturated a quantity of ether with acid air,

New acid discovered by Mr. Homburg.

Air, he admitted bubbles of common air to it, through the quicksilver by which it was confined, and observed that white fumes were made in it, at the entrance of every bubble, for a considerable time. 2. Having at another time, saturated a small quantity of ether with this kind of air, and the phials which contained it happening to be over-turned, the whole room was instantly filled with a white cloud, which had very much the smell of ether, but peculiarly offensive. Opening the door and window of the room, this light cloud filled a long passage and another room. The ether, in the mean time, was seemingly all vanishing: but, sometime after, the surface of the quicksilver in which the experiment had been made was covered with a very acid liquor, arising probably from the moisture in the atmosphere, attracted from the acid vapour with which the ether had been impregnated. This seems to show, that however much dispersed the marine acid may be to unite with phlogistic matters when in its aerial state, the attraction it has for them is but very slight, and still inferior to what it has for water.

Camphor was presently reduced into a fluid state by imbibing this acid air; but there seemed to be something of a whitish sediment in it. After continuing two days in this situation, water was admitted to it, upon which the camphor immediately refumed its former solid state; and to appearance was the same substance that it had been before.

Strong concentrated oil of vitriol, being put to marine acid air, was not at all affected by it in a day and a night. In order to try whether it would not have more power in a condensed state, it was confined with an additional atmosphere; but, on taking off this, the air expanded again, and was not in the least diminished. A quantity of strong spirit of nitre was also put to it without any sensible effect. From these last experiments it appears, that the marine acid is not able to disolve the other acids from their union with water.

Besides the acids already mentioned, Mr. Homburg describes an artificial one generated by mixing two ounces and a half of luna cornua, with an ounce and a half of tin calcined alone and without addition, by means of fire. The mixture is to be exposed to a naked fire in a coated retort, of which two-thirds ought to be let empty; when a brownish matter, an ounce and a half in weight, will adhere to the neck of the retort. This matter is tin combined with the marine acid, and the residuum is silver deprived of the same acid, which may therefore now be melted together without any loss. The sublimate, well powdered and dried, is to be equally divided into two phials, and sublimed; by repeating which operation two or three times, a volatile salt, of an acid nature, very white and transparent, is obtained. The residuum of these sublimations is always calx of tin.

§ 4. Of the Fluor Acid.

This acid was discovered some time ago by Mr. Margraf, and more fully investigated by Mr. Scheele. The experiments by which it was originally produced, and its properties ascertained, are as follows:

I. Two ounces of concentrated vitriolic acid were poured upon an equal quantity of fluor, which had been previously pounded in a gl. mortar, and then put into a retort, to which a receiver was adapted, and the juncture closed with grey blotting paper. On the application of heat, the mass began to effervescence and swell, invisible vapours penetrated everywhere through the joining of the vessels, and towards the end of the process white vapours arose, which covered all the internal parts of the receiver with a white powder. The mass remaining in the retort was as hard as a stone, and could not be taken out without breaking the vessel. The lute was quite corroded and friable.

II. The process was repeated exactly in the same manner, excepting only that a quantity of distilled water was put into the receiver. A white spot began to form on the surface of the water, just in the centre, and immediately under the mouth of the retort. This spot continually increased, till at last it covered the whole surface of the water, forming a pretty thick crust, which prevented the communication of the water with new vapours that came over. On gently agitating the receiver, the crust broke, and fell to the bottom; soon after which a new crust like the former was produced. At last the receiver, and soon after the retort also, became white in the inside. The vessels, when cooled, were found much corroded internally. In the receiver was an acid liquor mixed with much white matter, separable by filtration.

III. This white matter when edulcorated and dried, which showed itself to be siliceous earth by the following properties.

1. It was rare, friable, and white.
2. It was not sensibly soluble in acids.
3. It did not make a tough paste with water, but was loose and incoherent after being dried.
4. It diffolved by boiling in lixivium tartar, and the solution in cooling assumed a gelatinous consistence.
5. In its pure state it suffered no change in the strongest heat; but when mixed with alkali, it boiled, frothed up, and formed a glafs in a melting heat.
6. It diffolved in borax without swelling.

IV. To determine whether this earth was formed during the process, he poured vitriolic acid upon powdered fluor contained in a cylinder of brass which was closed exactly with a cover, after having suspended over the mixture an iron nail and a bit of charcoal. On opening the vessel two hours afterwards, he found the nail and charcoal unchanged; but on moistening them, he found both covered with a white powder in a short time. This powder had all the properties of siliceous earth; and as in the experiment he had made no use of glass vessels, he concluded that it did not proceed from the glasg vessels as might have been suspected from their being so much corroded, but was generated in some other way.

V. Having recomposed fluor by saturating the artificial acid with calcareous earth, he treated the compound in flour yields the same manner as the natural fluor, with a similar similiar result; and repeating the experiment five times over, he constantly found the siliceous earth and acid diminished considerably, so that at last scarce any mark of acidity was left. Thence he concluded, that all the fluor acid united itself by degrees with the vapours of the water, and thus formed the siliceous earth. "It may be objected (says Mr. Scheele), that the fluor acid is perhaps already united by nature with a fine siliceous powder,
Mr Scheele proved the following experiment. Up to this time fluoric acid on one ounce of pure levigated fluoric tartar with alcohol, he poured three ounces of concentrated oil of vitriol, and distilled the mixture in a sand-bath, having previously put 12 ounces of distilled water into the receiver. He then took three ounces of the same acid diluted with 24 ounces of water, to which he afterwards added two ounces of pure levigated fluoric tartar previously weighed, till he attained the exact point of saturation. After the distillation he weighed the remaining lixivium; having kept up such a degree of heat for eight hours as was not sufficient to raise the vitriolic acid. On breaking the retort, and reducing the mass to powder he boiled it in a glass vessel with 24 ounces of water for some minutes; after which it he added just as much lixivium tartar as he had found before to be requisite for the saturation of three ounces of the vitriolic acid, and continued the boiling for a few minutes longer. On examining the solution, it was found to contain a vitriolated tartar perfectly neutralized, neither acid nor alkali prevailing in any degree; which showed that no vitriolic acid had passed into the receiver. The saline matter being then extracted with hot water, the remaining earth was found to weigh 9½ drachms. Two drachms of this distilled in muriatic acid, excepting only a small quantity of matter which seemed to be fluoric undecomposed, and which on being dried weighed only nine grains. Into one part of this solution he poured some acid of sulfur, and into another vitriolic acid. The former produced sedecated lime, and the latter gypsum. A third part was evaporated to dryness, and left a deliquescent salt; and the remaining part of the earth burned in a crucible, produced a real quicklime.

Thus it appeared that the real basis of sulfur is quicklime, and like-wise that the fluoric acid is different from the basis of vitriol, as appears farther from the following considerations: 1. Pure fluoric acid does not precipitate terra ponderosa, nor solution of lead in nitrous acid. 2. The same acid, when saturated with alkali of tartar, evaporated to dryness, and afterwards melted with powdered charcoal, does not produce any bilar fulphur.

Mr Monnet, in order to support his hypothesis, de- creased that flour contains any calcareous earth. In proof Mr Monnet, of which he addsuce the following experiment: Equal quantities of alkali and flour were melted together, with little or no change on the mineral; for, after having taken away by lixiviation the alkali employed, he distilled the flour remaining on the filter in nitrous acid, adding vitriolic acid to the solution; and because he obtained no precipitate, concluded at once, that flour contains no calcareous earth. Mr Scheele on the contrary affirms, that all solutions of flour yield a precipitate of gypsum whenever vitriolic acid is added to them. He explains Mr Monnet's failure, by supposing that he had diluted his solution with too great a quantity of water.

Mr Wiegell, dissatisfied with the hypothesis of Wiegell's Scheele, as well as others, concerning the flour acid, experiments on the origin of the flour acid, and its combinations. He began a new set of experiments on the mineral. Having first accurately repeated those made by Mr Scheele, he proceeded to inquire into the origin of the calcareous earth, in the following manner: Having first weighed the retorts destined for the experiment,
an accurate manner, and found that its weight was

Flour acid and its combinations.

an accurate manner, and found that its weight was
two ounces and five drachms, he put into it two ounces of calcined flour in powder, adding, by means of a glass tube, 2½ ounces of oil of vitriol. The retort was then placed on the furnace; and a receiver, which when empty weighed two ounces, two drachms, and 30 grains, and now contained two ounces of distilled water, was luted to it. The distillation was conducted with all possible care, and at last pulsed till the retort grew red hot; but it was found impossible to prevent a few vapours from penetrating through the tube. Next day the retort, separated from the receiver, was found to weigh, together with its contents, five ounces, five drachms, and 30 grains; and consequently had lost in weight one ounce, three drachms, and 30 grains. The receiver, which, with the water, had originally weighed four ounces, two drachms, and 30 grains, now weighed five ounces and three drachms, and had therefore gained one ounce and 30 grains. This gain, compared with the loss of the retort, shows that the retort lost more by three drachms than the receiver gained; so that these must have undoubtedly passed through the losing in form of vapour.

To determine the point in question, the empty vessel, with what had been put into it, were accurately weighed; when the weights and lots upon the whole were found to be as follows.

Deducting this grain of weight in the receiver from the loss of weight in the retort, we find, that three drachms were wanting on the whole, which must undoubtedly, as already observed, have been dispersed in vapour. The retort being now broken, and the dry earth both in its neck and arch separated as accurately as possible, it was found to weigh three drachms; the residuum in the retort weighed three ounces, two drachms, and 40 grains. Now, as the mass in the retort had originally weighed four ounces and four drachms, it appeared, by deducting the residuum, to have suffered, on the whole, a loss of one ounce, one drachm, and 20 grains. To determine the loss more accurately, the following calculations were made:

Here Mr Wieglet was surprised to find, that the material which came from the decomposed to have flour acid by five drachms ten grains that the mass in the retort and its had lost of its original weight; to illustrate which it was necessary to weigh the retort and receiver by themselves. The pieces of the retort now weighed only one ounce seven drachms and 50 grains; whereas, before the process, the weight of the retort was two ounces five drachms. It appeared, therefore, that it had lost five drachms ten grains, the very quantity which had been gained by the receiver. This loss had lost nothing of its original weight.

The fluid in the receiver was next diluted with four ounces of distilled water, and the whole poured on a filter, in order to separate the earthy matter with which it was mixed, and fresh water poured upon it to take out all the acid: after which the earth was dried, and found to weigh 57 grains. The clear liquor was then diluted with more distilled water, and afterwards precipitated with spirit of sal ammoniac prepared with fixed alkali. A brisk effervescence took place before any precipitate began to fall, but ceased soon after the precipitation took place. The whole mixture become gelatinous; and the precipitate, when dry, weighed two drachms. The whole quantity of earth, which was obtained in this process amounting to drachms 47 grains, which is forty-seven grains more than the retort had lost in weight. This excess is, by our author, attributed to part of the acid still adhering to it, and to the accession of some moisture from the air; to determine which he heated each of the parcels of earth red hot separately, and thus reduced them to four drachms 52 grains, which is less by 18 grains than the loss of the retort, and which, he is of opinion, must have escaped in the three drachms of vapour.

From this experiment, Mr. Wieglet concludes, that the earth produced in the distillation of flour proceeds neither from the spar nor from a combination of the acid with water, but from the solution of the glass by the soury acid. To his opinion also Dr. Grell accedes. "In distilling flour (says he), with oil of vitriol, I have found the retort as well as the receiver very much corroded. I poured the acid obtained by the process into a phial furnished with a glass stopper, and observed after some time considerable deposition. I then poured the liquor into another phial like the former; and that it might neither on the one hand attack the glass, nor on the other compose a filmous earth with the particles of water, according to Mr. Scheele's hypothesis, I added highly rectified spirit of wine. I saw, however, after some time, another considerable deposition. This seemed also to proceed from the glass that had been before disdolved, which the acid let fall in consequence of the gradual combination with the spirit of wine; otherwise we must suppose, what to me appears incredible, that the acid decomposes the spirit, attracts the water, and forms the earth."

This singular acid has been still further examined by Mr. Meyer. He informs us, that, among Mr. Scheele's experiments, he was particularly struck by one in which no earthly crust was obtained, after putting spirit of wine into the receiver. Mr. Meyer repeated this experiment, hoping, that when but little spirit was put into the receiver, he might be able to procure a new kind of ether. An ounce of finely powdered flour, which had been previously heated red hot, was put into a glas.
CHEMISTRY.

Flour acid, and its combinations.

The distillation was continued for three hours with a gentle heat: when the acid, having made its way through the bottom, put and end to the process. No crust could be perceived on the surface of the spirit; but in the place where it had been in contact with the receiver there was a thin ring of transparent jelly. The same mixture of oil of vitriol and flour was therefore again put into a retort of very strong glass, and the same spirit put into the receiver. The distillation was conducted two hours with a gentle and afterwards with a stronger, heat. When it was half over, the spirit began to change into a thin jelly; and at the end of the process some smaller pieces were found at the bottom. These were washed with spirit of wine; and in order to obtain the spirit together with the acid in a pure state, it was put into a large retort, and again subjected to distillation. As the retort grew warm, the opal-coloured spirit became clear and swelling, what remained becoming again gelatinous; a good deal of earth remained behind, but did not adhere firmly to the retort, which was smooth in the inside, though full of hollow excoriations. It was also evident, that the glafs was actually corroded, and that the earthy matter is not a mere crust adhering to the inside. The jelly being thoroughly digested, as well as the earth, that remained in the retort after the redistillation, and that which was dissolved in the water precipitated by spirit of sal ammoniac, the whole quantity amounted to two drachms. That which had separated spontaneously was semitransparent. As this earth (says he) showed the properties of silicious earth, and the glafs, which was so much corroded, consists in great measure of it, the greatest part of it might come from the glafs, and the rest of it perhaps be a constituent part of the fluid itself. In order to ascertain this it was necessary to obtain the fluor acid quite free from silicious earth. I therefore exposed the ley, which I had procured by the precipitation of the earth with sal ammoniac, to a gentle evaporation in a slightly covered glafs vessel. The product was one drachm 56 grains of an ammoniacal salt; the glafs did not appear to have been attacked. Half a drachm of this salt was sublimed in a funnel retort, which, towards the end of the operation, was laid on the bare fire. No crust appeared on the surface of the water in the receiver. At the bottom of the retort lay a little flocculent earth of a light grey colour, above which the internal surface was covered with a white pellicle that reflected various colours; and in the neck there was a sublimate. The thin pellicle easily separated in many places from the glafs, which was smooth beneath, though not without some small furrows. I poured water both upon the ammoniacal salt and crust; in consequence of which it acquired a very fine taffe, and coloured the tincture of turnfole red. The white crust that was left behind and dissolved weighed five grains, and melted into a green glafs without addition. This was nothing but the glafs that had been corroded by the flour acid; but as this acid can be set loose only by strong heat, it had done no more than corrode the glafs, without passing over along with it in the form of vapour, and then depositing it again on the water. For, upon pouring two drachms of oil of vitriol upon half a drachm of this ammoniacal salt a little moistened, and placed in a glafs retort, a great flour acid foam arose, and the thick vapours that ascended covered and heated the water in the receiver with a white crust. A scrub of the salt on solution, left behind a grain of earth, which, as I conjecture, had taken up during the evaporation in the glafs vessel.

To prevent this, our author distilled half an ounce of flour with an ounce of oil of vitriol for five hours. The cruffs were separated from th. water; they weighed, after being well washed and dried, eleven grains; they were white and very flocculent; thirty-two grains of silicious earth were precipitated from the filtered water; the ley was then evaporated in a leaden vessel and yielded 68 grains of salt. As glafs vessels were no longer to be trusted, a piece of a gun-barrel furnished with a cover, and terminated by a bent tube, intended to serve instead of the neck of a retort, was afterwards used; and with this apparatus the following experiments were made:

1. Half a drachm of the newly prepared sal-ammoniac was distilled for two hours with two drachms of oil of vitriol, into a glafs receiver containing an ounce of water. No velifice of a crust could be perceived on the water, but some earth was perceived in the receiver, where the vapours having ascended through the tube, came into contact with the wet glafs; and here the surface was become finely rough. On the addition of volatile alkali, a few flocculi of silicious earth, a mounting only to one-fourth of a grain, were thrown down out of the water.

2. A drachm of vitriol was added to a drachm and an half of the salt; but a leaden receiver was now used, containing an ounce of water as before. The water acquired an unpleasant smell, but showed no signs of a crust. On the addition of spirit of sal ammoniac, a little grey earth weighing half a grain fell to the bottom.

3. A scruple of this salt, mixed with an equal quantity of white sand in fine powder, and distilled with a formed by a drachm and an half of oil of vitriol, into an ounce of mixing water in the leaden receiver, showed no sign of a crust. The water had a putrid smell, and left on the filter two grains and an half of grey earth, which ran under the blow-pipe into a grain of lead. Volatile alkali precipitated five grains of grey earth, which melted on the addition of a little salt of tartar into a black globule, though the blow-pipe alone made no change in it.

4. To 13 grains of the fame ammoniacal salt a drachm of oil of vitriol and two scruples of green glafs, broken one by one into small pieces, were added. The iron tube had using powdert to become warm, when a great crust of silicious earth was perceived on the surface of the water, and the fame appearance on the moist sides of the vessel. It did not, however, seem to increase during the remainder of the distillation. A grain and a quarter of earthy matter remained on the filter, confiding partly of white films, and partly ran under the blow-pipe into a greenish glafs.

5. To ascertain this matter still more closely, a different species of mineral flour was used, which being distilled with a double quantity of oil of vitriol, and with a drachm of water in the receiver, yielded a thin pellicle of the appearance of lead, but no silicious crust. Volatile alkali threw down 24 grains of grey earth.
FLOUR ACID AND ITS COMBINATIONS.

C H E M I S T R Y.

489

A drachm mixed with the same quantity of pulverized sand afforded a pellucid lead interperfed with a few particles of white earth, which ran into the glafs under the blow-pipe. Volatile alkali precipitated eight grains. A drachm, mixed with an equal quantity of green glafs reduced to powder, swelled a good deal, and yielded a thick silicious crust.

6. To a drachm of green earth that had been heated and powdered were added two drachms of oil of vitriol, still employing the iron tube. A piece of wet charcoal was also suspended in the inside, a cover fixed on the tube, and the latter heated for about 15 minutes in a sand-bath. Observing now that the charcoal was dry, and had no earth upon it, a crepule of sand in fine powder was added, the charcoal was wetted and replaced, but nothing appeared. Some bits of green glafs were then thrown into the mixture which instantly foamed up and ran over. The charcoal was not replaced in the tube, nor was it any longer necessary, as it gained a covering of white powder by being held a very few moments over the orifice.

Mr Scheele, in one of his experiments, observes, that he observed the white powder on a piece of charcoal that had been moistened and suspended over flour to which vitriolic acid was added. As this experiment was made in metallic vessels, Mr Meyer conjectures, that the manner used for reducing the flour to powder was of soft glafs, and that the phenomenon was occasioned by the abrasion of some particles of glafs.

7. To determine whether the acid can carry up much more of the silicious earth than is sufficient to saturate it, an ounce and a half of pure oil of vitriol was added in a retort of glafs, and three ounces of water put into the receiver. The retort was corrodcd through in an hour’s time, and the crust on the water weighed ten grains. The liquid being then filtered and divided into two equal parts, one was precipitated with caustic volatile, and the other with mild fixed vegetable alkali. The former yielded 25 grains of silicious earth, and the latter 66 grains of a precipitate, which flowed under the blow-pipe, ran into the pores of charcoal, and gave off strong vapours of flour acid. The reason of this difference shall be explained when we come to treat of silicious earth.

8. To a mixture of half an ounce of flour and the same quantity of glafs, in powder, 12 drachms of oil of vitriol were put in a small retort, half filled with the mixture. The ingredients acted upon each other so violently that they rose up in the neck of the retort; and the operation being interminable on account of the noxious vapour they emitted, the retort was found next day covered with fuscated crystal-like hoarfrost. The experiment being repeated in a more capacious retort, and the mixture thoroughly blended by agitation, it became a thick mass, and swelled like dough in fermentation: the bottom of the retort grew very hot, and the silicious crust аппаратed on three ounces of water in the receiver. The distillation being continued for three hours, 16 grains of silicious earth were found on the surface, and the precipitate by volatile alkali weighed 66 grains; the retort was much less corroded than usual.

9. Thirty grains of this precipitate, distilled in a

VOL. IV.

with the same quantity of silicious earth, produced no silicious earth on the water in the receiver, or that with which the earth was edulcorated. The ley of fluorated volatile alkali was mixed with a solution of chalk in nitrous acid till no more precipitation took place. The mixture was passed through nitrous acid, and the precipitate edulcorated. It weighed, when dry, two drachms and 36 grains.

10. Two drachms of oil of vitriol being added to a drachm of this precipitate contained in a glafs retort, the precipitate was attacked in the cold, but no crust appeared; the heat, however, was scarce applied, when the whole surface of the water was covered, and the same phenomena exhibited which are produced by the natural flour.

11. Mr Scheele having observed that a mixture of Farther flour as transparent as mountain crystal, and oil of proofs that vitriol in a metallic cylinder, produced no appearance of the earthly silicious earth, on a wet sponge suspended on the inside, at Mr Meyer’s request he made a new experiment by adding oil of vitriol to portions of flour of this transparent kind placed in two tin cylinders; some silicious earth was put into one, and a wet sponge suspended in both. The next morning the sponge that was suspended over the cylinder which held the silicious earth, was covered with the white powder, but no appearance of it was seen on the other. The experiment was repeated by Mr Meyer with the same result, but the white crust did not appear till after a night’s standing.

12. A drachm of flour, mixed with two drachmes of oil of vitriol, afforded, after a distillation of two hours, a thin film of lead on the surface of the water in the receiver, but no silicious earth. The same mixture was afterwards distilled with the use only of a glafs receiver instead of a lead one. In the beginning of the distillation a small spot appeared under the neck of the retort, and the neck itself was covered with white powder, but it soon disappeared; and though the empty part of the receiver was corroded, yet no more than half a grain of earth was procured.

These experiments so clearly point out the origin of the silicious crust on the surface of the flour acid, that its existence as a distinct acid is now universally allowed, even by those who formerly contended for its being only the vitriolic or some other acid diffiused. Experiments of a similar kind were made by Mr Wolstenholme, who performed his distillation in a leaden retort, furnished with a glafs receiver. The water was covered with a variegated crust, and yielded a gelatinous precipitate with fixed alkali. On examining the receiver, he found its internal surface corroded, so that it appeared as if it had been rubbed with coarse sand. By substituting a leaden receiver, however, instead of a glafs one, he obtained the acid entirely free from silicious matter, and containing only a small quantity of iron and aluminous earth.

The flour acid may also be procured by the nitrous, fluoric, and phosporic acids. Mr Scheele distilled one part of the mineral with two of concentrated nitrous acid. One part went over into the receiver along with the flour acid, and a thick crust was formed on the water of the receiver. The mafs remaining in the retort was calcareous earth faturated with nitrous acid.
With an equal quantity of marine acid, that of fluor
pallid over into the receiver with a large quantity of
the mucric; the internal surface of the receiver, as
well as the water contained in it, being covered with
a white crust. The residuum was fixed alkali am-
monic acid.

Phosphoric acid digested with powdered fluor, dif-
solved a good deal of it; and on distilling this solu-
tion, the fluor acid went over together with the watery
properties of the ashes of bones.

The fluor acid procured in any of these ways is not
distinguishable from the floe of that of a fluid; in
some cases it acts as mucric acid, in others like that
of tartrar, but in most cases it flows properties pecul-
ar to itself.

With fixed alkali the fluor acid forms a gelatinous
and amorphous matter, which refuses to crystallize.
By evaporation a saline mafs was obtained, which was
in weight only the fifth part of the fixed alkali dif-
solved; did not change the color of syrup of viotars,
but precipitated lime water, and likewise the solutions
of gypsum and Ephom falt. With mineral alkali
the same phenomena were produced as with the ve-
gerable.

Volatile alkali with fluor acid formed likewise a
ejelly, which when separated from the liquor appeared
to be ftillicious earth. The clear liquid tained like vi-
trio ammoniac, and got into very small crystals, which
by sublimation yielded first a volatile alkali; and
then a kind of acid as fii amonic acid. By distillation
with chalk and water, all the volatile alkali quickly came
over. Lime water instantly threw down a regenerated
fluor, which was the cafe also with solutions of lime
in the nitrous and mucric acids.—Solution of silver
let fall a powder, which, before the blow-pipe, re-
formed its metallic form, the acid being diilipated, and
forming a white spot on the charcoal round the re-
duced silver. Solution of quicksilver in nitrous acid
was precipitated, and the powder was entirely volatile
in the fire; but a solution of corrosive sublimates re-
amained unchanged. Lead was totally precipitated
from nitrous acid; and a solution of Ephom falt was
rendered turbid. Oil of vitriol produced a flour acid
dbilled, which formed at the fame time a thick
brust on the water of the receiver. The regenerated
fluor procured either by means of lime water or solu-
tions of the earth in acids, was decomposed by fixed,
but not by volatile alkali.

With lime, magnesia, and earth of alum, this acid
became gelatinous. Part of the two latex were dif-
solved.

Gold was not touched by the flour acid either alone
mixing with that of nitre. Silver, in its metallic
state, underwent no change. Its calx, precipitated by
an alkali, was partly dissolved; but the remainder
formed an infoluble mafs at the bottom. Vitriolic
acid expelled the flour acid in its usual form. Quick-
silver was not dissolved, but its calx precipitated from
the nitrous solution was partially fo. The remaining
infoluble part of the calx united with the acid, and
formed a white powder, from which the flour acid was
expelled by the vitriolic. The fame powder formed,
by means of the blow-pipe, a yellowish glafs; which,
however, evaporated by degrees, leaving a small glo-

...
came in contact with this air, its surface became opaque and white by a foamy film, which retarded the ascent of the water, till the air insinuating itself through the pores and cracks of the crust, the water gradually rose as the air diminished; and breaking the crust, presented a new surface to the air, which was immediately covered with another crust. Thus one foamy incrustation was formed after another till every particle of the air was united to the water; and the different films being collected and dried, formed a white powdery substance, generally a little acid to the taste; but when washed in much pure water, perfectly insipid. The property of corrod ing glafs he found to belong to the fluor acid air only when hot. From some other experiments he concluded, that the fluor acid air was the same with what he had formerly obtained from vitriolic acid: but the experiments made since that time by various chemists, have now convinced him that it is an acid of a nature entirely different from all others.

By means of the fluor acid, a new art has been discovered, viz. that of engraving upon glafs. For this purpose a looking-glafs plate is to be covered with melted wax or mastic; and when the coating becomes hard, it is to be engraved upon by a very sharpened needle or other implement of that kind. A mixture of oil of vitriol and fluor acid are then to be put upon the plate, and the whole covered with an inverted China vessel, to prevent the evaporation of the fluor acid. In two days the glafs plate may be cleared of its coating, when all the traces of the needle will be found upon it.

§ 5. Of the Sal Sedativeus, or Acid of Borax.

Found in a mineral in Germany, &c.

This is a saline substance of a very singular nature, and till lately found nowhere but in borax itself. Its origin in different parts of the world is related under the article Borax; but since that article was printed, we have accounts of its being discovered in a mineral of a peculiar kind found at Lunenburg near Hartz. This is frequently transparent, but sometimes also a little opaque, and strikes fire slightly with steel. It has hitherto been found only in small crystals involved in a gypseous matter. These generally affect the cubical form, though they are sometimes irregular, and from the truncatures frequently appear to be of different kinds. One of them had fourteen faces, six small square planes, and eight hexahedral; though all these are modifications of cubes. Mr Wetttrumb analyzed it with some difficulty; but at last found that 100 parts of the mineral contained 60 of sedative salt, ten of magnesia, and ten of calcareous earth; of clay and flint five parts, sometimes ten of iron, though frequently but five. The same acid has also been discovered in Peru, and a little in Hungary from an analysis of petroleum. This bismuth arises from a rock between Pecklenice and Mofcowina. It seems at first to be white, butsoon grows black by exposure to the air. It was analyzed by professor Winter, who found it to contain a transparent oil in a butyrous form, and a true sedative salt, united with the oil by means of an excess of phlogiton. The sedative salt was first discovered by Bech, and afterwards more accurately described by Homberg; but its nature was at first very much misunderstood, being named the narcotic salt of virtil, on account of the vitriolic acid used in preparing it from the borax. From this it is separable either by sublimation or crystallization. The method of sublimation is that recommended by Homberg.

His process consists in mixing green vitriol with borax, dissolving them in water, filtering the solution, and evaporating till a pellicle appears; the liquor is then to be put into a small glafs alembic, and the sublimation promoted till only a dry matter remains in the cucurbit. During this operation, the liquor passes into the receiver; but the internal surface of the capital is covered with a saline matter forming very small, thin, laminated crystals, very shining, and very light. This is the sedative salt. The capital is then to be unluted, and the adhering salt swept off with a feather; the part of the liquor, which passed last into the receiver, is to be poured on the dry matter in the cucurbit; and a new sublimation is to be promoted as before, by distilling till the matter in the cucurbit is dry. These operations are to be frequently repeated in the same manner, till no more sedative salt can be obtained.

To obtain the sedative salt by crystallization, borax is to be dissolved in hot water; and to this solution any one of the three mineral acids is to be gradually added, by a little at a time, till the liquor be faturated, and even have an excess of acid, according to Mr Beaumé's process. The liquor is then to be left in a cold place; and a great number of small, shining, laminated crystals will be formed; these must be washed with a little very cold water, and drained upon brown paper. The sedative salt obtained by this process is somewhat denser than that obtained by sublimation; the latter being so light that 72 grains are sufficient to fill a large phial.

Sedative salt, though thus capable of being once fixed in sublimed, is not, however, volatile; for it arises only the fire, by means of the water of its crystallization; and when it has once lost its water by drying, it cannot be raised into vapours by the most violent fire, but remains fixed, and melts into a vitreous matter like borax itself. This glafs is soluble in water; and then becomes sedative salt again. A great quantity of water is required to dissolve the sedative salt, and much more of cold than of boiling water; whence it is crystallizable by cold, as it also is by evaporation; a singular property, which scarce belongs to any other known salt.

This substance has not an acid, but a somewhat project biterith, tafte, accompanied with a slight impression of ties, coollness. It neverthelesse unites with alkaline salts as acids do, and forms with them neutral salts. It is soluble in spirit of wine, to which it communicates the property of burning with a green flame. It makes no change on the blue colour of vegetables, as other acids do. It expels the other acids from their bases, when distilled with a strong heat; though these are all capable of expelling it in the cold, the acid of vinegar not excepted.

The composition of sedative salt is very much unknown, and no means sufficient for its decomposition delin's ex have hitherto been found out. Mr Bourdelin, who periments, made many experiments on this salt, found that it was unalterable by treatment with inflammable matters, with sulphur, with mineral acids diffused, or united with metallic substances, and with spirit of wine. He could
could only perceive some marks of an inflammable matter, and a little marine acid. The former discovered itself by its communicating a fulphureous smell to the vitriolic acid employed; and the latter by a white precipitate formed in a solution of mercury in the nitrous acid, by the liquor which came over on distilling the salt with powdered charcoal.

Mr Cadet, in the Memoirs of the Royal Academy of Sciences for 1766, has given an account of some experiments made by him on borax and its acid: from which he infers (1). That the acid contained in borax itself is the marine, and not fedative, salt. (2.) That it is the marine, he proves by having made a corrosive sublimate with this acid and mercurius precipitatus per /?.

That fedative salt does not enter the composition of borax itself, he proves, by the impossibility of recomposing borax from uniting the fedative salt with fossile alkali. The salt so produced, he owns, is very like borax, but unfit for the purposes of soldering metals as borax is. He therefore thinks, that, in the decomposition of borax, the principles of the salt are somewhat changed, by the addition of that acid which extricates the fedative salt; and that this salt is composed of the marine acid originally existing in the borax, of the vitriolic acid employed in the operation, and of a vitriifiable earth. (If this is true, then fedative salt either cannot be procured by any other acid than the vitriolic, or it must have different properties according to the acid which procures it.) The vitriifiable earth, he says, is that which separates from borax during its solution in water, and which abounds more in the unrefined than refined borax, and which he thinks consists of a calx of copper, having obtained a regulus of copper from it.

As he has never been able, however, to compose borax by the union of these ingredients, his experiments are by no means decisive. Mr Beaumé has asserted that it is always produced by rancid oils; but Dr Black thinks his proofs by no means satisfactory.

Sedative Salt COMBINED.

I. With Vegetable Alkali. This salt forms a compound very resembling borax itself in quality; but in what respects it differs from, or how far it is applicable to, the purposes of borax, hath not yet been determined.

II. With Mineral Alkali. This salt has generally been thought to recompose borax: and though Mr Cadet has denied this, yet as his experiments are hitherto imperfect and unsupported, we shall here give the history of that salt, as far as it is yet known.

This salt is prepared in the East Indies. It is said, that from certain hills in that country there runs a green saline liquor, which is received in pits lined with clay, and suffered to evaporate with the sun's heat; that a bluish mud which the liquor brings along with it is frequently stirred up, and a bituminous matter, which floats upon the surface, taken off; that when the whole is reduced to a thick confluence, some melted fat is mixed, the matter covered with vegetable substances and a thin coat of clay; and that when the salt has crystallized, it is separated from the earth by a sieve. In the same countries is found native the mineral alkali in considerable quantity; sometimes tolerably pure, at other times blended with heterogeneous matters of various kinds. This alkali appears to exist in borax, as a Glauber's salt may be formed from a combination of borax with vitriolic acid. For a further account see Borax.

Borax, when imported from the East Indies, consists of small, yellow, and glutinous crystals. It is refined, some fay, by dissolving it in lime-water; others, in alkaline lixivium, or in a lixivium of caustic alkali; and by others, in alum-water. Refined borax consists of large eight-sided crystals, each of which is composed of small, soft, and bitterish scales. It has been said that crystals of this size can by no means be obtained by dissolving unrefined borax in common water; that the crystals obtained in this way are extremely small, and differ considerably from the refined borax of the shops; infomuch that Cramer calls the large crystals, not a purified, but an adulterated borax. When dissolved in lime-water, the borax shoots into larger crystals; and largest of all, when the vessel is covered, and a gentle warmth continued during the crystallization. All this, however, is denied by Dr Black; who says, that in order to accomplish the purification, we have only to dissolve the impure borax in hot water; to separate the impurities by filtration, after which the salt shoots into the crystals we commonly see. During the dissolution, borax appears glutinous, and adheres in part to the bottom of the vessel. From this glutinous quality, peculiar to borax among the salts, it is used by dyers for giving a gloss to silks.

All acids dissolve borax slowly, and without effect. Its properties from them most, but not at all, tinctures metallic substances; along with which a considerable part of the borax is generally deposited. It does not absorb the marine acid of luna cornea, or of mercury sublimate. It melts upon the surface of the former without uniting, and suffers the latter to rise unchanged; the borax in both cases becomes coloured; in the first, milky with red streaks; in the latter, amethyst or purple. Mixed with sal ammoniac, it extricates the volatile alkali, and retains the acid; but mixed with a combination of the marine acid with calcareous earths, it unites with the earth, and extricates the acid. It extricates the acid of nitre without seeming to unite with the alkaline basis of that salt; nor does it mingle in fusion with the common fixed alkaline salts, the borax flowing distinct upon their surface. A mixture of borax with twice its weight of tamar, dissolves in one sixtieth of the quantity of water that would be necessary to dissolve them separately: the liquor yields, on infusion, a viscous, tenacious mass like glue; which refuse to crystallize, and which deliquesces in the air. Borax affords likewise a glutinous compound with the other acids, except the vitriolic; whence this salt is generally preferred for making the sedative salt. It proves most glutinous with the vegetable, and least with the marine. With oils, both expressed and distilled, it forms a milky, semi-faponaceous compound. It partially dissolves in spirit of wine. In conjunction with any acid, it tinges the flame of burning matters green; the precipitate thrown down by it from metallic solutions has this effect. It does not deflagrate with nitre. Puffed with inflammable matters, it yields nothing sulphureous, as those salts do which

**CHEMISTRY.**

870 **Acetous acid and its combinations.** This combination produces Vegetable a flat to exceedingly deliquescent, that it cannot be procured in a dry form without the greatest difficulty. In a liquid flat, it is well known in medicine, as a sudorific, by the name of *spiritus minuendium.* It may, however, be procured in a dry form, by mixing equal parts of vitriolic salt ammoniac and terra foluta tartari, and subliming the mixture with a very gentle heat. When the flat is once procured, the utmost care is requisite to preserve it from the air.

871 **V. With Earths.** Combinations of this kind are but Anomalous and little known. With the carboaceous and argillaceous salts, earth compounds of an astringent nature are formed. According to the author of the Chemical Dictionary, the salt resulting from a combination of vinegar with carboaceous earth easily crystallizes and does not effervesce. With magnesia the acetous acid does not crystallize; but, when inspissated, forms a tough mass, of which two drachms, or two and a half, are a brisk purgative.

872 **With Copper.** Upon this metal the acid of vine-distilled vinegar does not act briskly, until it is partly at least calcined. If the copper is previously dissolved in a mineral acid, and then precipitated, the calx will be readily dissolved by the acetous acid. The solution is of a green colour, and beautiful green crystals may be obtained from it. The solution, however, is much more easily effected, by employing verdigris, which is copper already united with a kind of acetous or tartaraceous acid, and very readily dissolves in vinegar. The crystals obtained by this process are used in painting, under the name of *distilled verdigris.*

The most ready, and in all probability the cheapest, method of preparing the crystals of verdigris is that proposed by Mr Wenzel, by mixing together the solutions of fugar of lead and blue vitriol, when an exchange of bases takes place; the lead being infantly precipitated by the vitriolic acid, and the acetous acid uniting with the copper. From 15 ounces and two drachms of fugar of lead with twelve ounces of blue vitriol, five ounces of the crystals were obtained. The precipitate of lead, though washed several times with water, never lost its green colour. It may either be used, he says, in this state, as a green pigment, or it may be made perfectly white by digestion in dilute nitrous acid.

873 **VI. With Iron.** Vinegar acts very readily upon iron, and dissolves it into a very brown and almost black liq-

876 **Acetous acid and its combinations.** This acid is plentifully obtained from all vinous liquors, by a fermentation of a particular kind, (see *Fermentation, and Vinegar.* It appears first in the form of an acid liquor, more or less deeply coloured, as the vinegar is more or less pure. By distillation in a common copper-still, with a pewter head and worm, this acid may be separated from many of its oily and impure parts. Distilled vinegar is a pure water but not a stronger acid than the vinegar itself; for the acid is originally left volatile than water, though, by certain operations, it becomes more so. After vinegar has been distilled to about half of its original bulk, it is still very acid, but thick and black. This matter continues to yield, by distillation, a strong acid spirit, but tainted with an empyreumatic oil. If the distillation is continued, a thick black oil continues to come over; and at last some volatile alkali, as in the distillation of animal substanctes. The caput mortuum left that it is not easily preserved, even when put into water; but therefore, recommends the corks to be covered with a slight coating of vitriolic matter; otherwise they would transmit moisture enough to make the flat deliquate.

875 **II. With Fossil Alkali.** This alkali, combined with the acetous acid, forms a flat whose properties are not well known. Dr Lewis affirms, that it is nearly similar to the terra foluta tartari. The author of the Chemical Dictionary, again, maintains it to be quite different; particularly that it crystallizes well, and is not deliquescent in the air; whereas the former cannot be crystallized; and even when obtained in a dry form, unless great care is taken to exclude the air, will presently deliquate.

867 **How procured.** This acid is plentifully obtained from all vinous liquors, by a fermentation of a particular kind, (see *Fermentation, and Vinegar.* It appears first in the form of an acid liquor, more or less deeply coloured, as the vinegar is more or less pure. By distillation in a common copper-still, with a pewter head and worm, this acid may be separated from many of its oily and impure parts. Distilled vinegar is a pure water but not a stronger acid than the vinegar itself; for the acid is originally left volatile than water, though, by certain operations, it becomes more so. After vinegar has been distilled to about half of its original bulk, it is still very acid, but thick and black. This matter continues to yield, by distillation, a strong acid spirit, but tainted with an empyreumatic oil. If the distillation is continued, a thick black oil continues to come over; and at last some volatile alkali, as in the distillation of animal substanctes. The caput mortuum left that it is not easily preserved, even when put into water; but therefore, recommends the corks to be covered with a slight coating of vitriolic matter; otherwise they would transmit moisture enough to make the flat deliquate.

865 **I. With Vegetable Alkali.** The produce of this combination is the *terra foluta tartari,* or salt diureticus of the fops; but to prepare this falt of a fine white faky appearance, which is necessary for falt, is a matter of some difficulty. The best method of performing this operation is, after having saturated the alkali with the vinegar, which requires about 15 parts of common distilled vinegar to one of alkali, to evaporate the liquor to dryness; then melt the saline mafs which remains with a gentle heat; after which it is to be dissolved in water, then filtered, and again evaporated to dryness. If it is now dissolved in spirit of wine, and the liquid abstracted by distillation, the remaining mafs being melted a second time, will, on cooling, have the faky appearance defired.

A good deal of caution is necessary in the first melting: for the acetous acid is easily diffusible, even when combined with fixed alkali, by fire. It is proper, therefore, that, when the salt is melted, a little should be occasionally taken out, and put into water; and when it readily parts with its blackness to the water, must then be removed from the fire. The falt, when made, has a very strong attraction for water, insomuch that it is not easily preserved, even when put into glass bottles. To keep it from deliquating, Dr Black, therefore, recommends the corks to be covered with some bituminous matter; otherwise they would transmit moisture enough to make the falt deliquate.

Acerous acid and its combinations.

875

Carrous.

to put vinegar into such earthen vessels as are glazed with lead. In the metallic state, only a drachm of lead can be dissolved in eight ounces of distilled vinegar.

If lead is exposed to the vapours of warm vinegar, it is corroded into a kind of calx, which is used in great quantities in painting, and is known by the name of cerufs or white lead. The preparation of this pigment has become a distinct trade, and is practised in some places in Britain where lead is procurable at the lowest price. The process for making cerufs is thus given by the author of the Chemical Dictionary.

"To make cerufs, leaden rolls ought to be so supported in the pots that they do not touch the vinegar, but that the acid vapour may circulate freely between the circumvolutions. The pots are to be covered, and placed in a bed of dung, or in a sand-bath, by which a gentle heat may be applied. The acid of vinegar being thus reduced into vapour, easily attaches itself to the surface of these plates, penetrates them, and is impregnated with the metal, which it reduces to a beautiful white powder, called cerufs. When a sufficient quantity of it is collected on the plates, the rolls are taken out of the pots, and unfolded; the cerufs is then taken off, and they are again rolled up, that the operation may be repeated.

"In this operation, the acid being overcharged with lead, this metal is not properly in a single plate; hence cerufs is not in crystals, nor is soluble in water: but a single property would render it unfit for painting, in which it is chiefly employed."

Though this process may in general be just, yet there are certainly some particulars necessary to make cerufs of a proper colour, which this author has omitted; for though we have carefully treated thin plates of lead in the manner he directs, yet the calx always turned out of a dirty grey colour. It is probable, therefore, that after the lead has been corroded by the steam of vinegar, it may be washed with water slightly impregnated with the vitriolic and nitrous acids.

This preparation is the only white hitherto found fit for painting in oil; but the discovery of another would be very desirable, not only from the faults of cerufs as a paint, but also from its injurious the health of persons employed in its manufacture, by affecting them with a severe colic; which lead, and all its preparations, frequently occasion.

If distilled vinegar is poured on white lead, it will dissolve it in much greater quantity than either the lead in its metallic form, or any of its calxes. This solution filtered and evaporated, yields into small crystals of an aethere sweetish taste called sugar of lead. These are used in dyeing, and externally in medicines. They have been even given internally for sputting of blood. This they will very certainly cure; but at the same time they as certainly kill the patient by bringing on other diseases. If these crystals are repeatedly dissolved in fresh acids, and the solutions evaporated, an oily kind of substance will at last be obtained, which can Acerous acid and its combinations.

878

VIII. With Tin. The combination of acerous acid with tin is volatile known, that many have doubted whether distilled vinegar is capable of dissolving tin or not. Dr Lewis observes, "That plates of pure tin put into a common vinegar begun in a few hours to be corroded, without the application of heat. By degrees a portion of the metal was taken up by the acid, but did not seem to be perfectly dissolved, the liquor appearing quite opaque and turbid, and depositing great part of the corroded tin to the bottom, in a whitish powder. A part of the tin, if not truly dissolved, is expulsed divided in the liquor; for, after standing many days and after passing through a filter, so much remained suspended as to give a whiteness and opacity to the fluid. Acid juices of fruits, substituted to the vinegar, exhibited the same phenomena. These experiments are not fully conclusive for the real solubility of tin in these acids, with regard to the purposes for which chemists have wanted such a solution: but they prove what is more important; that tin, or tinned vessels, however pure the tin be, will give a metallic impregnation to light vegetable acids suffered to stand in them for a few hours."

With regard to other metallic substances, neither the degree of attraction which the acerous acid has for them, nor the nature of the compounds formed by the union of it with such substances, are known; only, that as much of the reginule part of antimony is dissolved in this acid as to give it a violent emetic quality. See Regulus of Antimony.

Concentration of the Acerous Acid.

881

Common vinegar, as any other weak acid, may be Concentrated advantageously by frost; also may its vert spirit or the distilled vinegar of the shops: but as the gar.

In this country, is seldom or never so intense as to freeze vinegar, this method of concentration cannot be made use of here. If distilled vinegar be left in a water-bath, the most aqueous part will arise, and leave the more concentrated acid behind. This method, however, is tedious, and no great degree of concentration can be produced, even when the operation is carried to its utmost length. A much more concentrated acid may be obtained by distilling in a retort the crystals of copper, mentioned (n° 872) under the name of distilled verdigris. A very strong acid may thus be obtained, which has a very pungent smell, almost as suffocating as volatile sulphurous acid. The Count de Lauraguais discovered that this spirit, if heated in a wide-mouthed pan, would take fire on the contact of flaming substances, and burn entirely away, like spirit of wine, without any residuum.

The same nobleman also observed, that this spirit, when well concentrated, easily crystallizes without ad-

This
Chemistry.

This may seem to be the most proper method of obtaining the acetic acid in its greatest degree of strength and purity; but as the process requires a very strong heat to be used towards the end of the operation, it is possible that part of the acetic acid may be by that means entirely decomposed. It would seem preferable, therefore, to decompose pure termi foliata tartari by means of the vitriolic acid, in the same manner as nitre or sea-salt are decomposed for obtaining their acids. In this case, indeed, the acetic acid might be a little mixed with the vitriolic; but that could easily be separated by a second distillation. A still better method of preparing the acid seems to be by distilling fugar of lead with oil of vitriol. The proportion used by M. Lorenzen of Copenhagen, is three ounces of vitriolic acid to eight of the fugar of lead. Mr Dollfus recommends two parts of fugar of lead to one of vitriolic acid.

Dr Priestley, who gives us several experiments on the vegetable acid when reduced to the form of air, mentions his being easily able to expel it from some exceedingly strong concentrated vinegar, by means of heat alone. This seems somewhat contrary to the count de Lautaguis's observation of the disposition of the spirit of verdigris, as it is commonly called, to crystallize: but a still greater difference is, that the vegetable acid air extinguished a candle, when according to the Count's observation, it ought to have been inflammable. This most curious property observed by Dr Priestley is, that the vegetable acid air being imbied by oil olive, the oil was rendered less viscid, and clearer, almost like an essential oil. This is a useful hint; and, if purified, might lead to important discoveries.

Acetous acid combined with Inflammable Matter.

The only method yet known, of combining acetous acid with the principle of inflammability, is by mixing together equal parts of the strongly concentrated acid called spirit of verdigris, and spirit of wine. The result is, a new kind of ether, similar to the vitriolic, nitrous, and marine. This ether, however, retains some of the acridity and peculiar smell of the vinegar. By rectification with fixed alkali, it may be freed from this acidity, and then finel. more like true ether, but still retaining something of the smell, not of the acid, but the inflammable part of the vinegar.

If to this process a greater quantity of ether is obtained than by employing the vitriolic acid; which shows that the vegetable acid is essentially fitter to produce ether than the vitriolic. For making the acetic ether readily, Mr Dollfus recommends eight ounces of fugar of lead dried by a very gentle heat, until it looses the water of crystallization, when it will weigh five ounces and fix drachms. It is then to be put into a glads retort and a mixture of five ounces of vitriolic acid, with eight of spirit of wine, poured upon it, and the whole distilled with a very gentle fire. The first ounce that paffes over will be dulcified acetous acid, the next almost all ether; and the third ether in its purest state.

An ether may also be obtained from vinegar of wood. To make it, the most concentrated acid of this kind is to be made use of. For this purpose an em-
Acid of tartar and its combinations. 

This acid of a peculiar kind, joined with a great deal of water, and more liable to the effects of impurities; but really a compound salt, containing an alkali joined with an acid; and that the alkali produced from burnt tartar is not generated in the fire, but pre-existent in the salt.

The whole sediment contained in this experiment, is the calcareous earth combined with the acid of tartar, which may justly be called selenites tartareae. If some diluted vitriolic acid is poured upon this selenites tartareae, the vitriolic acid expels the acid of tartar, forming a true selenite with the earth, while the liquor contains the pure acid of tartar. By inspissation this acid may be made stronger, and even formed into small white crystals, which do not deliquate in the air.

A particular species of tartar extracted from forrel hath been fold for taking spots out of clothes, under the name of effenti.al fall of lemons, and which is now discovered to be the same with the acid of fugar.

This experiment was soon after confirmed by Dr Black, who farther observed, that if quicklime was used instead of chalk, the whole acid would be absorbed by the lime, and the remaining liquor, instead of being a solution of soluble tartar, would be a caustic lixivium. The most ready method, however, of procuring the pure acid of tartar seems to be that recommended by Mr Schiller in the Chemical Annals for 1787. One pound of cream of tartar thrown in as much liquid deal of water, and a quartar of a pound of oil of vitriol added by little and little, by which means a perfect solution will be obtained. By continuing the boiling, all the vitriolated tartar is precipitated. When the liquor is evaporated to one half, it must be filtered; and if, on the renewal of the boiling, any thing farther is precipitated, the filtration is to be repeated. The clear liquor is then to be reduced to the consistence of a syrup, and set in a temperate, or rather a warm place, when very few crystals will be formed, and as much acid obtained as is equal in weight to half the cream of tartar employed. If too small a quantity of vitriolic acid has been employed, the undecomposed cream of tartar falls along with the vitriolated tartar.

Acid of Tartar Combined,

I. With Vegetable Alkali. If the pure acid of tartar be combined with this alkali to the point of saturation, a neutral salt is produced, which deliquesces in the air, and is not easily crystallized, unless the liquor be kept warm, and likewise be somewhat alkaline. This salt, called soluble tartar, is used in medicine as a purgative; but as its deliquescence does not admit of its being kept in a crystalline form, it is always sold in powder.

Hence those who prepare soluble tartar, take no further trouble than merely to rub one part of fixed alkaline salt with three parts of cream of tartar, which renders the compound sufficiently neutral, and answers all the purposes of medicine. Dr Black informs us, that in medical prescriptions, where soluble tartar is ordered as a purgative along with a decoction of tamarinds, the acid of the latter will decompose the soluble tartar, and thus the prescription may perhaps be rendered inefficient. The saline mixture used in fevers is nothing but tartaric soluble salt in solution.

According to Mr Scheele, cream of tartar may be decomposed from the pure acid and alkali in the following manner: "Upon fixed vegetable alkali, a solution of the acid of tartar. Continue this till the effervescence is over; the fluid will then be transparent; but if more of the acid is added, it will become turbid and white, and small crystals like white sand will be formed in it. These crystals are a perfect cream of tartar.

Upon these principles, another method of decomposing cream of tartar might be tried; namely, adding to it as much oil of vitriol as would saturate the alkali, then dissolving and crystallizing the salt: but, by this method, there would be danger of the acid being adulterated with vitriolic tartar.

II. With Fossil Alkali. The salt produced from an Siegnette's union of cream of tartar with fossil alkali, has been long known under the names of Siegnette's salt, salt Ru-pellenfis, or Rochelle salt; but as the cream of tartar is now discovered to be not a pure acid, but adulterated with a portion of soluble tartar, possibly some differences might be observed if the pure acid was used.

This salt was first invented and brought into vogue by one Siegnette, an apothecary at Rochelle, who kept the composition a secret as long as he could. Meilrs Boylduc and Geoffroy afterwards discovered and published its composition.

To prepare this salt, crystals of mineral alkali are to be dissolved in hot water, and powdered cream of tartar added to it, and then the undecomposed, and even formed into small crystals, like white sand, will be dissolved in it. This crystal is easily distinguished from the others, not only by its breadth, but also by two distinct diagonal lines which intersect each other in the middle. The following method of preparing Siegnette's salt, recommended by Mr Scheele, is preferable to any other on account of its ease and cheapness. Thirty six ounces of crystals of tartar are to be saturated with potash, and eleven ounces of common salt dissolved in the ley. When it is grown cold, and the vitriolated tartar has subsided to the bottom, it is filtered and evaporated till a pellicle appears; the two first crystallizations yield a fine Siegnette's salt; the third contains some digestive salt; and the fourth is entirely composed of it. The reason of this formation of Siegnette's salt is, that the vegetable alkali has a greater attraction for acids than the mineral, and therefore decomposes the sea-salt, whose basis is then at liberty to combine with the acid of tartar; while the stronger marine acid takes the vegetable alkali. A salt of the same kind will be produced by adding Glau-bee's salt instead of common sea-salt.

III. With Volatile Alkali. With regard to this combination, we know as yet, that if the alkali is over-faturared with acid, a cream of tartar, almost as difficult of dissolution as that of fixed alkali, will be obtained. When the saturation has been pretty exact, a beautiful salt, composed of four fixed pyramids, and which does not deliquate in the air, is produced. It is instantly depoindown, and emits a pungent volatile smell on being mixed with fixed alkali.
CheMistry.

IV. With Earths. All that is as yet known concerning these combinations, is, that with the calcareous earth a compound not easily soluble in water is formed. The other properties of this substance, and the nature of combinations of tartaric acid with other earths, are entirely unknown.

V. With Copper. In its metallic state, cream of tartar acts but weakly on the metal, but dissolves very readily and completely than diluted vinegar can.

The solution of cream of tartar, being evaporated, does not crystallize, but runs into a gummy kind of matter; which, however, does not affect the moiure of the air. It readily dissolves in water, and makes a beautiful bluish green on paper, which has the property of always thinning, as if covered with varnish. The effects of the pure acid on this metal have not yet been tried.

VI. With Iron. The effects of a combination of iron with the pure acid have not hitherto been tried. Cream of tartar dissolves this metal into a green liquor, which being evaporated runs per deliquium. It has been attempted to substitute a solution of this kind to the liquor used in printing calceoles formed of iron and beer; but this gave a very dull brownish colour with madder. Possibly, if the pure acid was used, the colour might be improved. In medicine, a combination of cream of tartar with iron is used, and probably may be an useful chalybeate.

VII. With Regulus. See Sect. III.

§ 8. Of the Acid of Sugar.

That sugar contains an acid, which on distillation by a strong fire arises in a liquid form, in common with that of most other vegetable substances, has been generally known; but how to obtain this acid in a concrete form, and to appearance as pure and crystallizable as the acid of tartar, we were entirely ignorant, till the appearance of a treatise intitled, Differtatio Chemica, de acido Sacchari, autore Johanne Aftelio Arvidfon, 4to, Upsala.

Of the method of procuring, and the properties of this new acid, we have the following account in the Edinburgh Medical Commentaries, vol. iv. 1. To an ounce of the finest white sugar in powder, in a tubulated retort, add three ounces of strong spirit of nitre.

2. The solution being finished, and the phlogiston of the spirit of nitre mostly exhaled, let a receiver be properly fitted to the retort and luted, and the liquor then made to boil gently.

3. When the solution has obtained a brownish colour, add three ounces more of spirit of nitre, and let the ebullition be continued till the fumes of the acid are almost gone.

4. The liquor being at length empyred in a larger vessel, and exposed to a proper degree of cold, quadrangular prismatic crystals are observed to form; which being collected, and dried on felt paper, are found to weigh about 100 grains.

5. The remaining liquor being again boiled in the same retort, with two ounces of fresh spirit of nitre, till the red vapours begin to disappear, and being then in the same manner exposed to crystallize, about 43 grains of fatty spiculae are obtained.

Vol. IV.

"6. To the liquid that still remains, about two. Acid of sucrose more of spirit of nitre being added, and after-wards the whole being, both by boiling and evaporation, reduced to a dry mass, a brown, fatty, gelatinous kind of substance is produced, which, when thoroughly dry, is found to weigh about half a drachm.

"In the same manner, a similar acid, we are told, may be obtained from different faccharine substances, as gum-arabic, honey, &c.; but from none in such quantities, or so pure, as from fine sugar."

This salt possesse some very singular properties, of Presump-
Acid of fugar and its combinations.

Acid of phosphorus and its combinations.

Fia the salt appears in form of a white powder, soluble neither in water nor spirit of wine, unless the acid prevails. It has a stronger affinity with magnesia than any of the alkaline salts. With earth of alum, no crystals are obtained; but a yellow pellucid mask, of a sweetish and somewhat astringent taste; which, in a moist air, liquefies, and increases two-thirds in weight.

This acid acts upon all metals, gold, silver, platina, and quicksilver, not excepted, if they have been previously dissolved in an acid, and then precipitated. Iron in its metallic state is dissolved in very large quantity by the faccharine acid; 42 parts of iron being soluble in 55 of acid. By evaporation, the liquor shrinks into yellow prismatic crystals, which are easily soluble in water. With cobalt, a quantity of yellow-coloured crystals are obtained, which being dissolved in water, and sea-salt added to the solution, form a sympathetic ink. The elective attractions of this singular acid are, first, lime, than the terra ponde roja, magnesia, vegetable alkali mineral alkali, and lastly clays. With spirit of wine an ether is contained, which cannot easily be set on fire unless previously heated, and burns with a blue instead of a white flame.

Towards the conclusion of his dissertation the author observes, that some may imagine that the acid of nitre made use of in these experiments, may have a considerable share in the production of what he has termed acid of fugar. But though he acknowledges that this acid cannot in any way be obtained but by the assistance of spirit of nitre, he is thoroughly convinced that it does not, in any degree, enter into its composition.

What occurs to us on this subject is, that if the acid really pre-exists in the fugar, it must give some tokens of its existence by mixing the fugar with other substances besides spirit of nitre. The author himself thinks that lime acts upon the acid part of the fugar: from whence we are apt to conclude, that by mixing lime, in a certain proportion, with fugar, a compound should be obtained somewhat similar to what was formed by a direct combination of lime with the pure acid. In this case, we might conclude that the nitrous acid produces this salt, by combining with the inflammable part of the fugar, becoming thereby volatile, and flying entirely off, so as to leave the acid of the fugar pure. In the distillation of dulcified spirit of nitre, however, we have an instance of the nitrous acid itself being very much altered. This must therefore suggest a doubt that the acid salt obtained in the present cafe is only the nitrous acid deprived of its phlogiston, and united with some earthy particles.

In a treatise lately published by Mr Rigby, however, we are informed that fugar itself may be reconstituted by uniting the acid of fugar with phlogiston; which assertion, if well founded, undoubtedly decides the dispute in favour of the faccharine acid being originally contained in the fugar. Late experiments have determined it to be the same with that of foor; for which, as well as many other valuable acquisitions, the honour of chemistry is indebted to Mr Scheele.

Having dissolved as much acid of fugar in cold water as the liquor could take up, he added to this solution some lixivium of tartar drop by drop, waiting a little after each drop, and found the mixture, during the effervescence, full of small crystals, which were genuine salt of wood-foor. M. Klaproth having precipitated a nitrous solution of quicksilver with salt of wood-foor, perfectly neutralized by vegetable alkali, obtained a white precipitate; which, when evaporated and dried, and gently heated in a tea-spoon, fulminated with a noise not inferior to that of fulminating gold. Acid of fugar perfectly neutralized with vegetable alkali, afforded the same precipitate, and fulminated in the same manner.

§ 9. Of the Acid of Phosphorus.

This acid was first discovered by Homberg in phosphoric urine; afterwards by Margraaf in mustard and cruciferous plants; M. Bochante discovered it in wheat; and lastly, M. Hassenfratz has traced it in the mineral kingdom with great attention. He has found that phosphorated iron is contained in all the Prussian blues, when not purified; but that this acid is produced by the coals employed in the process, and is no constituent part of the tingeing matter. According to him it occurs almost universally in the minerals of iron which are found in the slimy strata of the earth, as well as those which are undoubtedly modern, whether primary or secondary; unless the iron be so far of a metallic nature as to be attracted by the magnet, or very near that state. It is afforded by the ochry strata, and those which contain haemastics as well as the slimy kind. Into these it is supposed to have come by the decomposition of vegetables; and to investigate this matter he examined the hibiscus palustris, solidago, virga aurea, antirrhinum, lonaria, folanum nigrum, vulgatum, flacchys palustris, artemisia Zeylandica, ruta graveolens, lycopus Europeus, carex acuta, vinca major, nepeta Pannonica, and noa Abyssina. All these plants afforded the acid of wood-foor and the phosphoric acid. The quantity of the former varied from two ounces to two drachms 18 grains of acid salt containing some calcareous earth, to two drachms 24 grains in a pound of each plant; the quantity of calcareous phosphoric salt being from one ounce six drachms 48 grains to one drachm 12 grains. M. Hassenfratz also observes, that the phosphoric acid is procured from all sorts of iron; though in some it seems to proceed from that contained in the earth, and in others from the coals employed in the reduction. The phosphoric acid is also found by Dr Marquart to be contained in the gastric juice of animals. One pound four ounces of the gastric juice of oxen gave 10 grains of a lymopathic matter, exactly like the blood in its qualities; 16 grains and six-sevenths of phosphoric acid, which with a blow-pipe was changed into a very pure and deliquescent glass of phosphorus; five grains of phosphorated lime, two grains of reftin, 14 grains of full ammonis, 29 grains of common salt, a very small quantity of an extract whose nature was difficult to ascertain; one pound three ounces six drachms and 67 grains of water; so that the solid contents were only 166th part of the bulk.

In sheep, the quantity of gastric juice was about eight ounces in quantity, of a deeper and brighter green
Acid of phosphorus and its combinations.

green than that of oxen or calves; but affording the same ingredients, though in a different proportion; though no other acid than that of phosphorus could be discovered. It was also more disposed to putrefaction.

Calves furnished from four to six ounces of gastric juice, which contained very little lymph, but afforded some quantity of dry jelly, though the whole was not equal to the proper proportion of lymph. The phosphorised lime was in the usual quantity, but the difengaged phosphoric acid in a very small proportion. The tincture was found in great quantity; to which, along with that of phosphorus, our author supposes the property of curdling the milk in the animal's stomach to be owing.

The phosphoric acid has also been found in very large quantity in the calcareous flounces of Andalusia; and Mr Klaproth has found the same combined with calcareous earth in a kind of beryl, crystallized in hexagonal prisms, called by M. Martin sparites. Formerly the best method of obtaining it was from urine, where it is contained in very considerable quantity in combination with the volatilate calcareous earth, and forming a salt called the microcosmic, or essential salt of urine.

To procure this, a large quantity of urine is to be evaporated to the consistence of a thin syrup; which, being set in a cold place, will yield, in three or four weeks, four brown-coloured crystals, which are the microcosmic salt, mixed with the urine, and other salts of urine. These crystals are to be distilled in hot water; the solution filtered whilst it continues hot, and set to crystallize again; and the solution, filtration, and crystallization, repeated till the salt becomes pure and white. In all the crystallizations the microcosmic salt flows first, and is easily distinguished and separated from the others. If the urine which remains after the first crystallization be further evaporated, and again set in the cold, it will yield more crystals; but browner and more impure than the former; and therefore requiring to be purified by themselves. From 20 gallons of urine may be obtained four ounces of pure salt; a considerable part being still left in the retortum.

In these operations the heat ought to be gentle, and the vessels either of glass or compact fome-ware. Urine being evaporated in a copper vessel, afforded only a green solution of that metal.

Concerning the nature of the microcosmic salt obtained by the above process, Mr Margraff gives the following account in the Berlin memoirs for 1746.

"Sixteen ounces of the salt, distilled in a glass retort, in a heat gradually raised, gave over eight ounces of a volatile urinous spirit, resembling that made from malm ammoniac by quicklime. The retortum was a porous brittle mass, weighing eight ounces. This, urged with a stronger fire in a crucible, bubbled and frothed much, and at length sunk down into the appearance of glasis, without seeming to suffer any further diminution of its weight in the most vehement heat.

The vitreous matter dissolved in twice or thrice its quan­ty of water, into a clear, transparent, acid liquor, somewhat thick, not ill resembling in consistence concentrated oil of vitriol. This liquor totally corroded zinc into a white powder, which, being diluted with water, appeared in great part to dissolve, fixed alkalies occasioning a plentiful precipitation. It acted powerfully upon iron, with some effervescence; and changed the metal into a kind of muddy substan­ce inclining to bluish, in part soluble in water like the preceding. It dissolved likewise a portion of regulus of antimony, and extracted a red tincture from cobalt. On lead and tin it had very little action. Copper it corre­oded but slightly. On bismuth, silver, and gold, it had no effect at all, either by strong digestion, or a boiling heat. Nor did the adding of a considerable portion of nitrous acid enable it to act upon gold."

"The vitreous salt in its dry form, melted with metal­lic bodies with a strong fire, acts upon them more powerfully. In each of the following experiments, two drachms of the salt were taken in two crucibles of the metal reduced to small parts. (1.) Gold communicated a purple colour to the vitreous salt; on weighing the metal, however, its diminution was not considerable. (2.) Silver lost four grains, or \( \frac{1}{6} \); and rendered the salt yellowish, and moderately opaque. (3.) Copper lost only two grains, or \( \frac{1}{3} \), though the salt was tinged of a deep green colour. It seemed as if a portion of the salt had been retained by the metal, which, after the fusion, was found to be whiter and more brittle than before. (4.) During the fusion with iron, flashes like lightning were continually thrown out; a phosphorus being generated from the combination of the acid with the inflammable principle of the iron. Great part of the mixture rises up in froth; which, when cold, appears a vitreous sioria, covered on the surface with a kind of metallic skin, which, on being rubbed, changes its green colour to a yellowish. The rest of the iron remains at the bottom of the crucible, half melted, half vitrified, and fpongy. (5.) Tin lost 18 grains, or nearly one-half its weight, and rendered the salt whitish; the remaining metal being at the same time remarkably changed. It was all over leavy and brilliant, very brittle, internally like zinc. Laid on burning coals, it first began to melt, then burnt like zinc, or phosphorus. (6.) Lead lost 16 grains, and gave the same whitish colour to the sioria that tin does. The remaining lead was in like manner inflammable, but burnt less vehemently than the tin; from which it differed also in retaining its malleability. (7.) Mercury precipitated from aquafortis, and well edulcorated, being treated with the salt in a glass retort, with a fire raised to the utmost, only 12 grains of mercury sublimed; 28 remaining united with the acid, in a whitish, semi-opaque mass. A solution of this mixed in distilled water, deposited a quantity of a yellowish powder; which, by distillation in a glass retort, was in great part revived into a running mercury. A part also remained dissolved in the clear liquor; for a drop let fall on polished copper instantly whitened it. (8.) Regulus of antimony melted with the vitreous salt, lost eight or nine grains, (about \( \frac{1}{6} \ )); the regulus afforded a fine, brilliant, striated appearance; the sioria were somewhat opaque. (9.) Bismuth lost eight grains; the sioria were like the preceding, but the bismuth itself suffered little change. (10.) Zinc, mixed with the salt, and distilled in a glass retort, yielded a true phosphorus, which arose in a very moderate heat. The retortum was of a grey colour, a little melted at the
Acid of phosphorus and its combinations.

the bottom, in weight not exceeding two drachms; so that two cements had sublimed. This residuum, urged further in a small Hemian crucible to perfect fusion, emitted an infinity of phosphoric flames, with a kind of detonation. The matter, grown cold, looked like the scori- no of melted glafs. (11.) White arsenic, mixed with this salt, separated in the fire, greatest part of it subliming, and only as much remaining behind as increased the weight of the salt eight or nine grains. The compound appeared at first transparent; but, on being exposed to the air, became moist, and of an o- paque white, much resembling crystalline arsenic. (12.) Cinnabar totally sublimed; suffering no change itself, and occasioning none in the salt. Sulphur did the same. (13.) One part of the salt, mixed with ten of manganse, and melted in a clofe vessel, gave a semi-transparent mafs, some parts of which were bluishe. The crucible was lined with a fine purple glaze, and the edges of the mafs itself appeared of the same colour.

The vitreous salt dissolved also, in fusion, metallic calces and earths. Chalk, with one-third its weight of the salt, formed a feelimtransparent vitreous mass: calcined marble, with the same proportion, flowed so thin as to run all through the crucible; gypsum, likewise, ran moistly through the crucible; what remained was feelimtransparent. Lapis specularis ran entirely through the vessel. Spanish chalk gave a feelimtransparent mass, which sparkled on breaking; and fine white clay, a similar one. Saxon topaz and flint were changed into beautiful opal-coloured masses; the earth of alum into a feelimtransparent mass, and quicklime into an opaque white one. The masses with flints imbued moisture from the air; the others not.

Oil of vitriol, poured upon one-fourth its weight of this salt in a retort, raised an effervescence, acquired a brownish colour, and afterwards became turbid and white. On raising the fire, the oil of vitriol diffused, and the matter in the bottom of the retort melted. In the neck was found a little sublimate, which grew moist in the air; as did likewise the remaining salt, which was opaque and whitish. Concentrated spirit of nitre, diffused with this salt in the above proportion, came over unchanged; no sublimate appeared; the residuum looked like glafs of borax. The diffused spirit did not set in the leaf upon gold, even by coction. Strong spirit of sea-salt being diffused in the same manner, no sensible change was made either in the spirit or the salt.

Equal parts of the vitrified microcosmic salt and salt of tartar being urged with the strongest fire that a glafs retort could bear, nothing feible came over, nor did the mixture appear in thin fusion. Dissolved in water, filtered, and duly evaporated, it afforded, very difticult, oblong crystals, somewhat alkaline; the quantity of alkali having been more than enough to ftaturate the acid. A whitish matter remained on the filter, amounting to seven or eight grains, from two drachms of the mixture; this, after being washed and dried, melted before a blow-pipe, as did likewise the mixture.

This salt seems to exerminate, in part, the acids of vitriolated tartar, nitre, and sea-salt. (1.) On diffus- ting a mixture of it with an equal quantity of vitriolated tartar, there came over some ponderous acid drops, which, faturated with fixed alkali, formed a neutral salt of greatly resembling the vitriolated tartar. The residuum readily dissolved in water, and diftically crystallized. (2.) Nitre, treated with the fame proportion of the salt, began to emit red vapours. The residuum was of a pech-blooming colour, appeared to have melted less perfectly than the preceding, and dissolved more difficultly in water. The solution deposited a little earthy matter; and, on being slowly evaporated, shot into crystals, which did not defagglize in the fire. (3.) Sea-salt, diffused in the same manner, manifestly parted with its acid; the residuum was whitish, readily dissolved in water, and afforded some cubical crystals. (4.) Sal ammoniac suffered no change. (5.) Borax, with an equal quantity of vitreous salt, run all through the crucibles.

"Solutions of this salt precipitate the earthy part of lime-water, of solution of alum, of flint dissolved in fixed alkali, and the combination of marine acid with chalk or quicklime. The precipitate from this last liquor is tenacious like glass, and does not difsolve even in boiling water; exposed to a strong fire, it froths prodigiously, and at last melts into a thick scoria."

"Solutions of this salt precipitate alkaline metallic solutions; as butter of antimony, solutions of silver, copper, lead, iron, mercury, and bismuth, in the nitrous acid; and of tin in aqua-regis. The precipitate of iron from spirit of salt is a tenacious mass; that of silver from aquafortis, sometimes a white powder, sometimes tenacious. Copper from aquafortis is sometimes thrown down in form of a white powder, and sometimes in that of a green oil, according to the proportions and dilutene[s] of the liquor. Silver is not precipitated at all by this acid from its solution in vinegar, nor gold from aqua-regis."

"An ounce of the vitreous salt, well mixed with half an ounce of foot, and committed to distillation, yielded a drachm of fine phosphorus. The black residuum, being elixated with boiling water, and the liquor passed through a filter, there remained upon the filter eight scruples of a black matter; and, on evaporating and crystallizing the liquor, about seven drachms were obtained of oblong crystals, which did not deliquesce in a moist air, but became powdery in a warm one. Thee crystals, treated asher with inflammable matter, yielded no phosphorus. Before a blow-pipe they melted into a transparent globular mass, which on cooling, became turbid and opaque. Dissolved in water, they precipitated solutions of silver, mercury, copper, and of chalk; though they did not act upon the latter so powerfully, nor produce with it a gluey mafs, as before they had been deprived of their phosphoric acid."
CHEMISTRY.

§ II. Of the Acid of Amber.

The nature of this acid is as yet but little known, and Mr Pott is the only chemist who seems to have examined it with accuracy. We shall therefore give an abstract of the principal observations and experiments he has made on this salt.

"Salt of amber requires a large quantity of water Mr Pott's for its solution. In the first crystallization (being experiment much impregnated with the oil which rives from the amber along with it), it shews into fowy flakes, in colour resembling brown sugar-candy; the crystals which succeed prove darker and darker coloured. On repeating the depuration, the crystals appear at top of a clear yellow or whitish colour, in form of long needles or feathers; at bottom, darker, and more irregular, as are likewise the crystals which shew afterwards. The crystals neither liquefy nor become powdery in the air: rubbed, they emit a pungent smell like that of radishes, especially if warmed a little; their taste is acid, not in the least corrosive, but with a kind of oily pungency.

"This salt, kept in the heat of boiling water, loses nothing of its weight, and suffers no alteration. In a great heat it melts like oil; after which a little oily acid arises, then oily fumes appear in the lower part of the retort, and the salt sublimes into the neck, partly in the form of a dark yellow botter, and partly in that of feathers, a black coaly matter remaining at bottom; so that, by this process, a part of the salt is destroyed.

"Oil of turpentine has no action on this salt. Highly rectified spirit of wine gains from it a yellow colour in the cold; and, on the application of heat, dissolves a considerable quantity, but deposits great part of it on cooling. The salt thus deposited is somewhat whiter than before, but still continues sensibly yellow. The dulcified spirit of salt ammoniac dissolves it readily, without effervescence, into a yellow liquor; if the salt was foul, the solution proves of a red colour; on burning of the visous spirit, a neutral liquor remains.

"A solution of salt of amber in water, saturated with a pure alkaline lixivium, yielded, on insufflation, a saline matter, which would not crystallize, and which when exsiccated by heat, deliquated in the air, leaving a considerable proportion of an earthy, unctuous matter. Being again gently insufflated, it left a brownish salt very soluble, weighing one half more than the salt of amber employed. This salt effervesced with the vitriolic and nitrous acids: the vapour, which exhaled, was not acid, but oily and sulphurous. On repeating the experiment, and fully saturating the alkali with the salt of amber, the neutral salt made no effervescence with these acids. This salt did not perfectly melt before a blow-pipe; continued in the fire for some time, it effervesced with aquafortis. In distillation it yielded a bitter, oily, alkaliescent spirit, much resembling the spirit of tartar; and towards the end, an empyreumatic oil. The residuum eluted, yielded the alkaline salt again of a brown colour.

"Salt of amber effervesces strongly with volatile alkalies; and, on saturation, forms with them an oily am-
CHEMISTRY.

Acid of Ammonia and its combinations.

Ammoniacal liquor, which, in distillation, totally arises in a fluid form, except that a small portion of a penetrating, oily, fatty matter, concretes towards the end.

On distilling salt of amber with an equal quantity of common salt ammonia, on the application of heat, the whole coagulates into the consistence of a jelly. In distillation, the spirit of salt arose first; then almost the whole of the salt of amber, partly like firm butter, partly like long-striated plumose alundum, very pure, and of a fine white colour, its oily matter being changed into a liquid form at the bottom. The salt, thus purified, makes no precipitation in the solution of silver, and concomitantly retains nothing of the marine acid; nor does it precipitate solution of quicklime made in spirit of ammonia.

Mrs. Scheele first perceived, from some experiments on manganese, that arsenic contained phlogiston; from whence he was led to an analysis of this substance, which produced an acid of a very singular kind; by uniting with which it phlogiston in certain proportions, either white arsenic or its regulus may be composed at pleasure.

White arsenic may be decomposed in two ways. Two ways

1. Put two ounces of it reduced to a fine powder in a vessel glafs mortar into a retort of the same materials; pour upon it seven ounces of pure muriatic acid, whole specific gravity is to that of water as 10 to 8; and let it upon a receiver. The arsenic is quickly dissolved in a boiling heat, which must be brought on as quickly as possible. After the solution is accomplished, while the nitrous acid is capable of dissolving arsenic behind. The nitrous acid is capable of dissolving arsenic; but this cannot be done without solution, and the nitrous acid is capable of dissolving arsenic only in

Practice.

Acid of arsenic and its combinations.

Solution of salt of amber makes no precipitation in solution of silver or quicksilver. It dissolves zinc as all acids do: fixed alkalies precipitate the zinc; the volatile do not; and when a sufficient quantity of the volatile has been added, the fixed make no precipitation. It acts exceedingly slowly and difficulty upon copper; but corrodes calcined copper in a shorter time. It foons corrodes iron, by coction, into a crocus, and dissolves a part into a liquid form: the solution has little colour; but alkaline salts readily discover that it holds iron, by rendering it turbid and whitish, and throwing down a considerable quantity of a greenish calx.

§ 12. Of the acid of arsenic.

The receiver is then to be put on again, but not luted; the mixture soon begins to effervescence, and red vapours go over into the receiver. The distillation is to be continued till these vapours cease; when an ounce of finely powdered arsenic is again to be added, the receiver applied as before, and a gentle ebullition continued till the second quantity of arsenic be dissolved. The ounce and an half of nitrous acid is then to be added, and the mixture distilled to dryness, increased the fire towards the end, so as to make the retort red hot. The acid which comes over into the receiver may serve again several times. The white mafs which remains in the retort is the dry acid of arsenic. It may be reduced to a liquid form by pouring upon it, in coarse powder, twice its weight of distilled water, and boiling for a few minutes, pouring back the liquor which comes over, and afterwards filtering the solution through blotting paper, which has been previously washed in hot water.

In this process the nitrous acid attacks the phlogiston of the arsenic, is volatilized in consequence of its union with it, and leaves the more fixed but less powerful acid of arsenic behind. The nitrous acid would alone be sufficient for this purpose, could it accurately come into contact with the particles of arsenic; but this cannot be done without solution, and the nitrous acid is capable of dissolving arsenic only in
Acid of arsenic and its combinations.

By dephlogisticated spirit of salt.

Acid of arsenic equal-ly poison-ous with the white arsenic it-self.

Proportion to the water it contains. Too great a quantity would therefore be required were this acid to be used by itself; but by the use of muriatic acid for the solution, a smaller quantity of spirit of nitre is admitted to intimate contact with all the arsenic particles, and has an opportunity of depriving them of their phlogiston. Aqua-regia might be poured upon the arsenic at once; but the greatest efficacy it excites would throw the mineral up to the top in such a manner that the menstruum could not act upon it. By the operation of dephlogistication, arsenic loses a fifth part, which is supposed to be pure phlogiston.

The other method of decomposing arsenic is, by means of the dephlogisticated spirit of salt. For this purpose, take one part of powdered manganese, and mix it with three of the muriatic acid above-mentioned. Put it into a retort, of which it may fill one-fourth; a receiver containing one-fourth of powdered arsenic, with one-eighth of distilled water, is to be luted on, and the retort put into a cold bath. The dephlogisticated muriatic acid, going over into the receiver, is instantly absorbed by the arsenic; which some hours afterwards will be dissolved, and two different liquid sirups, which cannot be mixed together, will be perceived in the receiver. This solution is now to be put into a clean glass retort, and distill'd to dryness; increasing the fire at last to such a degree as to make the whole red hot: and in this process also two different liquids pass over into the receiver which do not unite together.

Here the manganese attracts the phlogiston of the muriatic acid; and as this dephlogisticated acid has a very firm attraction for phlogiston, it deprives the arsenic of its phlogiston, and thus recomposes the ordinary dephlogisticated muriatic acid. This portion of recomposed acid dissolves part of the arsenic, forming with it what is called butter of arsenic. The other part of the arsenic which has been decomposed, dissolves in the water, and forms a liquid specifically lighter than the butter, and therefore swims above it. On rectifying the two liquids, the undecomposed portion of the arsenic arises along with the muriatic acid, and goes over into the receiver in form of an heavy oil, while the acid of arsenic remains behind in the retort.

The acid obtained in this way is precisely the same with the former; and one would hardly believe that it is an acid, because it has no acid taste; but after some days it grows moist in the air, and at last deliquesces, assuming the appearance of oil of vitriol. As the deliquesce, however, is very slow, it is proper to distil off in a certain quantity of water, when a small quantity of white powder remains undissolved, after preparing it by the fire, which is siliceous earth derived from the retort. This ought to be carefully separated from the acid by filtration; and in order to prevent the glue of the blotting-paper from mixing with the acid, it was directed to wash the filter with hot water previous to the operation.

The first experiment of Scheele tried on this acid after he had obtained it, was to discover if it was as noxious to animals as when combined with phlogiston. Having mixed a little with honey, the flies that eat of it died in an hour; and eight grains reduced a cat to the point of death in two hours. Some milk, however, being then given to the animal, it vomited violently, and ran away.

2. An ounce of dry acid of arsenic, heated in a small phial near the point of ignition, melts into a clear liquid, which congeals when cold; but if the heat be increased till the vessel begins to melt, the acid begins easily to boil, fumes its phlogiston, and arsenic sublimes in greater quantity as the heat is longer continued. After subjecting the acid to this violent heat in a retort for an hour, the vessel melted, and the acid had risen up as high as the neck.

3. In a crucible the arsenic attracts phlogiston in greater quantity, and is entirely disfigur'd in arsentic vapours; a little clear and difficultly fusible glass, consisting of clay and the acid of arsenic, remaining in the crucible.

3. With powder of charcoal the arsentic acid undergoes no change; but if the mixture be put into a and sub-retort, the moisture all driven off, a receiver then luted on, and the heat increased till the bottom of the retort coal. The arsenic becomes red hot, the whole mafs takes fire with violence; all the acid is reduced, and sublimed into the neck of the retort; a shining regulus is obtained, mixed with a little arsenic and charcoal dust. A few drops of water are found in the receiver, but they do not contain a particle of acid.

4. The arsentic acid, after some days digestion, appears with oil of turpentine, unctuous oil, and sugar, becomes once with black and thick. If some muriatic acid be distilled with oil of turpentine, &c., with this little nitrous acid added, and the distillation repeated, some acid of arsenic is left behind. Spirit of wine undergoes no change either by digestion or distillation with arsentic acid.

5. Six parts of acid digested with one of sulphur with sulphur, no change; but when the mixture is evaporated phlegmonously, to dryness, and then subjected to distillation in a glass retort, the two unite with great violence at that degree of heat in which sulphur melts; and the whole mafs rises almost in the same instant, in form of a red sublimate; a little sulphureous acid in the mean time going over into the receiver.

6. Acid of arsenic, saturated with vegetable fixed Combined alkali, forms a deliquecent salt which does not cry with vegetable, but turns syrup of a violet green, though it table fixed alkali produces no change on the tincture of lacmus.

On the addition of a little more acid, however, it redissolves lacmus, but makes no alteration on the syrup of violets, the liquor will afford fine crystals like Mr Macquer's neutral salt of arsenic. On keeping this salt for an hour in fusion in a crucible covered with another layer upon it, the inside of the vessel was found covered with a white glazing, and a salt remained, which was still the same arsentic salt with excess of acid.

7. On distilling this salt in a retort with an eighth of this part of charcoal-dust, it began to boil violently decomposing as soon as the retort became red-hot, and a very fine fire fed by regulus of arsenic sublimed. The black residue contained the alkali entirely separated from the arsentic acid.

8. With mineral alkali the acid of arsenic forms Combined crystals when perfectly neutralized, but not if added with minute excess. In that case, the mafs becomes deliquecent alkali like the former when neutral.

9. With volatile alkali a salt much resembling the With voila- two side alkali.
two former is produced. It does not change lacmus, but turns the syrup of violets green. A gentle heat drives off part of its volatile alkali, and leaves the remainder supersaturated with acid; in which case it shows into long radiated and deliquescient crystals. Thence, urged by a stronger heat, part with the whole of their alkali, which is partly decomposed; some arsenic is formed by the union of the phlogiston of the alkali with part of the arsenic acid; the remainder of which assumes a milky colour, and lies in the bottom of the retort.

10. Acid of arsenic diffused with vitriolated tartar expels the vitriolic acid in a violent heat, which comes over in a concentrated but sulphuriculate state, leaving the arsenic falt formed of the acid and alkali united. With Glauber's salt the vitriolic acid also rises, and with the fublimated earth, with a little sulphuric acid, it passes over into the receiver. The refiduum diffuses with difficulty in the vitriolic acid, though some crystals of alum will form in the space of two months.

20. Four parts of arsenic acid mixed with one with white powdered white clay, did not dissolve any part by clay digestion for a fortnight. By distillation in a retort till the vessel began to melt, it was converted into a thick flux, and a little arsenic sublimed. By mixing the refiduum with a little powdered charcoal, a shining regulus was sublimed.

21. Terra ponderosa diffuses readily in the acid of With terra arsenic, but precipitates again as soon as it has attained ponderosa, the point of saturation. The solution is precipitated by acid of vitriol, and forms regenerated ponderous spar.

22. Gold is not acted upon by acid of arsenic, either With gold, by digestion or otherwise; nor is its solution precipitated, though the retorts used in the operation were stained with red and yellow spots, which could not be taken off; nor is its action increased by mixture with muriatic or with nitrous acid.

23. Pure platina is not acted upon. Its solution Platina, is not precipitated by the pure arsenic acid, but readily by the arsenic farts. The precipitate is yellow, and diffuses in a large quantity of water, but contains no mark of arsenic acid. Addition of muriatic or of nitrous acid makes no change in its effects.

24. Pure silver is not acted upon by the arsenic acid in digestion. On augmenting the fire till the acid melted, and keeping up this degree of heat for half an hour, the metal dissolved, and on breaking the retort, a colourles glassy mass, nearly transparent, was found in it; the retort being covered with a flame-coloured glazing, which could not be separated from it. By a great degree of heat the silver was reduced without addition. Solution of silver is precipitated by pure acid of arsenic, but more effectually by the neutral arsenic farts: the precipitate is of a brown colour, and by digestion in muriatic acid is changed into niter corne; it is also soluble in spirit of fal ammoniac prepared with quicklime. The action of the arsenic acid upon silver is considerably increased by mixing it with spirit of sea-falt; the former attacking the phlogiston of the metal, while the latter attacks its earthly basis.

25. Quicksilver is not acted upon by digestion with Quick-arsenic acid. On putting the mixture into a retort, silver distilling to dryness, and then increasing the fire, the mass becomes yellow, quicksilver rises into the neck of the retort, with a little arsenic, and some yellow sublimate; but though the fire was augmented till the retort began to melt, the mass could not be fused. Three drachms and an half of quicksilver were obtained out of six employed in the experiment: the arsentic acid, therefore, contained while in the mass was somewhat yellow; it diffused very readily in muriatic acid, but scarcely at all in the nitrous or vitriolic; on evaporation to dryness and distillation, some corrosive sublimate
With copper.

27. Arsenical acid dissolves copper by a digesting heat. The solution is of a green colour; a quantity of light blue powder is deposited, and attaches itself to the copper. This powder consists of the acid of arsenic and calcined copper. On mixing two parts of dry acid of arsenic, in fine powder, with one of filings of copper, and digesting the mixture, some arsenic rose into the neck, and the mass melted and turned blue. On boiling it with water, the solution was similar to one made directly from acid of arsenic and copper. A little copper remained in the bottom of the retort, which was tinged with brown, red, and yellow spots, insoluble in any menstruum. The solutions of this metal are not precipitated by arsenical acid, but the action solution is neutral. Arsenical fahs throw down a blue precipitate, which by exposure to a strong fire, turns brown and covers the inside of the containing vessel with a yellow enamel. On mixing the scoria in a fine powder with a little lamp-black, some fine regulars of arsenic sublimed, and the copper in the residuum was reduced.

28. With iron. Iron the acid of arsenic forms a gelatinous solution, which by exposure to the air grows so thick that in two hours' time it will not flow out at the mouth of a phial. With alkali of tartar a whitish green powder is thrown down; which being edulcorated and distilled in a glass retort, yields some arsenic, and leaves a red ochre behind. On distilling four parts of arsenical acid with one of iron filings, the mass effervesces strongly towards the end; and when it became dry, took fire in the retort upon increasing the heat, when both arsenic and regulars of arsenic were sublimed. The residuum was black, friable, and contained but little acid of arsenic; the retort was covered with yellowish brown spots. Solutions of iron in mineral acids are not precipitated by acid of arsenic, but the acetic solution lets fall a dark brown powder. All the solutions are precipitated by the arsenical neutral fahs, the precipitates by a strong fire, converted into black scoria; which mixed with powdered charcoal, and calcined, yield copious vapours of arsenic, and are afterwards attracted by the magnet.

29. With lead. Lead digested with arsenical acid turns black at first, but in a few days is surrouned with a light greyish powder, containing some arsenic which may be separated by sublimation. On distilling one part of shavings of lead with two of dry acid of arsenic, the lead was dissolved, the mass flowed clear, and a acid of little arsenic rose into the neck of the retort. A part of the milky glass was found in the bottom, which by boiling in distilled water, let fall a quantity of white powder, the supernous acid being dissolved in the water; the edulcorated powder yielded regulars of arsenic by distillation with charcoal. Solutions of lead in nitrous and muriatic acids are precipitated by arsenical acid.

30. Tin digested with acid of arsenic becomes first with tin, black, then is covered with a white powder, and afterwards becomes gelatinous. One part of tin filings distilled with two of acid of arsenic, took fire as soon as the retort became red-hot, and immediately after both arsenic and a little regulars were sublimed. The tin was dissolved into a limpid liquor, which became milky when cold.—By washing in water, a quantity of white powder was separated, insoluble in any acid, and containing very little of that of arsenic.

31. Arsenical acid dissolves zinc with effervesence. With zinc. The metal grows black, and the transparency of the acid is destroyed by a quantity of black powder. This powder edulcorated, dried, and put on an iron plate heated nearly red-hot, emits a blue flame and white arsenical smoke in the dark, leaving behind a white powder; thus manifesting itself to be mostly regular of arsenic. One part of filings of zinc distilled with two of acid of arsenic, took fire in the retort with a very bright flame, and burst the vessel with an explosion. Some regulars of arsenic and flowers of zinc were found in the neck.

32. Bismuth digested with acid of arsenic is covered with bismuth precipitated by the pure acid, while precipitates the solution and the precipitate consists of calcined bismuth and acid of arsenic. On distilling one part of the bismuth with three of arsenical acid, the mass melted, the metal was calcined, but remained undissolved in the bottom of the vessel; a little arsenic rose into the neck; and after the retort became cool, water was poured on the residuum, which dissolved the acid, but the calc of bismuth remained unchanged. Solution of this metallic in the acid of nitre was precipitated by arsenical acid. This precipitate, as well as the calx, are very difficult of fusion, but on adding a little powdered charcoal, the mixture instantly melts, the arsenic goes off in vapours, and the bismuth is reduced.

33. With regulars of antimony a quantity of white regulars of powder is produced by digestion, and the clear solution is likewise precipitated by dropping it into pure water. This powder is soluble only by muriatic acid, and may be precipitated again by the addition of water. One part of regulars of antimony digested with three parts of arsenical acid, took fire as soon as the mass melted, and regulars of arsenic with a red matter were sublimed; a little volatile sulphureous acid came over into the receiver. On boiling the residuum in water, the acid was dissolved, a white flaming powder remained behind, which on being mixed with charcoal powder and distilled, an ebullition took place, some regulars of arsenic rose into the neck of the retort, and the antimony being reduced. Bottle of antimony was not precipitated by the pure acid, but very readily by the arsenical fahs. Acetas and tartaraceus solutions of glas of antimony are precipitated by arsenical acid.
Acid of arsenic and its combinations.

With cobalt.

34. Cobalt is partially dissolved, and the solution assumes a rose-colour; on putting the whole mass into a retort, distilling off the liquid, and then augmenting the fire, the mass melted, and a little arsenic was sublimed. The residue when cold had a semi-transparent violet colour. On pouring water upon it, and putting it on hot sand, the acid was dissolved, the violet colour disappeared, and the solution assumed a dark-red colour. The bottom of the retort had a blue tinge, which could not be taken off. Solutions of cobalt in mineral acids are readily precipitated by the arsenical neutral salts. The precipitate is of a rose-colour, but melts with difficulty into a dark blue liquor.

With nickel.

35. Nickel, with acid of arsenic, assumes a dark green colour, and lets fall a green powder containing arsenic in its substance, which may be separated from it by a gentle heat. One part of nickel diffused with two of dry arsenical acid, melted with some appearance of inflammation, yielding some arsenic at the same time. The mass was yellow, with a number of grey elevated streaks upon it, which appeared like vegetation, and were formed during the distillation. On boiling the yellow mass in water, the acid was dissolved, leaving a yellow powder behind; which, when treated with charcoal-powder, yielded regulars of arsenic, but was not reduced itself. The solutions of nickel in acids are not precipitated by arsenical acid, nor even that in vinegar, but the usual arsenical falls throw down a white green powder.

With manganeous.

36. Manganese in its natural state is dissolved only in small part; but when phlogisticated it dissolves readily and totally; though, whenever the acid arrives at the point of saturation, the solution coagulates into small crystalls.

With regulus of arsenic.

37. Regulus of arsenic digested with its own acid soon becomes covered with a white powder, which is arsenic in substance. On distilling one part of the regulus with two of the acid, the former sublimed and the latter melted. If small pieces of regulus of arsenic be gradually added to the acid of arsenic in fusion, an inflammation takes place, and arsenic is sublimed.

Strange phenomenon of arsenic with terra-follitacea tarratii.

On distilling a mixture of equal parts of terra-follitacea tarratii and arsenic, a limpid liquid like water first came over, settling strongly of garlic; on changing the receiver, a liquor of a brownish red colour was collected, which filled the receiver with a thick cloud, emitting an intolerable smell of arsenic. On pouring this upon a filter, hardly a few drops had passed when a very thick thinning broke suddenly arose as high as the ceiling of the room; an effusion ensued towards the edge of the filtering-paper, and a fine red-coloured flame broke out, that lasted for some moments.

§ 13. Of the Acid of Molybdena.

We owe this, as well as the succeeding acids to the industry of the late Mr Scheele. The substance from which he extracted it is named by Cronstedt molybdena membranacea nitris. As this substance is of a flaky nature, and incapable of pulverization by itself, our author mixed some pieces of vitriolated tarratii along with it in a glass mortar; by the action of which it was at last reduced to a fine powder, and which was afterwards freed from the vitriolated tarratii by washing with hot water. He then treated this powder with all the known acids, but found none of them to have any effect upon it except those of arsenic and nitre. No sensible effect was perceived from the action of nitric acid; but when the acid was heated to a red heat, after which, by increasing the fire, a little yellow orpiment was sublimed in the neck of the retort, and some sulphureous acid passed over into the receiver. On pouring two parts of concentrated nitrous acid upon one part of powdered molybdena, the mixture was scarce warm in the retort, when it passed altogether into the recipient with great heat, and in the form of dark red vapours. Had the quantity been larger, he had no doubt that it would have taken fire; for which reason the experiment was repeated with diluted nitrous acid. Six ounces of diluted nitrous acid being poured on an ounce and a half of powdered molybdena, no effect was perceptible till the liquor began to boil, after which a great number of red elastic vapours began to appear, and the mixture swelled considerably. The distillation being continued to dryness, the residuum appeared of a grey colour; the same quantity of nitrous acid was poured on, and the process repeated, when the residuum was whiter; and on still repeating the operation a fourth and fifth time, the remaining powder became at last as white as chalk. This residuum, after being edulcorated with hot water, was quite tasteless and inoffensive when dry. The limpid liquor which ran from it being evaporated to half an ounce, first assumed a fine blue colour, and then grew thick. On being examined, it was found to contain some iron, and was otherwise chiefly acid of vitriol. The colour disappeared on diluting the acid with water.

The white powder just mentioned is the true acid of molybdena, and may be obtained by the help of fire alone. A small piece of molybdena exposed on a silver plate to the blow-pipe, makes a beautiful appearance, when the white vapours attach themselves to the plate in the form of small shining scales, in the direction of the flame. This white sublimate becomes blue whenever it is in contact with the blue flame; but changes to white whenever the point of the flame is directed against it. An ounce of powdered molybdena was mixed with four ounces of purified nitre, and detonated in a crucible heated thoroughly red hot. The mass thus obtained was of a reddish colour. On diluting it in water, the solution was clear and colourless. A small quantity of red powder fell to the bottom of the vessel; which, when dry, weighed 11 grains, and showed itself to be an iron ochre; by evaporation vitriolated tarratii and nitre were obtained; but a good deal of liquivium remained, which refused to crystallize, though no mark of superfluous alkali remained. It was then mixed with some water, to which diluted acid of vitriol was added, until no more precipitate fell. The while powder which precipitated weighed three drachms; but if too much acid be added, the precipitate will be redissolved, and the water itself retains a part of it in solution. A precipitate is likewise obtained by means of nitrous or muriatic acid.

The precipitate thus obtained, like those which result from the two former processes, is the true acid of calamine molybdena, and has the following chemical properties.
The solution reduces lacmus, coagulates a solution of brass, and precipitates their sulphur. 2. If this solution be boiled with the filings of any of the imperfect metals, it affumes a bluish colour. 3. By the addition of a little alkali of tartar, the earth becomes soluble in greater quantity in water; and after evaporation shoots into small, pointed crystals. 4. Under the blow-pipe this earth is blackened by charcoal but, when placed on a silver plate it melts, and evaporates with the same phenomena as molybdæna itself. 5. By the addition of alkali, the earth is deprived of its property of being volatilized in the fire. 6. The solution, whilst hot, shows its acid power more evidently than when cold, and tinges lacmus of a deeper colour. It effervesces with chalk, with magnesia, and with earth of alum; with all of which it forms fumes very difficult of solution in water. 7. It precipitates, from the nitrous acid, silver, quicksilver, and lead, as also lead disolved in marine acid. These precipitates are reduced on burning charcoal, and the melted metal runs into the pores. Corrosive sublimate is not precipitated; neither are the solutions of the other metals. 8. Terra ponderosa is also precipitated from the nitrous and marine acids; and the precipitate is soluble in a large quantity of cold water. None of the solutions of the other earths are precipitated. 9. Fixed air is also expelled by this acid from the fixed and volatile alkalies, and forms with them neutral farts which precipitate all other metallic solutions. Gold, corrosive sublimate, zinc, and manganese, are precipitated in form of a white powder; iron and tin, from their solution in marine acid, of a brown colour; cobalt of a rose colour; copper of a blue; the solutions of alum and quicklime, white; and if the ammoniacal salt formed by the earth of molybdæna and volatile alkali be distilled, the earth parts with its alkali in a gentle heat, and remains in the retort in form of a grey powder. 10. Concentrated vitriolic acid dissolves a great quantity of this earth by means of heat. The solution acquires a fine blue colour; which, however, disappears on being heated, or by diluting the acid with water. In a stronger heat the acid flies off, leaving the earth unaltered behind. This solution becomes thick on cooling. 11. The nitrous acid has no effect upon the earth of molybdæna. 12. Boiled with the muriatic acid it dissolves in considerable quantity; and, on distilling the mixture to dryness, a dark-blue residue remains. On increasing the heat, white flowers arise, with a little blue sublimate, and a smoking muriatic acid is found in the receiver. The residue is of a grey colour. These flowers are only the earth of molybdæna volatilized by means of the muriatic acid, and therefore manifests the same properties. 13. If one part of this earth be distilled with two parts of vitriolated tartar, a little vitriolic acid passes over, at least when the heat is very strong; and the remaining earth is more soluble in water than before. With two parts of nitre it expels, by means of distillation, a strong nitric acid; the residue disolved in water is a neutral salt which precipitates all metallic solutions; and is similar to that formed by a direct union of the acid and fixed alkali. 15. Distilled with two parts of pure common salt, the acid is expelled in a smoking state, and white, yellow, and violet-coloured flowers arise, which become moist in the air, and when sprinkled on metals give them a blue colour. These flowers, as has been already remarked, are only the acid of molybdæna volatilized by that of sea salt. The blue colour acquired by this earth on the contact of lime, also in the moist way in some cases, shows that it is capable of contracting an union with the phlogiston. To reduce this to certainty, Mr Scheele distilled some of the earth of molybdæna in boiling water, with the addition of a little alkali. In this solution he poured some drops of muriatic acid, and divided it into several parts, into each of which he put filings of several metals. The solutions soon acquired a bluish colour, which grew deeper and deeper; and in a short time, during which the bottle was now and then shaken, the liquor assumed a dark blue. That this colour depends on phlogiston, he infers from the following circumstances: 1. If, instead of the metals themselves, you take their calces, no blue colour is produced. 2. If there be dropped into the blue solution a few drops of acid of nitre, and the solution be then put into a warm place, the colour disappears. It is therefore no matter of surprise, that both silver and quicksilver should be attacked, since a double selective attraction takes place; the muriatic acid uniting with the metallic calx, and the earth of molybdæna with the phlogiston of the metals. Gold, however, is not attacked in this way. 3. Too great a quantity of muriatic acid produces not a blue but a yellowish colour, which, at last turns brown if the mixture be digested; but in adding this solution to a solution of the earth of molybdæna, a blue colour as usual is produced. 4. Lithium fanginis, in which the acid prevails, throws down the earth of a brown colour, and the infusion of galls of a dark brown. The acid of molybdæna, treated with various fluxes, shows no effect, and with charcoal, shows no signs of containing any sign of corrosive sublimate, but remained in the retort in the form of a black powder; which, on being calcined in a crucible, sublimed in white flowers as usual. On inverting another crucible into the former, and luting the juncture, the earth remained unchanged and of a black colour, without any sign of fusion. This black powder did not dissolve in boiling water, nor even with alkali, which on other occasions so readily dissolves it; but when mixed with a triple quantity of salt of tartar, a great effervescence ensued; the produce was a neutral salt resembling that formed by the direct union of the acid and alkali.
Molybdaena recomposed by uniting its acid with sulphur.

§ 14. Of the Acid of Lapis Ponderosus, Tungsten, or Wolfram.

This substance has been analysed both by Mr Scheele and Mr Bergman, though the former has the merit of discovering the acid contained in it; which the latter considers, as well as the earth of molybdaena, not as truly acid, but as metallic earths. Mr Scheele's experiments for analysing this substance were as follow:

1. On one part of finely powdered tungsten were poured three parts of concentrated acid of vitriol. By distillation the acid passed over unchanged; the residuum, which was of a bluish colour, after being boiled for a short time, and the liquor filtered off, deposited some vitriolated lime or gypsum by standing.

2. Twelve feruples of common nitrous acid, or pure aquafortis, being poured on two of finely powdered tungsten, it became a little from the vitriolated tartar; and consequently there can appear but a slight vestige of vitriolic acid. This small quantity of acid likewise occasioned its more easy solubility in water.

3. The pure acid of molybdaena recomposes that substance by being combined with sulphur. Mr Scheele having mixed some very fine powder of this earth with sulphur, he subjected the mixture to distillation in a glass retort, the receiver was filled with the superfusible sulphurous vapours, which had also the feitid smell of volatile spirit of sulphur. In the retort a black powder remained, which on every chemical trial was found to be a true molybdaena; so that there is no doubt of this substance being composed of a particular kind of acid united to sulphur.

4. Boiled with a small portion of the nitrous or marine acids, the powder becomes yellow, and with the acid of vitriol bluish.

5. By faturating a solution of the acid with fixed alkali, a neutral salt is obtained.

6. With volatile alkali this acid forms an ammoniacal salt, that of nitre with the acid of tungsten.

7. Tungsten forms a salt very difficult of solution.

8. It precipitates a white colour from solutions of iron, zinc, and copper, in the vitriolic acid; silver, quicksilver, and lead, in that of nitre; and lead in the acid of caustic tartar. In combined with the same acid is thrown down of a blue colour; but corrosive sublimate and solutions of gold undergo no change. 9. On calcining the acid of tungsten in a crucible, it loses its solubility in water. 10. It turns black by calcination with inflammable matters and with sulphur, but in other respects continues unaltered.

11. Solution of hepar sulphuris is precipitated of a green colour by this acid, and the phlogificated alkali white; the latter precipitate being soluble in water. On the addition of a few drops of muriatic acid to a solution of the acid
Differences between the acid of tungsten and molybdæna.

Why he supposed the acids to be metallic.

Practice.

Acid of lapis ponderosus and its combinations.

Differences between the acid of tungsten and molybdæna.

Mr. Bergman observes, that the acid of tungsten is nearly allied to that of molybdæna; and both are in a state much resembling that of white arsenic. "It is well known (says he) that arsenic, in its gemmetalic state, is nothing but a peculiar acid saturated with phlogiston; and that the white calx is an intermediate state between acid and metal, containing just phlogiston enough to coagulate the acid, but remaining still soluble in water, and showing signs of acidity. If a conclusion from analogy be admissible, all the other metals should confide in a combination of the same nature of the different radical acids, which with a certain quantity of phlogiston are coagulated to a dry earthy substance; and on full saturation are reduced to the state of complete metals." The reasons which induced Mr. Bergman to suppose that the acids in question are metallic earths, are as follow: 1. They both show a striking resemblance to white arsenic in form, in producing effects like acids, and in their difficult solubility in water. 2. Their specific gravity; that of arsenic being 3750, the earth of molybdæna 3460, and the acid of tungsten 3000. 3. Their precipitation with phlogistated alkali; a property hitherto deemed peculiar to metallic calces. Arsenic also, properly dissolved in muriatic acid, gives, with the phlogistated alkali, a precipitate soluble in water, in the same manner as the acid of tungsten. 4. From their property of tinging vitreous matters; which, as well as that of precipitating with the phlogistated alkali, is reckoned to be a peculiar property of metals. The acid of tungsten produces by itself some effervescence with mineral alkali. With micrometallic salt it produces a globule at first of a light blue; more of the acid makes it a dark blue; but still it remains free from redness by refraction. A further addition makes it brown. Borax requires a flight tinge of blue, and with more of the acid becomes of a yellowish brown colour; but remains transparent, provided no further addition be made. This ultimate brown colour cannot be driven off either by nitre or the point of the flame urged by a blow-pipe. Acid of molybdæna is no less powerful; for with micrometallic salt it produces a beautiful green colour: borax well suffused with it appears grey when viewed by the reflected rays, but of a dark violet by the refracted.

§ 15. Of the Acid of Milk.

It is universally known, that in the summer-time milk grows four and thick in a few days, and that this frounness continues for some time to increase. It is strongest after a fortnight has elapsed; after which, if the whey be filtered and evaporated to one-half the quantity, a few curds will settle to the bottom. By saturating the whey with volatile alkali, a small quantity of animal earth precipitates; and the same thing takes place on the addition of lime-water. On the addition of a small quantity of acid of tartar, the latter foam becomes partially saturated with vegetable alkali, and is converted into tartar. Thus the acid of Component milk besides its proper acid part, contains animal earth and vegetable alkali in a loose state, and which is attracted by the acid of tartar; besides all these it has also a small quantity of the same alkali saturated with muriatic acid. It is no easy matter to separate those substances from one another; because the acid is not sufficiently volatile to rise in distillation by a gentle heat, nor are its principles sufficiently fixed to bear the action of a strong fire. With the one therefore it remains almost entirely in the retort, and with the other it is destroyed. Mr. Scheele therefore used the following process.

He evaporated four whey till only one-eighth part Scheele's remained; when the cheesy part being totally separated from the pure acid of milk, he employed the acid of sugar, which has a stronger attraction than any other for lime. This earth therefore being separated, the matter was evaporated to the consistence of honey, and highly rectified spirit of wine poured upon it to dissolve the acid part; which being accomplished, the other saline substances were left by themselves: and, lastly, the acid solution being diluted with pure water, and the spirit separated by distillation, the pure acid remained in the retort.

The properties of the acid of milk are, 1. Evaporated to the consistence of a syrup, it yields no crystals; of this acid, and when evaporated to dryness, it deliquesces. 2. By distillation it yields first water, then a weak acid like spirit of tartar; afterwards some empyreumatic oil, with more of the same acid, fixed air, and inflammable air; in the retort was left a fixed coal. 3. By saturation with fixed vegetable alkali it yields a deliquescent salt, soluble in spirit of wine. 4. A salt of a familiar kind is obtained by combining it with mineral alkali. 5. With volatile alkali a deliquescent salt is produced, which by distillation yields a great deal of its alkali before the acid is destroyed by heat. 6. It forms deliquescent salts with terra ponderosæ, lime, and clay; but with magnesia it forms small crystals, which, however, are again deliquescent. 7. It has no effect either by digestion or boiling in balsam, colbat, regulars of antimony, tin, quicksilver, or gold. However, after digestion with tin, it precipitated gold from its solution in aqua-regia, in the form of a black powder. 8. It dissolves iron and zinc, producing inflammable air during the solution. The liquor produced by the distillation of iron was brown, and yielded no crystals; but the solution of zinc crystallizes. 9. Copper dissolved in this acid communicates to the liquor a blue, then a green, and then a dark blue colour, without crystallizing. 10. Lead was dissolved after
The acid of milk is of a peculiar kind; and though it expels the vinegar from the acetated vegetable alkali, yet it seems defined, if I may so speak, to be vinegary; but from the want of such substances as, during fermentation, produce some spiritious matter, it seems not to be volatilized, though a portion of it indeed arrives at this point, and really becomes vinegar: for without a previous spiritious fermentation, or without brandy, there never arises any vinegar. But that the milk enters into a complete fermentation though there be no sign of brandy present, appears from the following experiment: If a bottle full of fresh milk be inverted into a vessel containing so much of the same liquor that the mouth of the bottle reaches below the surface of the latter, and if you expose this bottle to a degree of heat a little greater than that of summer, you will find, in the space of 24 hours, that the milk is not only coagulated, but in part expelled the greater part of it. It was said above, that the acid of milk cannot be converted into vinegar, from the want of such substances as during fermentation produce brandy; which appears to be evident from this: If to a kanne of milk you add five spoonfuls of good brandy, and expose the vessel, well corked, in such a manner, however, that you now and then give vent to the air developed during fermentation, you will find in a month, sooner or latter, that the whey will be changed into good vinegar, which, strained through a cloth, may be kept in bottles. The acid of sugar of milk is considerably different from that just now described. To procure it, Mr. Scheele poured 12 ounces of diluted nitrous acid on four ounces of finely powdered sugar of milk contained in a glass retort, to which a receiver was adapted. The retort was placed in a sand-bath, and as soon as the mixture acquired a certain degree of heat, it began to effervesce violently; for which reason, the retort and receiver were taken away from the fire. The mixture, however, continued to grow hotter and hotter, with a great emission of dark red vapours continually increasing, for half an hour. A considerable quantity of nitrous air and aerial acid were extricated during that time. Care must be taken, therefore, to have the retort and receiver both of a sufficient size, and not to make the retort too large. When the effervescence had subsided, the retort was again placed in the sand-bath, and the nitrous acid thus distilled off till the mass acquired a yellowish colour; on which the retort was immediately taken away from the fire. In two days time the solution seemed to have undergone no remarkable change, nor was there any appearance of crysals. Eight ounces more of the same nitrous acid were therefore added, and the whole exposed to the same degree of heat as before. When the mass grew warm, another, effervescence, though weaker than the former, ensued; the yellow colour disappeared, and the nitrous acid was again abstracted, till the solution, which had been rendered opaque by the appearance of a white powder in it, was boiled with a yellowish colour, on which the retort was again removed from the fire. It was redistilled in eight ounces of water, and filtered. Seven and a half drachms of white powder remained on the filter; the solution passed through the filter was very acid. It was evaporated to the conclusion of a syrup, four ounces more nitrous acid poured upon it, and the evaporation repeated in a sand-bath. After the whole was cool, some small long aerial crysals were found, together with a small quantity of white powder which was separated from it, and some more nitrous acid poured on the remaining mafs, and on evaporation, more such crysals made their appearance. The same process was repeated several times; by which means the whole mass was at last changed into such crysals, and weighed about five drachms, showing in every respect the same phenomena produced by acid of sugar. The white powder, weighing seven and a half drachms, was the true acid of sugar of milk; and its properties are,

1. It burns in a red hot-crucible like oil, without properties leaving behind it any mark or ashes. 2. It dissolves in boiling water in the proportion of one of salt to 60 of the liquid. 3. One fourth part of the distilled powder separates from the liquid on cooling, in form of very small crysals. 4. Half an ounce of the salt was dissolved in a glass vessel in 30 ounces of boiling water, and the solution filtered when cold. It had a yellow taffe, reddened the tincture of lacmus and effervesced with chalk. 5. Two drachms of the salt exposed to an open fire i a glass retort, melted, grew black, and fothed very much; a brown salt was found sublimed into the neck of the retort, which smelt like a mixture of salt of benzon and salt of amber, eleven grains of coal remaining in the retort. The receiver contained a brown liquid without any mark of oil, smelling like the sublimed salt. It contained also some of the salt dissolved, which was separated from it by a gentle evaporation. The sublimed salt weighed 35 grains, had a four taffe, and was easily solubel in spirit of wine, but with more difficulty in water, and burned in the fire with a flame. 6. Concentrated vitriolic acid, distilled with this salt, became very black, frothed much, and decomposed the salt entirely. 7. Acid of sugar of milk, gradually added to a hot solution of alkali, occasioned an effervescence and coagulation in consequence of the formation of a vast number of crysals, which require eight times their weight of water to dissolve them, and separate again in a great measure from the liquid on cooling. The same phenomena took place with the mineral alkali, only the salt was somewhat more soluble, requiring only five times its weight of water for solution. If to a solution of it a solution of alkali of tartar be added, a number of small crysals will soon be formed at the bottom of the vessel, on account of the greater attraction of this acid with the vegetable alkali. 8. With volatile alkali it forms a kind of salt amoniac, which, after being gently dried, has a four taffe. By distillation, the volatile alkali is first separated, the lime-water precipitates, and the residue yields the same products by distillation as the pure acid. 9. With all the earths, acid of sugar of milk forms insoluble salts.

CHEMISTRY.

§ 16. Of the Lithiasic Acid, or Acid of the human Calculus.

The calculi examined by Mr Scheele, with a view to discover their constituent parts, were, as he informs us, all of the same nature, whether flat and polished, or rough and angular. A small quantity of calculus in powder was put into a retort, and some diluted vitriolic acid, poured upon it. The powder was not affected by a digesting heat; however, it was dissolved when the acidity was abated by distillation. After the dissipation of the acid, a black coal was left in the retort, and the vitriolic acid which had passed into the receiver became sulphureous. The marine acid, whether diluted or concentrated, had no effect upon the calculus, not even when boiled with it. The nitric acid diluted, or aquafortis, had some effect on the calculus, even when cold. On the application of heat, an effervescence ensued with red vapours, and the calculus was dissolved. Repeating the experiment in a retort with line-water, the latter was precipitated. The solution of calculus is acid, though the menstruum be boiled with a supersaturated quantity of powder, so that there may remain a portion of it undissolved. It produces deep red spots on the skin in half an hour after it is applied; and if the saturated solution be a little more evaporated, it assails of itself a blood-red colour, which however, disappears on dropping in a single drop of nitrous acid. Terra ponderosa is not precipitated by it from the muriatic acid; nor are metallic solutions feebly changed. With alkalies it becomes somewhat more yellow when the alkal is supersaturated. The mixture, in a strong digesting heat assumes a rose colour, and stains the skin in the same manner, without any sensation of burning. The mixture likewise precipitates metals of different colours; vitriol, grey, black; of copper, green; solutio of silver, grey; corrosive sublimate, zinc, and lead, of a white colour. Lime water precipitates a white powder soluble in muriatic and nitrous acids without effervescence; and though there be an excess of precipitated powder, the solution will be acid. This white powder, therefore, is the acid of the calculus itself, the existence of which is also confirmed by Mr Bergman's experiments. The further analysis of this is related under the article CALCULUS, below.

§ 17. Of the Flowers of BENZOIN, Acid of LEMONS, with other anomalous vegetable acids, and the resemblance which the vegetable acids in general bear to one another.

It has long been known, that the resinsous sub斯坦ce, improperly called gum benzoin, yields by sublimation with a gentle heat a quantity of fine saline matter of a most agreeable odour, and slightly acid taste, called flowers of benzoin. Another method of obtaining this substanoe is by lixiviating the gum with water, by lixiviation and crystallizing the salt. Mr Scheele, determined to try what quantity of the flowers could be obtained from the resin, that, by sublimation, he was able to obtain from one pound of benzoin between nine and twelve drachms of flowers. By lixiviation the quantity obtained was considerably less than that of the mer, owing to the saline particles being so much covered by the resin, that the water could not have sufficient access to dissolve them. It was next attempted to procde all the flowers which the benzoin was capable of yielding. This was first done by boiling the flowers with pounded chalk and benzoin in water, and then filtering the yielding. benzoin from afterwards precipitated (for this salt, which is an acid, was wanted to the chalk); but the quantity of salt was no greater than that obtained by lixiviation. Alkaline was next tried, and the solution saturated with an acid, thus the salt of benzoin was obtained by precipitation, but here this inconvenience was met with, that the powder of benzoin lay together during the boiling, and floated on the surface like a tenacious resin. One only method, therefore, remained to be tried, and that was to boil the lime benzoin with quick-lime; and as the particles of lime, the belt by intermixing themselves between those of the benzoin would prevent their running together, and lime has likewise the property of acting upon the resinosous particles, this forms to be the best method of procuring the flowers of benzoin in the greatest quantity, and also of the best quality; and thus we may obtain from 12 to 14 drachms of flowers from a pound of benzoin. Mr Scheele's receipt for preparing them after Mr new method, is as follows: "Pour 12 ounces of Scheele's water upon four of unaltered lime, and after the bulb for preparation is over, add eight pounds of 12 ounces each) of preparing the flowers of water; put then a pound of finely powdered resin of benzoin into a tinned pan, pour upon it first about six ounces of the lime-water above-mentioned, mix this method well together, and thus add all the thod. lime-water in succession. The reason of adding the lime-water thus by portions, is, that it be poured in all at once, it will not mix with the benzoin, which will likewise coagulate and run together into a mass. This mixture must be boiled over a gentle fire for half an hour, agitating it constantly; then taking it from the fire, let it stand quiet for some time to settle, after which the clear liquor is to be poured off into a glass vessel. Pour then eight pounds of water more upon the lime in the vessel, and use this lime-water as before, repeating this process twice more, making four times.

996 Anomalous vegetable acids how divided.

997 Of the essential acids.

998 Empyreumatic acids.

999 Salt of lemon can not be converted into acid of furgar.

1000 Product of acid of tartar, and caustic earth.

1001 May not the acetic acid be mere acid of tartar, which did not meet with alkaline salt, and earthy enough with which it might combine and become more fixed; but, on the contrary, it would not fulfill its office, and thus become more volatile? In distilling terra liata tartari in the dry way, the acid of vinegar which enters its composition is almost entirely destroyed; but, after the residue, as well as the rest of that which comes over into the receiver, being entirely alkaline, and the same process of distillation is repeated, you have an acid of such a nature that it may be employed for the distillation of spirituous liquors.
same thing happens to the acid of tartar, the empyromeatic acid abovementioned being extremely weak. Mr Beaumé likewise informs us, that if any calcareous earth, egg-shells, for instance, be diffused in vinegar, and the crystallized salt be distilled, we obtain $\frac{1}{3}$ of a red and very fiery inflammable fluid, smelling like empyromeatic acetone ether, which reddeneth tincture of turnip. Mutlly, distilled before fermentation, yields only an empyromeatic acid resembling spirit of tartar. The conjecture therefore seems reasonable, that vinegar and tartar have for their basis the same species of acid, which in the case of vinegar is combined with a greater proportion of oil, and in tartar with more earth. To bring vinegar therefore nearer the state of tartar, we must deprive it of its fine volatilizing phlogiston, combine it with more fixed matter, and restore its greater oil. All this, however, is extremely difficult to be effected. Mr Wetrumb, who attempted it, added nitrous acid in various proportions, but could only produce a phlogification of the latter, and dephlogification of the vinegar; but as he could not think of any method of separating the two acids from one another, he was unable to investigate the properties of vinegar thus dephlogificated. Dr Crelle is of opinion, that this might have been done by vegetable alkali, lime, and terra ponders, as it would have been to the ordinary hexagonal crystals of nitre: the acco,

Mr Wetrumb's unsuccessful attempt. 
Dr Crelle's opinion of the possibility of transformation.

Method recommended by him for attempting the experiment.

Requisites for bringing vinegar nearer the state of tartar.

Mr Wetrumb's dephlogistication of the vinegar; but though the acid of vinegar is comb beside the cerebral fluid, which will not shoot, and hearerf the Dr Mr tranverse a, feparating the ley, which will not shot, Mr Weftrumb's dephlogistication of the vinegar; but Dr Trub's dephlogistication of the vinegar; but though the acid of vinegar is comb beside the cerebral fluid, which will not shot, and hearerf the Dr Mr tranverse a, feparating the ley, which will not shot, Mr Weftrumb, who attempted it, added nitrous acid in various proportions, but could only produce a phlogification of the latter, and dephlogification of the vinegar; but as he could not think of any method of separating the two acids from one another, he was unable to investigate the properties of vinegar thus dephlogificated. Dr Crelle is of opinion, that this might have been done by vegetable alkali, lime, and terra ponders. The nitrous acid, with vegetable alkali, would have been to the ordinary hexagonal crystals of nitre: the acco,

1. If the residuum of dulcified spirit of nitre be boiled with a large quantity of nitrous acid, care being taken at the same time to condense the vapours by a proper apparatus; and if the liquid which has passed over be saturated with vegetable alkali, nitre and terra foliata tartari will be obtained; and on separating the latter by means of spirit of wine, the vinegar may be had in the ordinary way of decomposing the salt.

2. On boiling the residuum over again with nitrous acid, the same products are obtained; and the more frequently this process is repeated, the less acid of fugar is procured, until at length no vestige of it is to be met with.

3. Pure acid of sugar, boiled with 12 or 14 times its quantity of nitrous acid, is entirely decomposed, and the receiver is found to contain phlogificated nitrous acid, vinegar, fixed air, and phlogificated air, while of fugar. From the residuum of dulcified spirit of nitre with chalk, there is formed an infoluble salt, spirit of which by treatment with vitriolic acid yields a real acid of tartar, constituting a cream of tartar with vegetable alkali.

6. On evaporating the liquor from which the tartarous selenite was obtained, a dark-coloured matter remains, yielding on distillation an empyromeatic acid of tartar, and a spongy coal. Hence it would seem, that from that spirit of wine conitls of acid of tartar, of water, the liquor and phlogiston; so that it is a native dulcified acid; in which tartarous and nitrous acid, on being mixed with it in moderate quantity, dissolves the acid of tartar. On the addition of more nitrous acid, the acid of tartar is resolved into acid of fugar and phlogiston; and by a still greater addition, the faccicatic acid is changed into solution of vinegar.

7. On boiling one part of the acid of sugar with one and a half of manganse and a sufficient quantity of nitrous acid and a sufficient quantity of nitrous acid.
Acid of fat. nitros acid, the manganese will be almost entirely dissolved, and phlogificated nitrous acid along with vinegar will pass over into the receiver.

From the solution of the same with vitriolic acid and that of tartar.

If acid of tartar be boiled along with vitriolic acid and manganese, the latter will be dissolved, and vinegar with vitriolic acid will pass over into the receiver.

On digesting acid of tartar and spirit of wine for several months, the whole is converted into vinegar, the air in the vessel being partly converted into cretaceous acid, and partly into phlogificated air.

On boiling spirit of wine with vitriolic acid and manganese, it will be converted into vinegar and phlogificated air.

By distilling spirit of wine upwards of 20 times from caustic alkali, it was changed into vinegar, and a considerable quantity of water was obtained.

From the solution of manganese with vitriolic acid and spirit of wine.

From the distillation of spirit of wine with caustic alkali.

This may be obtained from suet by means of many repeated distillations. A small quantity is separated at each distillation; but by distilling the empyreumatic oil into which the fat is thus converted over and over, a fresh quantity is always obtained. The acid of fat in some respects has a resemblance to that of sea-salt; but in others is much more like the vegetable kind, as being destructible in a strong fire, forming compounds which do not deliquece with calcareous earth, and uniting intimately with oily substances. With alkalis it forms salts entirely different; from those yielded by the other acids; with the volatile alkali, particularly, it produces a concrete volatile salt. When saturated with calcareous earth, it yields brown crystals; and a salt of the same kind was obtained by Dr Crel by a mixture of quicklime and fat distilled to dryness, and boiling up the residue with water. The crystals were hexagonal, and terminated by a plane surface; their taste was acid and salty; they did not deliquece in the air, and were easily and copiously dissolved in water. With magnesia and earth of alum a gummy mass is obtained, which refuses to crystallize.

With regard to the metals, Dr Crel informs us, that the acid of fat copiously dissolves manganese into a clear and limpid liquor. It dissolves the precipitate of cobalt, but not the regulus. White arsenic is acted upon sparingly, and nickel not at all, though it forms a green solution with the precipitate from nitrous acid. Regulus of antimony, by the influence of heat is dissolved into a clear liquor, which became milky in the cold; it crystallized on evaporation.

and did not deliquece in the air. Zinc readily dissolved, and imparted a peculiar metallic taste, falling line into the bottom in the form of a white powder on the addition of an alkali. Bismuth in the metallic state was not dissolved; but the precipitate was. It acted upon mercury after being twice distilled from it, and poured afresh upon the metal. The mercury could not be entirely precipitated by common salt. It acted more vigorously upon a precipitate from corrosive sublimate; from the solution of which a white sublimate was obtained after the liquor had been drawn off by distillation. A gold-coloured solution was obtained from platinia by distilling the acid from it to dryness, and then pouring it back again; the precipitate of this acid from aqua-regia by spirit of wine was dissolved in great abundance. Iron was very easily dissolved in it, and exhibited a liquor of an astringent taste, which scum into needle-like crystals that did not deliquece in the air. Lead was corroded and rendered the acid turbid. Minium was converted into a white powder, and then dissolved with greater ease. The solution has a sweet taste, and cannot be precipitated by sea-salt. Tin was corroded into a yellow calx, and dissolved but in very small quantity. Copper was dissolved, even in the cold, into a green liquor; but the solution was greatly promoted by heat. On evaporation it showed some disposition to crystallize, but again attracted moisture from the air. Silver-leaf was attacked only in a very small degree; however, some was precipitated by means of copper, and the mineral acid rendered the liquor turbid.

The calx precipitated from aquafortis was dissolved more copiously. Silver was precipitated of a white colour from aquafortis by the pure acid itself, as well as by its ammoniacal salt. Half an ounce of the acid distilled four times almost to dryness from some gold leaves, and it length poured back upon them, the precipitate of a dilute solution of tin obtained by it, gained almost only a faint colour, rather inclining to red; but a mixture of two parts of acid with one of aquafortis, dissolved gold very readily.

Of Fixed Alkaline Salts.

Of these there are two kinds; the vegetable and how prepared from the ashes of burnt vegetables. It is got in the greatest quantity from crude tartar; from which, if horned with proper care and attention, we may obtain one pound of alkali out of 2 of the tartar. The latter is found native in some parts of the earth. It is likewise found in very large quantities combined with the marine acid, in the waters of the ocean, and in the bowels of the earth; thus forming the common alimentary salt. It is also produced from the ashes of certain sea-plants, and of the plant called kali; from whence both the mineral and vegetable alkali have taken their name.

The vegetable alkali difficultly assumes a crystalline vegetable form; nevertheless, it may be partially united with alkali crystalline acids in such a manner as to crystallize, and lose its property of deliquescing in the air, without at the same time ceasing to be an alkali. Of this we have an example in the acid of ants abovementioned. Something
Practice.

Chemistry.

Fixed alkaline salts and their combinations. thing of the same kind we have observed in treating vegetable fixed alkali with spirit of wine. A gallon of pretty strong spirit of wine being drawn over from a pound of salt of tartrar, a black unctuous liquor was left, which soon into crystals very much resembling vitriolated tartrar, and which did not deliquesce in the air, but were nevertheless strongly alkaline. Dr. Black, however, informs us, that the vegetable alkali may be formed into fine crystals; but which cannot be preserved, on account of their great attraction for moisture, unless closely shut up from the air. They have not such a quantity of water as to undergo the aqueous fusion.

The mineral alkali in its natural state always assumes a crystalline form, somewhat resembling that of salt mirabile. It does not deliquesce in the air, nor does it seem to have so strong an attraction for water, even when in its most caustic state, as the vegetable alkali; hence mineral alkali is preferable to it in making soap, which is always of a firmer consistence with mineral than with vegetable alkali. If vegetable alkali is combined with spirit of salt, some change seems to be thereby induced upon it, as the vegetable alkali is preserved of the marine acid by means of the vitriolic, and then crystallizing the masses, crystallizes differently from vitriolated tartrar. Whether the vegetable alkali might be this means be entirely converted into the mineral, deserves a further inquiry.

Both mineral and vegetable alkalis, when applied to the tongue, have a very sharp, pungent, and urinous taste; but the vegetable considerably more so than the mineral. They both unite with acids, and form different neutral salts with them: but the vegetable alkali seems to have rather a greater attraction for acids than the other; although this difference is not so great as that a neutral salt, formed by the union of mineral alkali with any acid, can be perfectly decomposed by an addition of the vegetable alkali, unless in considerable excess.

Fixed Alkalies combined. Fixed alkaline salts and their combinations. Composed of a caustic salt and fixed air.

Hepar sulphuris. I. With Sulphur. The produce of this is the red ferric compound called hepar sulphuris, or liver of sulphur. It may be made by melting sulphur with a gentle heat, and filtering it into water. The whole readily melts and forms a red mass of a very feric smell, and which deliquesces in the air. If sulphur is boiled in a solution of fixed alkaline salt, a like combination will take place.

In this process, when the hepar is made either in the dry or the moist way, the fixed air of the alkali is discharged, according to Dr. Priestley's observation. Neither does a fixed alkali, when combined with fixed air, seem capable of uniting with sulphur; nor will the union be accomplished without heat, unless the alkali is already in a caustic state. Hence a cold solution of hepar sulphuris may be decomposed, partly at least, by fixed air. On adding an acid, however, the decomposition takes place more rapidly; and the sulphur is precipitated to the bottom, in form of a white powder.

During the precipitation of the sulphur from an alkali, by means of acids, a thick white smoke arises, of a moist fetid smell and suffocating nature. It burns quietly, without explosion, on a candle's being held in it. Calkes of silver, lead, iron, or bismuth, are rendered black by it. Hence, if any thing is wrote with a solution of lead, and a solution of hepar sulphuris is passed over it, and the writing, formerly invisible, will immediately appear of a blackish brown colour. Silver, in its metallic state, is prodigiously blackened either by the contact of this vapour, or by being immersed in a solution of the hepar sulphuris itself. Litharge is instantly reduced to its metallic state, on being immersed even in a cold solution of hepar sulphuris, the salt being disolved from the solid.

By being united with an alkali, the acid of sulphur phlogiston seems very much diffused to quench the phlogiston. If a of sulphur diffused is exposed to the air for some time, it is spontaneously decomposed; the phlogiston of the sulphur flying off, and the acid remaining united with the alkali into a vitriolated tartar. This decomposition takes place so remarkably, when liver of sulphur is dissolved in water, that by a single evaporation to dryness, it will be almost totally changed into vitriolated tartar. If this substance, in a dry state, be exposed to a moderate degree of heat, and the mass kept constantly frittering, a like decomposition will follow; the phlogiston of the sulphur will fly off, and the acid unite with the alkali.

Liver of sulphur is a great solvent of metallic matters; all of which, except zinc, it attacks, particularly in fusion. It seems to dissolve gold more effectually than other metals. This compound also dissolves vegetable coals, even by the humid way; and these solutions, if suffered to stand in the open air, always precipitate a black powder, no other than the coal they had dissolved, in proportion to the quantity of hepar sulphuris decomposed. When vegetable coal is thus dissolved by liver of sulphur in fusion, it is of a much deeper red than in its natural state. The solution in water is of a green colour. II. With Express'd Oils. The result of this combination is soaps; for the preparation of which in large quantities in the way of trade, see Soap. The soap which is used in medicine is prepared without heat, in the following manner, according to the author of the Chemical Dictionary.

"One part of quicklime, and two parts of good Spanish soda (the salt prepared from the ashes of the herb kali), are boiled together during a short time in an iron caldron. This lixivium is to be filtered, and evaporated by heat, till a phial, capable of containing an ounce of water, shall contain an ounce and 216 grains of this lixivium. One part of this lixivium is to be mixed with two parts of oil of olives, or of sweet almonds, in a glass or stone-ware vessel. The mixture soon becomes thick and white, and must be filtered from time to time with an iron spatula. The combi

Chemistry.

Fixed alkaline salts and their combinations.

Fixed alkali salts are gradually completed, and in seven or eight days a very white and firm soap is obtained."

In attempting combinations of this kind, it is absolutely necessary that the alkali be deprived of its fixed air as much as possible; otherwise the soap will be quite unctuous and soft: for fixed alkalies have a greater attraction for fixed air than for oil, and hence soap is decomposed by blowing fixed air into a solution of it in water. It may be made either with tallow, wax, spermaceti, butter of cocoa, the cores of resinous substances, or animal oils.

III. With Essential Oils.

The volatility of these oils in a great measure hinders them from being acted upon by alkalies: nevertheless, combinations of this kind have been attempted; and the compounds so produced have been called Starkey's soap, from one Starkey a chemist, who endeavoured to volatilize fat of tartrar by combining it with oil of turpentine. His method was to put dry salt of tartrar into a mortar, and pour upon it essential oil of turpentine at the height of two or three fingers breadth. In five or six months, a part of the alkali and oil were combined into a white polynaceous compound. This must be separated from the mixture, and more of it will afterwards be formed by the same method.

Chemists, imagining this soap to be possessed of considerable medical virtues, have endeavoured by various methods to shorten this tedious process. Of those one of the most expedients is that recommended by Mr Beaumé; which consists in triturating, for a long time, alkali salt upon a porphyry, and adding oil of turpentine during the triturating. According to him, the thick resinous part of the oil only can combine with the salt; and, during the time this combination is effected, the more soluble and attenuated parts will fly off. Hence he finds that the operation is considerably abridged by the addition of a little turpentine or common soap. The most expedients of all, however, is that mentioned by Dr Lewis; which consists in heating the alkali red hot, and then throwing it into oil of turpentine, stirring them well together; on which they immediately unite into a faponaceous mass.

This kind of soap is subject to great alterations from keeping; particularly the loss of its colour, and a kind of decomposition occasioned by the extraction of an acid from the oil of turpentine, which unites with the alkali and crystallizes not only all over the surface, but in the very substance of the soap. The nature of this salt is unknown, but certainly deserves consideration.

IV. With Phlogivirus. This combination is effected by calcining them with the charcoal either of vegetable or animal matters. The consequence is, that they are greatly altered in their properties; sometimes so much as to be enabled to precipitate calcareous earths from their solutions in acids. Metallic solutions precipitated by them in this state, assume different colours.

Differences observed between Fixed Alkalies obtained from different Vegetables.

These differences we must conceive to arise from some proportion of the oily and phlogistic matter of the vegetable remaining in the ashes from whence the salts are extracted; for when reduced to their unmodified purity, by repeated calcinations in a strong fire, and dilutions in the air, all of them, the marine alkali excepted, appear to be the very same.

On this subject Mr Gmelin has given a great number of experiments in the fifth volume of the Commentaria Petropolitana; and found very considerable differences, not only between the alkaline salts, but likewise the pure vegetable earths obtained from different vegetables by burning. The salts of the several plants examined were prepared with great care, and of all of them exactly in the same manner; each vegetable being burnt in a separate crucible, with the same degree of fire, till no remains of coaly matter could any longer be perceived; and the ashes elixated in glass vesicles with cold distilled water. The salts, thus obtained, were found to produce different colours on mixture with certain liquors, and to effervesce in very different degrees with acids: certain metallic solutions were by some precipitated, by others only rendered thicker, by others both precipitated and rendered thick; whilst some occasioned neither the one nor the other of these changes, but left the fluid clear and transparent. Thus, with the vitriolic acid, the salts of southerwood and sage struck a pale brown colour; those of pine-tops and rose, a yellow; that of fern, a reddish yellow; and that of citren, a deep-green, that of dill yielded a lead-green precipitate, with elegant green flakes floating in the liquor. This last also gave a greenish precipitate with the marine acid, and a red one with the nitrous. Solution of corrosive sublimate was changed yellow by salt of southerwood; of a brownish colour, by that of colt's-foot; of a deep red, by that of wormwood; and of a pitch-colour, by that of dill. That of fern threw down an opal-colour; of sage, a sulphur-yellow; of elder flowers, a citron yellow; of sanicle, a fennon colour; and of milfoil, a deep-red precipitate. From solution of silver, salt of cardui benedictus threw down a white; of camomile, a grey; of hyssop, a brownish; of dill, a blackish brown; of scabious, a yellowish; and that of pine-tree tops, a sulphur yellow precipitate.

Solution of vitriol of copper was changed by salt of southerwood to a bright sea-green; by that of dill, to an unlight green; of agrimony, to a greenish blue; and by that of milfoil, to a bright fly-blue: the salt of pennyroyal made the liquor thick as well as blue, and that of feverfew made it thick and green; the salt of hyssop threw down a green precipitate, that of fennon-grass a blue one, and that of fummory a greenish blue; whilst the salt of fern made scarcely any change either in the colour or consistence of the liquor.

This is a kind of salt obtained from all animal, whence some vegetable substances, from fruit by distillation obtained, with a strong heat, and from all vegetable substances by putrefaction. Though a volatile alkali is procurable from all putrid animal substances by distillation, yet the putrefactive process does not seem to prepare volatile alkali in all of these. Putrid urine, indeed, contains a great quantity of alkali ready converted, whence its use in scouring, &c., but the case is not so with putrid blood or flesh. These afford no alkali till after the phlegm has arisen; and this they would
Volatile alkali and its combinations.

Volatile alkali would do, though they had not been purified. According to Mr Wiegble, volatile alkali is found in limonite, lapis fulvus, chalk, mable, coals, turf, loam, clay, and many other kinds of earth. Its existence in these substances may be discovered merely by distilling them with a brisk fire, but still better by the addition of some quantity of fixed alkali or quicklime before the distillation. It has even been found in all mineral salts and their acids, as virriol, nitre, common salt, and the acid liquors drawn from these substances, also in gypsum and sulphur: from all which it may be separated by means of quicklime. In the vegetable kingdom it is produced by dry distillation from mustard-seed, elder flowers and leaves; the leaves of the wild cherry-tree, white water-lilies, tobacco, and fage; as well as from many other plants. According to our authors, the plainest proof of its existence is seen in our chimneys, where a volatile alkali is discharged, either with or without quicklime.

Volatile alkali, when pure, appears as a snowy whiteness, has a very pungent smell, without any disagreeable apprenna; is very easily evaporable, without leaving any residue; effervescences with acids much more strongly than fixed alkali; and forms with them neutral compounds called ammoniacal salts, which we have already described, and which are different according to the nature of the acid made use of. It is a volatile alkali, perfectly purified, to appear to be very same, without the smallest difference.

Like fixed alkalis, these salts contain a great quantity of fixed air, on which their solidity depends; and which may be so increased as perfectly to neutralize, and deprive them of their peculiar taste and smell. When neutralized by fixed air, they have a very agreeable pungent taste, somewhat resembling that of weak fermenting liquors. When totally deprived of fixed air, by means of lime, they cannot be reduced to a solid form; but are dissipated in an invisible and exceedingly pungent vapour, called by Dr Priestley alkaline air. When volatile alkaline salt is dissolved in water, the solution is called volatile alkaline spirit.

Distillation and Purification of Volatile Alkalis.

The materials most commonly used for preparing volatile alkalis are the solid parts of animals, as bones, horns, etc. These are to be put into an iron pot of the shape recommended for solution; to this must be fixed a flat head, having a hole in the middle about two inches diameter. From this a tube of plate iron must issue, which is to be bent in such a manner that the extremity of it may enter an oily jar, through a hole made in its upper part, and dip about half an inch under some water placed in the lower part. The mouth of the jar is to be fitted with a cover, luted on very exactly; and having a small hole, which may be occasionally stopped with a wooden peg. The junctures are to be all luted as close as possible, with a mixture of clay, sand, and some oil; and those which are not exposed to a burning heat, may be further secured by quicklime and the white of an egg, or by means of glue. A fire being now kindled, the air contained in the distilling vessel is first expelled, which is known by the bubbling of the water; and to this vent must be given by pulling out the wooden peg. A considerable quantity of phlegm will then come over, along with some volatile alkali, a great quantity of fixable air, and some fixed alkali. The alkali will unite with the water, and like wise the fixed alkali and some part of the fixed air, the oil floating above. A great many incoercible vapours, however, will come over, to which vent must be given from time to time, by pulling out the peg. The distillation is to be continued till all is come over; which may be known by the effervescence, or very slow bubbling of the water. The iron pipe must then be separated from the cover of the distilling vessel, and the liquid in the jar should return into it, on the arm being condened by its cooling. In the jar will be a volatile spirit, more or less strong according as there was left or more water put in, with an exceedingly fbid black oil floating upon it.

The rectification of the volatile alkali is most commodiously performed at once by combining it with an amnification, and, as spirit of salt has the least affinity with inflammable matter, it is to be chosen for this purpose, in preference to the vitriolic or nitrous. As the spirit is excessively oily, though already much weakened by the admixture of the water in the jar, if a very large quantity was not originally put in, an equal quantity of water may be added, on drawing off the spirit. That as little may be possible, the spirit should be received in a stone bottle; and the marine acid, likewise in a distilled state, added by little and little, till the effervecees cease. The liquor, which is now an impure solution of salt ammoniac, is to be left for some time, that the oil may separate itself; it is then to be filtered, evaporated, and crystallized in a leaden vessel. If the crystals are not sufficiently pure at the first, they will easily become so on a second distillation.

From salt ammoniac thus obtained pure, the volatile volatile salt alkali may be extricated by distillation with chalk, alkaline salts, or quicklime. Alkaline salts are more briskly than chalk, and give a much stronger volatile alkali. The strength of this, however, we know may be altered at pleasure, by adding to, or depriving it of, its natural quantity of fixed air. Hence, perhaps, the best method would be, to prepare volatile alkalis altogether in a fluid state, by means of quicklime; and then add fixed air to them, by means of an apparatus similar to that directed by Dr Priestley for impregnating water with fixed air. To prevent lime from adhering to the distilling vessels in which it is put, the translator of Wiegble's chemistry recommends the putting in three or four ounces of common salt along with the other ingredients.

Volatile alkalies combined.

1. With Metals. There are only three metals, viz. Cuprum, copper, iron, and lead, upon which, while in their ammoniacal metallic form, volatile alkalies are capable of acting. Copper-filings are dissolved by volatile alkali, especially in its caustic state, into a liquor of a most admirable blue colour. It is remarkable, that this colour depends entirely upon the air having access to the solution; for if the bottle containing it is close stoppt, the liquor becomes colourless; but, however, refumes its blue colour on being exposed to the air. On evaporation, a blue ftable mel is obtained, which, mixed with fat, or other inflammable matters, form their flame green, leaving a red calc of copper, ftable again in volatile spirits as at first. This is the substance...

Practise.

Spiritus volatilis succinatus.

Volatile alkali and its combinations.

Sal volatile used for removing pains, and sometimes with success.

With essential oils, volatile alkalies may be united, either in their dry or liquid form, by means of distillation.

Composition of this kind are frequently employed in a bottle, and the volatile spirit is called "sal volatile oleosum," it is much more frequently used in a liquid than in a dry form. The general method of preparation is by distilling volatile alkali along with essential oils and spirit of wine, or the aromatic substance from whence the essential oils are drawn. These compositions are volatile alkali and its combinations.

F. Eau de Luce. This is a name given to a very exceedingly volatile spirit, which some years ago was pretty much in vogue; and indeed seems very well calculated to answer all the purposes for which volatile alkalies can be used. It was of a thick white colour, and smelled somewhat of oil of amber. A receipt appeared in Lewis's Dispensatory for the preparation of this fluid, under the name of spiritus volatilis succinatus. The method there directed, however, did not succeed; because, though the alkaline spirit is capable of keeping a small quantity of oil of amber suspended, the colour is greatly more dilute than that of genuine eau de luce.

In the Chemical Dictionary we have the following receipt: "Take four ounces of rectified spirit of wine, and in it dissolve 10 or 12 grains of white soap; filter this solution; then distill off in it a draught of rectified oil of amber, and filter again. Mix as much of this solution with the stronger volatile spirit of ammoniac as will be sufficient, when thoroughly shaken to give it a beautiful milky appearance. If upon its surface be formed a cream, some more of the oily spirit must be added."

This receipt likewise seems insufficient. For the oil of amber does not distill in spirit of wine: neither is it probable that the small quantity of soap made use of could be of any service; for the soap would distill perfectly in the alkaline spirit, without suffering any decomposition. The only method which we have found to answer is the following. Take an ounce, or any quantity at pleasure, of balsamum Canadensif, place it in a small china basin, in a pan of boiling water, and keep it there till a drop of it taken out appears of a resinosous consistence when cold. Extract a tincture from this resin with good spirit of wine; and having impregnated your volatile spirit with oil of amber, lavender or any other essential oil, drop in as much of the spirituous tincture as will give it the desired colour. If the volatile spirit is very strong, the eau de luce will be thick and white, like the cream of new milk; nor is it subject to turn brown with keeping.

IV. With Volatile Tincture of Sulphur. This is a Volatile combination of the caustic volatile alkali, or spirit alkali composed of sal ammoniac, with sulphur. It is usually distilled with rectified water or with spirit, and the spirit sulphur and afterwards with the sal ammoniac, and distilling the whole in a retort, but the produce is by this method very small, and even the success uncertain. A preferable method seems to be, to impregnate the strongest caustic volatile spirit with the vapour which arises in the decompositions of hcpur sulphur by means of an acid, in the same manner as directed for impregnating water with fixed air.

This preparation has a most nauseous fetid smell, sympathetic which spreads to a considerable distance; and the effec of the fluid will blacken silver or copper, if barely placed in the neighbourhood of the untoppffed bottle. This property renders it capable of forming a curious kind of sympathetic ink; for if paper is wrote upon with a solution of saeccharum saturni, the writing, which disappears when dry, will appear legible and of a brownish

CHEMISTRY.

Phenomena from mixtures of acids, &c. salts.

1. If concentrated oil of vitriol is mixed with strong spirit of nitre, or spirit of salt, the weaker acid will become exceedingly volatile, and emit very elastic fumes; so that if a mixture of this kind is put into a close stop bottle, it will almost certainly burst it. The same effect follows upon mixing spirit of salt and spirit of nitre together. In this case, both acids become surprizingly volatile; and much of the liquor will be distilled in fumes, if the mixture is suffered to stand for any considerable time. Such mixtures ought therefore to be made only at the time they are to be used.

2. If vitriolated tartar is dissolved in an equal quantity of strong spirit of nitre, by heating them together in a mortar, the stronger vitriolic acid will be dissolved by the weaker nitrous one, and the liquor, on cooling, will shew into crystals of nitre. The same thing happens also upon dissolving vitriolated tartar, or Glauber's salt, in spirit of salt. This observation we owe to Mont. Beaumé, and the reason of it has been already explained. See n° 285.

3. If vitriolated tartar, or Glauber's salt, is dissolved in water, and this solution mixed with another containing calcareous earth, silver, mercury, lead, or tin, dissolved in the nitrous or marine acids, the vitriolic acid will leave the fixed alkali with which it was combined, and, uniting with the calcareous earth or metal, fall with it to the bottom of the vessel. This decomposition takes place only when the vitriolic acid meets with such bodies as it cannot easily dissolve into a liquid, such as those we have just now mentioned; for though vitriolated tartar is mixed with a solution of iron, copper, &c. in the nitrous or marine acids, no decomposition takes place. The case is not altered, whatever acid is made use of; for the marine acid will effectually separate silver, mercury, or lead, from the vitriolic or nitrous acids.

4. According to Dr Lewis, if a solution of vitriolated tartar is dropped into lime-water, the acid will unite with the lime, and precipitate with it in an indiffusible felinite, the alkali remaining in the water in a pure and caustic state.

5. If green vitriol is mixed with any solution containing substances which cannot be dissolved into a liquid by the vitriolic acid, the vitriol will be immediately decomposed, and the liquor will become a solution of iron only. Thus, if green vitriol is mixed with a solution of faccharum fustrem, the vitriolic acid immediately quits the iron for the lead, and falls to the bottom with the latter, leaving the vegetable acid of the faccharum fustrem to combine with the iron.

6. If solution of tin in aque-regia is mixed with solution of faccharum fustrem, the marine acid quits the tin for the lead contained in the faccharum; at the same time, the vitriolic acid, which was combined with the lead, is unable to dissolve the tin which was before kept suspended by the marine acid. Hence, both the faccharum fustrem, and solution of tin, are very effectually decomposed, and the mixture becomes entirely useless. Dyers and calligraphers ought to attend to this, who are very apt to mix these two solutions together; and no doubt many of the faults of colours dyed or printed in particular places, arise from injudicious mixtures of a similar kind. See DYEING.

7. If mild volatile alkali, that is, such as remains in a concrete form, by being united with a large quantity of fixed air, is poured into a solution of chalk in the nitrous or marine acids, the earth will be precipitated, and a true ful ammoniac formed. If the whole is evaporated to dryness, and a considerable heat applied, the acid will again part with the alkali, and combine with the chalk. Thus, in the purification of volatile alkalis by means of spirit of salt, the same quantity of acid may be made to serve a number of times. This will not hold in volatile spirits prepared with quicklime.

8. If equal parts of ful ammoniac and corrosive sublimate mercury are mixed together and sublimed, they unite in such a manner as never to be separable from one another without decomposition. The compound is called ful alumbreth; which is said to be a very powerful solvent of metallic substances, gold itself not excepted. Its powers in this, or any other respect, are at present but little known. By repeated sublimations, it is said this salt becomes entirely fluid, and resolves in the strongest heat.

9. If vitriolic acid is poured upon any salt difficult solution of solution in water, it becomes then very easily soluble, and only by means of vitriolated tartar, or cream of tartar, may be dissolved in a very small quantity of water.

SECT. II. EARTHS.

The general divisions and characters of these substances we have already given; and most of the combinations with saline substances have been mentioned, excepting only those of the terra ponderosa; a substance whose properties have been but lately inquired into, and are not yet sufficiently investigated. In this section, therefore we have to take notice of their various combinations with one another, with inflammable, or metallic substances, &c. As they do not, however, act upon one another till subjected to a vitrifying heat, the changes then induced upon them come more properly to be treated of under the article GLASS. Upon metallic and inflammable substances (fulphur alone excepted), they have very little effect; and therefore what relates to these combinations shall be taken notice of in the following sections. We shall here confine ourselves to some remarkable alterations in the nature of particular earths by combination with certain substances, and to the phosphoric quality of others.
§ 1. The Terra Ponderosa.

This earth is of the true calcareous kind, and capable of being converted into a very acid lime; but in other respects is very different. It is most commonly met with in the veins of rocks, united with the vitriolic acid in a mass somewhat resembling gypsum, but much heavier and more opaque; and from the great weight of this substance the earth itself has its name, though when freed from the acid it is by no means remarkable for this property. Its properties were first taken notice of by Thomas Fermor; but they have been more accurately investigated by Dr Withering, who has published his observations in the 74th volume of the Philosophical Transactions. His experiments were not made on the gypseous substance above-mentioned; but on a combination of the earth with fixed air, which is much more uncommon, and like the other possesses a very considerable degree of specific gravity. Both these combinations have the general name of *fractum ponderosum,* or *ponderous spar;* the former being also called barofeltenite, &c.

The spar used by Dr Withering was got out of a lead mine at Allon Moor in Cumberland. Its appearance was not unlike that of a lump of alum; but on closer inspection it appeared to be composed of slender flakes in close contact, more or less diverging, and so thin that it might be cut by a knife; its specific gravity from 4.200 to 4.338. It effervesced with acids, and melted, though not very readily, under the blow-pipe. In a common fire it lost its transparency; and on being urged with a stronger heat in a melting furnace, it adhered to the crucible, and showed signs of fusion; but did not appear to have lost any of its fixed air, either by diminution in weight, becoming caustic, or losing its power of effervescing with acids.

Five hundred grains of this spar, by solution in muriatic acid, lost 104 grains in weight, and left an infusible residuum of three grains. In another experiment, 100 grains of spar lost 21; and there remained only 0.6 of a grain of infusible matter.

On dissolving another hundred grains in dilute muriatic acid, 25 ounce-measures of air were obtained, which by proper trials appeared to be pure aerial acid; and, on precipitating the solution with mineral alkali, 100 grains of earth were again obtained; but on dissolving the precipitate in fresh muriatic acid, only 20 ounce-measures of air were produced.

Mild vegetable alkali precipitated a faturated solution of this spar in marine acid, with the escape of a quantity of fixed air; and the same effect took place on the addition of fosili alkali; but with caustic alkalis there was no appearance of effervescence, though a precipitate likewise fell.

Fifty parts of spar, dissolved in marine acid, lost 105; and with caustic vegetable alkali, a precipitate weighing 45; was obtained. Phlogilificated alkali precipitated the whole of the earth, as appeared by the addition of mild fixed alkali afterwards, which occasioned no further precipitation.

Part of the precipitate thrown down by the mild alkali was exposed to a strong heat in a crucible, and then put into water. The liquid was instantly converted into a very acid lime-water, which had the following remarkable properties: The smallest portion of vitriolic acid, added to this water, occasioned an immediate and copious precipitation, which appeared even after the liquid was diluted with 200 times its bulk of pure water. 2. A single drop let fall into a solution of Glauber’s salt, vitriolated tartar, alum, vitriolic ammoniac, Epom salt, or felinite, occasioned an immediate and copious precipitate in all of them: the reason of which was the superior attraction of the ponderous earth for the acid of these salts, which forming with it an indissoluble concrete, infanty fell to the bottom.

The precipitate thrown down by the caustic vegetable alkali was put into water, but exhibited no foeh appearances as the other; even the mixture was boiled nor had it any acrimonious taste. On adding the three mineral acids to separate portions of the precipitate itself, neither effervescence, nor any sign of solution, appeared. After standing an hour, water was added, and the acids were suffered to remain another hour on the powder; but on decanting them afterwards, and adding fosili alkali to the point of saturation, no precipitate appeared.

The precipitate thrown down by the phlogilificated alkali, mixed with nitre and borax, and melted with a blow-pipe on charcoal, formed a black glass; on frit-glas, a white one; and on a tobacco-pipe, a yellowish white one. Another portion, melted with soaps and borax in a crucible, formed a black glass.

The small quantity of infusible residuum formerly mentioned, appeared to be the combination of ponderous earth with vitriolic acid, called heavy gypsum, marmor metallicum, barofeltenite, &c.

From these experiments the Doctor concludes, that Analysis 100 parts of this spar contain 78.6 of pure ponderous earth, 4½ of a grain of marmor metallicum, and 20.8 grains of fixed air. 2. The quantity of mild alkali necessary to saturate any given portion of acid, contains a greater quantity of fixed air than can be absorbed by that quantity of terra ponderosa which the acid is able to dissolve. 3. The terra ponderosa, when precipitated by means of a mild alkali, readily burns to lime; and this lime-water proves a very nice test of the presence of vitriolic acid. 4. In its native state the terra ponderosa will not burn to lime; when urged with a strong fire, it melts and unites with the crucible, without becoming caustic; nor can it be made to part with its fixed air by any addition of phlogiston. He conjectures, therefore, that as caustic lime cannot unite to fixed air without moisture, and as this spar seems to contain no water in its composition, it is the want of water which prevents the fixed air assuming its elastic aerial state. "This supposition (says he) becomes still more probable, if we observe, that when the solution of the spar in an acid is precipitated by a mild alkali, some water enters into the composition of the precipitate; for it has the same weight as before it was dissolved, and yet produces only 20 ounce-measures of fixed air, while the native spar contains 25 of the same measures; so that there is an addition of weight equal to five ounce-measures of air, or three one-half grains, to be accounted for; and this can only arise from the water. 5. The precipitate formed by the caustic alkali, taking some of the latter down with it, forms a substance neither soluble in acids nor water. This infusible compound is also formed by adding the lime-water already
CHEMISTRY.

Dr Withering having exposed 100 grains of the Terra ponderosa and its combinations to a red heat for an hour in a black crucible, found that it had lost five grains of its weight; but as a sulphureous smell was perceptible, he suspected that a decomposition had taken place, and therefore exposed another portion to a similar heat in a tobacco-pipe, which had no smell of sulphur, nor was it diminished in weight. It melted with borax into a white opaque glass, but was barely fusible by itself under the blow pipe. It did not seem to dissolve in water, nor in any of the acids, except the vitriolic, when by long boiling it had become very concentrated in the dry and almost red hot. It then appeared perfectly dissolved; but separated again unchanged on the addition of water. On exposing the vitriolic solution to the atmosphere for some days, beautiful radiated crystals were formed in it.

On adding a solution of mild vegetable alkali to this precipitated vitriolic solution, a precipitate appeared; but it consisted of marmor metallicum unchanged. An ounce of it in fine powder was then fused with two of salt of tartar until it ran thin, when six drachms of a residuum insoluble in water were left. On the addition of nitrous acid, only 52 grains were left, which appeared to be marmor metallicum unchanged. On saturating the alkaline solution with distilled vinegar, and warming under the precipitate, the liquor was found to contain terra roffa tartar, formed by the union of the acetous acid with part of the alkali; and of vitriolated tartar, formed by that of the alkali with the native acid of the marmor metallicum.

The salt formed by the nitrous acid that readily entered into beautiful permanent crystals of a rough bitterniss nature.

Some of the salt degenerated with nitric and charcoal, left by washing the terra ponderosa very white, capable of being burnt into lime, and again forming an insoluble compound with vitriolic acid. An hundred grains of aerated terra ponderosa, dissolved in marine acid, and precipitated by the vitriolic, were augmented 17 grains in weight. Hence it appears,

1. That the marmor metallicum is composed of vitriolic acid and terra ponderosa.
2. That this compound has very little solubility in water.
3. That it is the only one of this kind that can only be dissolved in highly concentrated oil of vitriol, from which it separates unchanged on the addition of water.
4. That it cannot be decomposed in the moist, by mild fixed alkali, though it may be so in the dry.
5. That it may be decomposed by the union of inflammable matter to its acid, by which sulphur is formed, though the acid cannot be distilled by mere heat.
6. An hundred parts of this substance contain 32.8 of pure vitriolic acid, and 57.2 of terra ponderosa. The marmor metallicum, our author remarks, may possibly be useful in some cafes where a powerful flux is wanted; for having mixed some of it with the black flux, and given the mixture a strong heat in a crucible, it ran entirely through the pores of the vessel.

Dr Withering describes two other kinds of this substance, known by the name of Cauck, and found in the mines of Derbyshire, and other places. These differ from the other only in containing a small proportion of iron. On the whole, he concludes, that the terra ponderosa seems to lay claim to a middle place between the earths and metallic calces. Like the forma-
CHEMISTRY.

Transmutation of flints into an earth soluble in acids.

This is effected by mixing powdered flints with an earth soluble in acids, and melting the mixture by a strong fire. The melted mass dissolves in the air, like alkaline salts; and if the earth be then precipitated, it becomes soluble in acids, which it entirely refists before.

In this process the alkali, by its union with the flint, is deprived of its fixed acid, and becomes caustic. To this causticity its solvent power is owing; and therefore the flint may be precipitated from the alkali, not only by acids, but by any substance capable of furnishing fixed air, such as magnesia alba or volatile alkali. The precipitate in both cases proves the same; but the nature of it hast not hitherto been determined. Some have conjectured that the vitriolic acid existed in the flint; in which case, the alkali made use of in this process ought to be partly converted into vitriolated tartar.

The above process is delivered on the authority of Mr Bergman, who has published a dissertation on this subject, affirms that it cannot be dissolved except by the alkali. The vitriolic, nitrous, or marine acids, have no effect upon it, even when newly precipitated from the liquor of flints washed and still wet, and though a thousand parts of acid be added to one of the earth, and boiled upon it for an hour; but when three parts of alkaline silt are melted in a crucible with one of quartz, the salt dissolves at the same time about seven hundred parts of its own weight of the clay which composes the crucible; and the solubility of this is given occasion to the mistake above mentioned. If the fusion be performed in an iron vessel, no soluble part will be obtained, excepting the very small portion of clay which the quartz contains; and when this is once exhausted by an acid, no more can be procured by any number of fusions with alkali.

The flour acid, he observes, is never obtained entirely free from siliceous earth, and consequently its power as a menstruum must be weakened in proportion to the quantity it contains. In order to observe its solvent power, however, our author, in the year 1772, put some quartz, very finely powdered, into a bottle containing 3 of a kame of flour acid. The bottle was then tightly corked, and set by in the corner of a room. Two years afterwards it was examined; and on pouring out the liquor there found concreted at the bottom of the vessel, besides innumerable small prismatic spicules, 13 crystals of the size of small peas, but mostly of an irregular form. Some of these resembled cubes, whose angles were all truncated, such as are often found in the cavities of flints. These were perfect siliceous crystals, and very hard, but not comparable with quartz, though they agreed with it in essential properties. "Possibly (says he) the length of a century may be necessary for them to acquire, by excretion, a sufficient degree of hardness."

The bottom itself, as far as the liquor had reached, was found covered with a very thin siliceous pellicle, which was scarcely visible, but separated on breaking the bottle. It was extremely pelliculose, flexible, and showed prismatic colours. These phenomena show that much siliceous matter is dissolved and suspended in the flour acid. "Whether any of the quartz was taken up in this experiment is uncertain; but it appears probable that little or none was dissolved; since, by the help of heat during the distillation, the acid had previously taken up so much siliceous earth, that upon flow evaporation it was unable to retain it. Hence appears the origin of the crystals and the pellicle; and hence appears the canite which impedes the action of flour acid upon flint; namely, that the acid obtained in the ordinary way is already saturated with it."

The volatile alkali precipitates siliceous earth merely from flour acid; and thus we find, that one part of it is contained in 600 of the acid, diluted to such a degree, that its specific gravity is only 1.064. This precipitate has all the properties of pure flour; but that precipitated either by vegetable or mineral fixed alkali does not afford a pure siliceous earth, but a peculiar kind of triple salt, formed of the earth, flour acid, and fixed alkali, which dissolves, though with difficulty, in warm water, especially the earth procured by vegetable alkali, but is easily decomposed by lime-water and leaves the mineral flour regenerated.

Fixed alkaline salts attack this earth by boiling, but not unless it be reduced to very fine powder, and newly precipitated from the liquor. Oil of tartar per diem takes up about one-sixth of its weight, and the liquor becomes gelatinous on cooling, though at first diluted with 16 times its weight of water. This solution is effected only by the caustic part; for when fully saturated with fixed acid, it cannot enter into any combination with it. Volatile alkali, even though caustic, has no effect.

The attraction between siliceous earth and fixed alkali is much more remarkable in the dry way; for it is thus melted with one half its weight of alkali into an hard, firm, and transparent glass, the aerial acid and water going off in a violent effervescence. In proportion as the alkali is increased, the glass becomes more soft and lax, until at last it dissolves totally in water, as has been already mentioned. The siliceous matter thus precipitated is of a very rare and pungent texture, and so much swelled by water, and its bulk of water when wet is at least twelve times greater than when dry; nor does it contract more than suffices to remain a long time in the water. Hence it is easy to reduce the liquor of flints to a jelly, by boiling it with four or eight times its weight of water, and adding a sufficient quantity of precipitate; but if an over proportion of water be used, for instance, 24 times the weight, the liquor will then remain limpid though we add as much acid as is sufficient for saturating the alkali. The reason of this Mr Bergman supposes to be, that the siliceous particles are removed to such a distance from one another, that they cannot overcome the heat.
From attending to the qualities of this stone, and Phosphoric the requited for making this phosphorus, we are naturally led to think, that the Bolognian phosphorus is no other than a compose of sulphur and quicklime. The stone itself, in its natural state, evidently contains the phos-

vitic acid, from its not ever sepicing with acids of any kind. This acid cannot be expelled from earthy substances by almost any degree of fire, unless inflammable matter is admitted to it. In this case, part of the acid becomes sulphurous, and flies off; while part is converted into sulphur, and combines with the earth. In the above mentioned process, the inflammable matter is furnished by the coals in contact with which the cakes are calcined, and by the mucilage of gum tragacanth with which the cakes are made up. A true sulphur must therefore be formed by the union of this inflammable matter with the vitriolic acid contained in the stone; and part of this sulphur must remain united to the earth left in a calcareous state, by the dilution, or conversion into sulphur, of its acid.

In the year 1730, a memoir was published by Mr. Allcalcado Fay; wherein he afferts, that all calcareous stones, whether they contain vitriolic acid or not, are capa-

ble of becoming luminous by calculation: with this difference only, that the pure calcareous stones require a stronger, or more frequently repeated, calculation to convert them into phosphors; whereas those which contain an acid, as seifines, gypsum, spars, &c., become phosphoric by a lighter calculation. On the contrary, Mr. Margraaf afferts, that no other stones can be rendered phosphoric but those which are fatu-

rated with an acid; that purely calcareous stones, such as marble, chalk, limestone, stalactites, &c., cannot be rendered luminous, till saturated with an acid previously to their calculation.

We have already taken notice, that the compounds formed by uniting calcareous earths with the nitrous and marine acids become a kind of phoshor: the former of which emits light in the dark, after having been exposed to the fun through the day; and the latter becomes luminous by being struck. Signior Signior Beccaria found, that this phosphoric quality was capa-

ble of being given to almost all substances in nature, metals perhaps excepted. He found that it was widely diffused among animals, and that even his own hand and arm poiselled it in a very considerable degree. In the year 1775, a treatise on this kind of phosphor was published by B. Wilson, F. R. S. and a member of the Royal Academy at Upal. In this treatise, he shows, that oyster-stills, by calculation, acquire the phosphoric quality in a very great degree, either when combined with the nitrous acid or without it.

The first experiment made by our author was the pouring some aquafortis, previously impregnated with copper, on a quantity of calcined oyster-stills, so as to form them into a kind of paste; he put this paste into a crucible, which was kept in a pretty hot fire for about 40 minutes. Having taken out the mass, and waited till it was cool, he presented it to the external light. On bringing it back suddenly into the dark, he was surprized with the apparence of a variety of colours like those of the rainbow, but much more vivid. In consequence of this appearance of the prismatic colours,

§ 5. Of Metallic Substances.

Gold.
Practice.

Gold.

Fusion for half an hour, during which time a full quarter of the tin was calcined; yet the gold remained altogether unchanged.

7. The mixture of gold and tin produced in exp. 1, was melted a second time in a stronger fire than at first, and kept in fusion for half an hour; during which time six grains of weight were lost, but the gold remained perfect as before.

8. and 9. The mixtures of exp. 2, and 4, viz. 90 and 140 grains to 12 ounces of gold, were re-melted separately, and an ounce of copper added to each. On being cast as usual, they bore all the operations of manufacturing as before, though sensibly harder. The last cracked at the edges as it had done without the copper, but bore cutting rather better than in its former state.

10. and 11. A quarter of an ounce of the last mixture, being tin 140 grains, and copper an ounce, and gold 12 ounces, with as much of the bar from experiment 3, consisting of 140 grains of tin to 12 ounces of gold, were each melted by a jeweller in a common sea-coal fire, into small buttons, without any loss of weight. These buttons were afterwards forged into small bars, healing them often with the flame of a lamp, and afterwards drawn each about twenty times through the apertures of a steel plate, into fine wire, with as much ease as coarse gold commonly passes the like operation.

12. Sixty grains of tin were added to 12 ounces of standard gold; fine; and the compound passed every one of the operations already described, without showing the least alteration from the tin.

Several other trials were made with different mixtures of copper, tin, and silver, with gold, even as low as two ounces and a half of copper, with half an ounce of tin, to twelve ounces of gold; all of which bore hammering and flatting by rollers to the thinnes of stiff paper, and afterwards working into watch-castes, cane-heads, &c. with great ease. They grew more hard and harsh in proportion to the quantity of alloy; but not one of them had the appearance of what workmen call brittle gold. Mr Alchorne therefore is of opinion, that when brittleness is occasioned by the addition of tin to gold, the former has been adulterated with arsenic; as he has found, that by adding 12 grains of regulus of arsenic to as many ounces of fine gold, the compound has been rendered altogether unmeliable.

When gold is struck during a certain time by a hammer, or when violently compressed, as by the wire-drawers, it becomes more hard, elastic, and less ductile; so that it is apt to be cracked and torn. Its ductility is, however, restored by the same means, with other metals, namely, heating it red hot, and letting it cool slowly. This is called annealing metals; and gold seems to be more affected by this operation than any other metal. The ductility of the parts of gold is also very surprising; for a wire of 1/16 of an inch in diameter will support a weight of 300 pounds.

Gold is unalterable by air or water. It never contracts ruff like other metals. The action of the fiercest waters and acids has no alteration in it. Kunckel kept gold in a glaas Furnace for four months, and Boyle kept some exposed to a great heat for a still longer time, without the loss of a single grain.

It is said, however, to be dissipable in the focus of a large burning mirror.

Mr Boyle relates a very curious and extraordinary experiment, which he thought was sufficient to prove the total destructibility of gold. About an eighth part of a grain of powder, communicated by a stranger, was projected upon two drachms of fine gold in fusion, and the matter kept melted for a quarter of an hour. During the fusion, it looked like ordinary gold; except only once, that his assistant observed it to look exactly of the colour of opal. When cold, it was of a dirty colour, and, as it were, overcast with a thin coat, almost like half-vitriified litharge: the bottom of the crucible was overlaid with a vitriified substance, partly yellow, and partly reddish brown; with a few small globules, more like impure silver than gold. The metal was brittle, internally like brass or bell-metal; on the touchstone more like silver than gold: its specific gravity was to that of water only as 15; to 1. There was no absolute loss of weight.

By cupellation, 60 grains of this mafs yielded 32 grains of pure gold, with seven grains of a ponderous substance, fixed, dark-coloured substance.

We have already mentioned, that in certain circumstances gold is soluble in the nitrous and marine acids separately. It is, however, always soluble by the two united, but dissolves slowly even then. The most commodious method of obtaining this solution is, by putting the gold, either in leaves, or granulated, or cut into small thin pieces, into a proper quantity of aquafortis; then adding, by degrees, some powdered sal ammoniac, till the whole of the gold is dissolved. By this means a much smaller quantity of the menstruum proves sufficient, than if the sal ammoniac was previously dissolved in the aquafortis; the conflict, which each addition of the salt raises with the acid, greatly promoting the dissolution. Aquafortis of moderate strength will, in this way, take up about one-third of its weight of gold; whereas an aqua-regis, ready prepared from the same aquafortis, will not take up above one-fifth its weight. Common salt answers better for the preparation of the aqua-regis than sal ammoniac.

This solution, like all other metallic ones, is corrosive. It gives a violet colour to the fingers, or to any of the solubil animal matters. If the solution is evaporated and dried, yellow transparent crystals will be formed: but, if the evaporation is carried too far, the acids with which the gold is combined may be driven from it by heat alone; and the gold will be left in the state of a yellow powder, called calx of gold.

Gold may be precipitated from its solution by those substances which commonly precipitate metals, such as alkali salts and calcarious earths. It may also from its solution, be precipitated in a fine purple powder, by tin or its solution.

When fixed alkalies are made use of, the precipitate weighs about one-fourth more than the gold employed. With volatile alkalies also, if they are added in no greater proportion than is sufficient to saturate the acid, the quantity of precipitate proves nearly the same; but if volatile spirit is added in an over-proportion, it redissolves part of the gold which it had before precipitated, and the liquor becomes again considerably yellow. The whole of the precipitate, however,
Aurum fulminans. — Gold precipitated from its solution in aqua-regia explodes by heat with much greater violence than any other substance in nature. This property was known in the 15th century; but whether the ancient alchemists knew anything of it or not, is a matter of uncertainty. Basil Valentine first gave any distinct account of it. He directs the gold to be dissolved in aqua-regia made with fæt ammoniac, and then precipitated by vegetable fixed alkali, to be twelve times washed with water, and lastly dried in the open air, where the sun's rays cannot reach it. He forbids it to be dried over a fire, as it explodes with a gentle heat, and flies off with inconceivable violence.

Succeeding chemists have performed this operation with some little differences; but the necessity of employing volatile alkali was but little regarded till the beginning of the present century. The calx of gold is always somewhat increased in weight by being converted into aurum fulminans; but authors are not agreed about the quantity of augmentation. Becher makes it heavier by one-fifth part; Lefery by one-fourth; and Juncker by one-fourth. All agree, however, that it explodes with a violence almost inconceivable. Crollius relates, that 20 grains of this powder explodes with more force than half a pound of gun powder, and exerts its force downwards, though M. Teykmeyer frequently flowed in his lectures that it would throw a florin upwards above six feet. A great number of experiments were made before the Royal Society at London, in order to determine the comparative forces of these two powders.

Equal parts of gunpowder and aurum fulminans were included in iron globes placed among burning coals; those which contained the former burst with great violence, but the globes containing the aurum fulminans remained perfectly silent. But though no explosion takes place in close vessels, the utmost caution is necessary in managing this substance in the open air; especially when it is subjected to friction, or to a flight of dust, for such is the nature of the calx we speak of, that it is not necessary, in order to cause it to explode, to touch it with an ignited substance; or to make it red-hot. The heat requisite for this purpose is, according to Dr Lewis, intermediate between that of boiling water and the heat which makes metals of an obscure red. With friction, however, it seems still more dangerous; for in this case it explodes with what we should think scarce sufficient to communicate any degree of heat whatever. Orfchel relates, that this powder ground in a jasper mortar, exploded with such violence as to burst the vessel in a thousand pieces; Dr Lewis gives an instance of a similar kind in England; and Dr Birch tells us of doors and windows torn to pieces by the violence of this explosive matter. Mr Macquer relates the following accident to which he was witness. "A young man, who worked in a laboratory, had put a drachm of fulminating gold into a bottle, and had neglected to wipe the inner surface of the neck of the bottle, to which some of the powder adhered. When he endeavoured to close the bottle, by turning round the glass stopper, the friction occasioned an explosion of part of the powder. By this the young man was thrown some steps backward, his face and hands wounded by the fragments of the bottle, and his eyes put out; yet, notwithstanding this violent explosion, the whole drachm of fulminating gold certainly did not take fire as much of it was afterwards found scattered about the laboratory."

It has already been mentioned, that some imagine the force of this explosion to be directed downwards; but Dr Lewis is of opinion that it is equally directed every way. Certain it is, that the quantity of from 10 to 12 grains of aurum fulminans, exploded on a metallic plate, lacerates it; a smaller quantity forms a cavity, and a still smaller only scratches the surface; effects which are never produced by gunpowder in ever so large a quantity. A weight laid upon the powder is thrown upwards in the moment of explosion. If it be of silver or copper, this weight is marked with a yellowish spot, as the supports will also be, if made of either of these metals. A large grain, says Mr Bergman, brought near to the side of the flame of a candle, blows it out with great noise; and a few ounces exploding together by incautious drying, has been known to shatter the doors and windows of the apartment; hence it is evident, that aurum fulminans expels its force in all directions; yet it cannot be denied, that it strikes bodies with which it is in contact more violently than those which are at a small distance, though in its vicinity; thus, if a small portion of it explodes in a paper box, it lacerates only the bottom, unless the top be pressed down close, in which case it perforates both the top and bottom. When carefully and gradually exploded in a glass phial or paper box, it leaves a purple foot, in which are found many particles of shining gold; and if the quantity exploded be large, several grains remain totally unchanged, as it is only the lowermost stratum that is inflamed.

Aurum fulminans, when moist, does not explode at all; but as it dries, the grains go off in fuscussion like of mois, the deprecation of common salt,—In glass vessels closed, or with their mouths immersed in water, it explodes, but with a very weak report. An elastic vapour, in the quantity of seven inches, from half a drachm of the powder, broke forth in the moment of explosion, which, but for our authors account, seems to be phlogisticated air. In metallic vessels sufficiently strong, the gold is silently reduced when they are perfectly...
Gold

Causes of this explosion attributed to a faîne principle.

This opinion shown to be erroneous by Mr. Bergman.

Aurum fulminans can be made without nitrous or marine acids.

Fixed air not the cause of the explosion.

CHEMISTRY

Gold has been attributed chiefly to a faîne principle, viz. The combination of nitrous acid with volatile alkali; and this opinion has been supported by an affinity, that the fulminating property is destroyed by treating the calx with vitriolic acid or with fixed alkali; the former expelling the nitrous acid, and the latter diffusing the volatile alkali. Mr. Bergman allows that fixed alkali destroys the fulminating property; but affirms, that it acts only by separating the particles when the two are triturated together; and this might be done by many other substances as well as fixed alkali; but when the alkali, instead of being triturated in the dry way with the calx, was boiled in water along with it, the explosion not only took place, but was much more violent than usual. It must be observed, however, that heat alone destroys the fulminating property of this calx; and therefore, if the alkaline solution be made too strong, the additional heat which it then becomes capable of sustaining, is sufficient to deprive the calx of its fulminating property. The case is the same with the vitriolic acid; for this has no effect upon the calx, either by digestion in its concentrated state, or by boiling in its diluted state. If it be boiled in its concentrated state indeed with the fulminating calx, the heat conceived by the acid is sufficient to destroy the fulminating property of the former; and in like manner, unless the calx be in some measure destroyed, or reduced to its metallic state, it can never be deprived of its fulminating property.

It was further proved, that the fulminating property did not depend on the presence either of nitrous or marine acids, for it can be made without them. A calx of gold, not fulminating, dissolved in vitriolic acid, and precipitated by caustic volatile alkali, had acquired this property. A solution of the same calx in nitrous acid, let fall a precipitate by the addition of pure water, and this precipitate is precipitated and digested with volatile alkali, fulminated as if it had been originally precipitated with that alkali. The experiment was repeated on the other non-fulminating precipitates with the same success. Left any faticitie, however, should remain, that a small quantity of aqua regia might still be left, which, by combining with the volatile alkali, would make a proportionable quantity of nitrous flammans, the precipitate was digested 24 hours in vitriolic acid, then washed in pure water, and immerced in aqueous and spirituous solutions of alkali, both mild and caustic; but the event was the same. Lastly, an inert calx of gold may always be made to fulminate by digesting it with volatile alkali; nor can this property be communicated to it by any means without the use of this alkali.

It has been suppos'd some very eminent chemists, among whom we may number Dr. Black, that fixed air is the cause of the fulmination of gold; but it is evident that this cannot be the case: because, 1. Gold fulminates as well when precipitated by the caustic volatile alkali, as by that which contains fixed air, 2. This metal does not combine, during precipitation, with fixed air. 3. Gold, when precipitated by mild fixed alkali, does not fulminate, unless the menfrum contain volatile alkali.

The fulminating calx of gold may be prepared either with the compound aqua regia of pure nitrous and marine acids; or of pure nitrous acid and almaniac; or of a compound of alum, nitre, and sea-salt. When this kind of liquor is made use of, the acid of the alum expels the other two, and thus forms an aqua regia. This was formerly called menfrum fine firepsiti. By whatever method the gold is dissolved, it always affords a yellow calx with alkalis, but the volatile alkali most readily throws down the metal. The phlogitecated spirit of salt very readily dissolves gold, and produces a fulminating precipitate as well as aqua regia.

We shall conclude this account of aurum fulminans with an abstract of Mr. Bergman's theory of the explosion. - He observes, that volatile alkali contains phlogiston; an undoubted proof of which is given by Dr. Priestley, by covering alkaline into phlogisticated air. This phlogiston, says he, may be separated by means of a superior attraction; so that the volatile alkali is decomposed, and the residuum diffus'd in form of an elastic fluid, altogether similar to that which is extricated during the fulmination; the source from whence the elastic fluid is derived must be obvious; and it only remains to examine the medium by which the volatile alkali is dephtlogitecated.

In those metals which are called perfect, so great is the firmness of texture, and so close the connection of the earthly principle with the phlogiston, that by means of fire alone these principles cannot be diffus'd: but when dissolved by acid menfrus, they must necessarily lose a portion of their phlogiston; and therefore, when afterwards precipitated by alkalis which cannot supply the loss, they fall down in a calcined state, though they attract phlogiston so strongly, that they can be reduced to a metallic state, merely by an intense heat penetrating the vessels. It may therefore be laid down as a fundamental position, that gold is perfect and contains phlogiston.

Let us now consider the consequence of expounding the powder consisting of calx of gold and volatile alkali the alkali intimately united, to an heat gradually increasing of the fed. The calx which is united with the volatile alkali, by the assistance of a gentle heat, excites its phlogiston; and when this is taken away, the residuum of the falt is instantly expanded into the form of an elastic fluid, which is performed with so much violence, that the air muf t yield a very acute sound.

Our author proceeds to explain this phenomenon upon the principles ascribed to him and Mr. Seebree, exhibits of heat being a composition of light, and the phlogiston or principle of inflammability; but as this hypothesis is by no means satisfactory, we shall omit his reasoning founded upon it; That the volatile alkali, however, is really capable of producing a flash is easily proved, because it exhibits one when thrown into a hot crucible. A single cubic inch of gun-powder generates about 244 of elastic fluid; but the same quantity of aurum fulminans yields at least four times as much; and hence we may easily understand the difference in their explosive force.

That careful calculations should destroy the fulminating power of the fixed alkali; therefore, the volatile alkali must be employed, if the fulminating property be to be produced.
...tion for phlogiston; it also acts upon the phlogiston of the volatile alkali, and lefions its connection; which two circumstances must tend to the union producing the explosion. But this effect has a maximum; and at this period the slightest friction supplies the defect of necessary heat, and produces the fulmination. The calcined gold also seems to collect and fix the matter of heat, though still insufficient by means of its phlogiston, in a certain degree; so that by means of friction, though but very slight, it becomes capable of exerting its force; but when the heating is often repeated without procuring its effect, the volatile alkali is by degrees dissipated, and at length so much diminished that the calx becomes inert.

"But if aurum fulminans is capable of producing such a prodigious quantity of elastic fluid, how does it happen that it remains mute and inert when reduced in close vessels? Of this the reason may be, that every elastic fluid, in the act of breaking forth, requires a space to expand in; and if this be wanting, it remains fixed. Taking this for granted, a calx of gold cannot be reduced in close vessels either by heat or by the phlogiston of volatile alkali; for in either case it must evolve its elastic fluid, which by suppulsion it cannot do. Nothing remains to solve this difficulty but the ignition of the surrounding metal; by means of which the calx, in virtue of its superior attraction, seizes the phlogiston of the metal, which that substance here, as well as in other instances, is capable of losing without the eruption or absorption of any fluid whatever."

Several chemists have asserted, that the calces of copper or silver may be made to fulminate like that of gold. But Mr. Bergman informs us, that these experiments never succeeded with him; "so (says he) they have either been silent upon some circumstances necessary in the operation, or perhaps have been deceived by the detonation of nitrum flammos, or some other accidental occurrence. It is not sufficient for the volatile alkali to adhere to the precipitate; for platina thrown down by this alkali retains a portion of it very obstinately, but yet does not fulminate on the exposition of fire — Besides the presence of volatile alkali, it seems to be necessary that the metallic calx should be reducible by a gentle heat, in order to decompose it; but every explosion is not to be derived from the same cause; nay, in this respect, aurum fulminans, gold-powder, and pulvis fulminans, differ very much, though they agree in several particulars." Of late, however, it has been found that the calx of silver may be made to fulminate in a manner still more extraordinary than that of gold. See the next article.

If gold is melted with an hepur sulphur, composed of equal parts of sulphur and fixed alkaline salt, the metal readily unites with it into an uniform mass, capable of dissolution in water without any separation of its parts. The solution, besides a nauseous taste from the sulphur, has a peculiar penetrating bitterness, not discoverable in any other metallic solution made by the same means.

Though the compositions of sulphur and alkali seem to unite more intimately with gold than any other metal, their affinity with it is but slight; copper, or iron, added to the matter infusion, dissolute, and precipitate the gold. The metal thus recovered, and purified by the common processes, proves remarkably paler-coloured than at first. In an experiment related by Dr. Brandt, in the Swedish Memoirs, the purified gold turned out nearly as pale as silver, without any diminution of weight.

Gold has been thought to be possessed of many ex-traordinary virtues as a medicine; which, however, virtues of are long ago determined to be only imaginary. It is not indeed very easy to prepare this metal in such a manner that it can be safely taken into the human body. The solution in aqua-regia is poisonous; but if any efferential oil is poured on this solution, the gold will be separated from the acid, and united to the efferential oil; with which, however, it contracts no lasting union, but in a few hours separates in bright yellow film to the sides of the glasses. Vittorio ether disolves the gold more readily and perfectly than the common efferential oils; and keeps it permanently suspended, the acid liquor underneath appearing colourless. The yellow ethereal solution poured off, and kept for some time in a glass stop with a cork, so that the spirit may slowly exhale, yields long, transparent, prismatic crystals, in shapes like those of nitre, and yellow like topaz. What the nature of these crystals is, either as to medicinal effects, or other purposes, is as yet unknown.

Rectified spirit of wine mingle uniformly with the solution of gold made in acids: if the mixture is suffered to stand for some days in a glass slightly covered, the gold is by degrees revived, and arises in bright pellicles to the surface. Groffer inflammable matters, wine, vinegar, solutions of tartar, throw down the gold, in its metallic form, to the bottom. It is the only metal which is thus separable from its solution in acids by these substances; and hence gold may be purified by these means from all admixtures, and small proportions of it in liquors readily discovered.

When the colour of gold is by any means rendered pale, it may be recovered again by melting it with gold red-copper, and afterwards separating the copper; or by red.

A mixture of verdigris and sal ammoniac with vitriol or nitre. The colour is also improved by fusion with nitre, injecting sal ammoniac upon it in the fusion, quenching it in urine, or boiling it in a solutition of alum. When borax is used as a flux, it is customary to add a little nitre or sal ammoniac, to prevent its being made pale by the borax. Juncker reports, that by melting gold with four times its weight of copper, separating the copper by aquafortis unpurified, then melting the gold with the same quantity of fresh copper, and repeating this process eight or nine times, the gold becomes at length of a deep red colour, which sustains the action of lead, antimony, and aquafortis.

### Silver.

I

#### The density of silver.

This, next to gold, is the most perfect, fixed, and durable of all the metals. Its specific gravity is to that of water nearly as 11 to 1. A single grain has been drawn into a wire three yards long, and flated into a plate an inch broad. In common fire it suffers no diminution of its weight; and, kept in the vehement heat of a glafs-house for a month, it loses no more than one sixty-fourth. In the focus of a large burning-glafs, it smokes for a long while, then contracts a greyish ash on the surface, and at length is totally distillated.

Silver is somewhat harder and more fonorous than gold, and is fusible with a less degree of heat. The tenacity of its parts also is nearly one half less than that of gold; a silver wire of . of an inch diameter being unable to bear more than 270 pounds.

Mercury unites very readily with silver-leaf, or with the calx of silver precipitated by copper; but does not touch the calces precipitated by alkaline salts. The vapours of sulphureous solutions stain silver yellow or black. Sulphur, melted with silver, debases its colour to a leaden hue, renders it more easily fusible than before, and makes it flow so thin as to be apt in a little time to penetrate the crucible: in a heat just below fusion, a part of the silver-flows up, all over the surface, into capillary efflorescence. Aquafortis does not act upon silver in this compound; but fixed alkaline salts will absorb the sulphur, and from a heap of sulphur, which, however, is capable of again dissolving the metal. If the sulphurated silver is mixed with mercury sublimated, and exposed to the fire, the mercury of the sublimate will unite with the sulphur, and carry it up in the form of cinnabar, whilst the marine acid of the sublimate unites with the silver into a luna cornes, which remains at the bottom of the glafs. Fire alone is sufficient, if continued for some time, to expel the sulphur from silver.

From the bafer metals, silver is purified by copulation with lead. (See refining.) It always retains, however, after that operation, some small portion of copper, sufficient to give a blue colour to volatile spirts, which has been erroneously thought to proceed from the silver itself. It is purified from this admixture by melting it twice or thrice with nitre and borax. The fcoria, on the first fufion, is common blue; on the second, green; and on the third, white, which is a mark of the purification being completed.

The most effectual means, however, of purifying silver, is by reviving it from luna cornes; because spirit of falt will not precipitate copper as it does silver. The silver may be recovered from luna cornes, by fusion with alkaline and inflammable fluxes; but, in these operations, some fofs is always occasioned by the diffusion of part of the volatile calx, before the alkali or metal can absorb its acid.

Mr. Margraaf has discovered a method of recovering the silver with little or no loss; mercury affiited by volatile falt, imbuing it by trituration without heat. One part of luna cornes, and two of volatile falt, are to be ground together in a glafs-mortar, with a much

#### The attraction of lead.

Silver is purified and whitened externally by boiling it in a solution of tartar and common falt. This is no other than an extraction of the cuprous particles from the surface of the silver, by the acid of the tartar acuated by the common falt.

M. Berthollet has lately discovered a method of purifying the calx of silver a fulminating property, ting silver, and that much more terrible than fulminating gold itself. His receipt for making it is,

CHEMISTRY. Practice.

Silver.

It has been informed how the atoms came there, considering what we have just now related, "the portion touched by the hand fulminated, and of course that which fell upon the ground. A drop of water which fell upon this powder caused it to fulminate. A single grain of fulminating silver, which was in a glass cup, reduced the glass to powder, and pierced several dozen of paper.

If the volatile alkali, which has been employed with the above powder, be put into a thin glass matraps and boiled, then, on standing in the cold, small crystals will be found sublimed on the interior sides of the vesel, and covering the liquor. On touching one of these crystals the matraps will be burnt with considerate explosion.

The dangerous properties of this powder suggest the necessity of not preparing it but when the face is covered with a mask with glass eyes; and to avoid this rupture of the glass cups, it is prudent to dry the fulminating silver in small metallic vessels." To this we may add, that as the powder does not fulminate when wet, it may in that state be put up in very small quantities on paper, to be fulminated afterwards as occasion offers. This will perhaps account for the appearance of the few atoms abovementioned on the paper which the wind over Turned.

With regard to the case of this extraordinary fulmination we can say nothing satisfactory; the following curious fact is alligned by the antiphlogists; which at once shows the futility of their theories, and sets in a very ridiculous light the hard words with which they would obviate the science of chemistry.

"The oxygenous principle* (say they) unites with the hydrogenous principle† of the volatile alkali, and forms water in a vaporous state. This water (in a vaporous state) being infaunaneously thrown into a state of vapour, polluting elasticity and expansive force, is the principal cause of this phenomenon, in which the actoæ air which is detached from the volatile alkali, with its whole expansive power, has a great share."

But this, as well as other theories, in which elastic fluids are alleged to be the cause of the phlogiston, it is obvious to remark, that should we allow this to be the case, we are utterly at a loss to find a source of heat sufficient to rarefy the vapour to such a degree as is necessary for producing the effect ascribed to it. In the present cafe, we can scarce suppose a grain weight of metallic salt, already dry, to contain as much either of fire or water as is necessary to produce the effect; nor can we explain why the touch of any cold body, and which may be supposed to contain less fire than the salt itself, should produce such an effect. As to the oxygenous and hydrogenous principles, they were there before the touch, and ought to have produced their effects, not to mention that the water produced by them could not have amounted to the thousandth part of a grain. It is much more probable, therefore, that the whole is to be considered as an effect of electricity, though we cannot tell how the fluid comes here to be excited in such a violent manner.

§ 3. COPPER.

This is one of those metals which, from their destructibility by fire, and contragging rust in the air, are called imperfect. Of these, however, it is the most perfect and indestructible. It is of a reddish colour when pure; easily tarnishes in a moist air, and contracts a green rust. It is the most famous of all the metals, and the hardest and most elastic of all but iron. In some of its states, copper is as difficultly extended under the hammer as iron, but always proves softer to the file; and is never found hard enough to strike a spark with flint or other stones; whence its use for chiefls, hammers, hoops, &c. in the gunpowder works. When broke by often bending backwards and forwards, it appears internally of a dull red colour without any brightness, and of a fine granulated texture resembling some kinds of earthen ware. It is considerably ductile, though lefs so than either gold or silver; and may be drawn into wire as fine as hair, or beaten into leaves almost as thin as those of silver. The tenacity of its parts is very considerable; for a copper wire of 51⁄₄ of an inch diameter will support a weight of 399 pounds without breaking. The specific gravity of this metal, according to Dr Lewis, is that of water as 8.830 to 1.

Copper continues malleable when heated red; in which respect it agrees with iron; but is not, like iron, capable of being welded, or having two pieces joined into one. It requires for its fusion a stronger heat than either gold or silver, though less than that requisite to melt iron. When in fusion, it is remarkably impatient of moisture; the contact of a little water occasioning the melted copper to be thrown about with violence, to the great danger of the by-standers. It is, nevertheless, said to be granulated in the brass-work at Bristol, without explosion or danger, by letting it fall in little drops, into a large cistern of cold water covered with a brass-plate. In the middle of the plate is an aperture, in which is secured with Sturbridge clay a small vessel, whose whole capacity is not above a spoonful, perforated with a number of minute holes, through which the melted copper paffes. A stream of cold water paffes through the cistern. If suffered to grow hot, the copper falls liquid to the bottom, and runs into plates.

Copper, in fusion, appears of a blufh green colour, nearly like that of melted gold. Kept in fusion too long, it becomes gradually more and more brittle; but does not scorify considerably, nor lose much of its weight. It is much lefs destructible than any of the imperfect metals, being very difficulty subdued even by lead or bisnuth. If kept in a heat below fusion, it contracts on the surface thin powdery scales; which, being rubbed off, are succeeded by others, till the whole quantity of the metal is thus changed into a scoria or calx, of a dark reddish colour. This calx does not melt in the strongest furnace fires; but, in the focus of a large burning mirror, runs easily into a deep red, and almost opaque, glass. A flaming fire, and strong draught of air over the surface of the metal, greatly promote its calcination. The flame being tinged of a green, blufh, or rainbow colour, is a mark that the copper burns.

This metal is very readily fusible by almost all fuid substances; even common water, suffered to stand long in copper-vessels, extracts so much as to gain a coppery taffe. It is observable, that water is much more impregnated with this taffe, on being suffered to stand in the cold, than if boiled for a longer time in the vessel. The fame thing happens in regard to the mild vegetable acids. The confectioners prepare the most acid syrups, even those of lemons and oranges, by
CHEMISTRY.

Practice.

Copper.

by boiling in clean copper-vessels, without the preparations receiving any ill taste from the metal; whereas, either the juices themselves, or the syrups made from them, if kept cold in copper vessels, soon become impregnated with a disagreeable taste, and with the pernicious qualities of the copper.

1151 Altered by combination with vegetable acids.

By combination with vegetable acids, copper becomes in some respects remarkably altered. Verdigris, which is a combination of copper with a kind of acetic or tartaraceous acid, is partially soluble in distilled vinegar; the residuum, on being mixed with borax and linseed oil, yields a brittle metallic substance, of a whitish colour, not unlike bell-metal. The copper also, when revived from the diluted verdigris, was found by Dr. Lewis to be different from the metal before dissolution; but neither of these changes have yet been sufficiently examined.

Copper, in its metallic state, is very difficultly amalgamated with mercury; but unites with it more easily if divided by certain admixtures. If mercury and verdigris be triturated together with common salt, the amalgam is separated in the amalgamation, thus filled, are to be placed in a furnace sunk in the ground, the form of which is that of the frustum of a hollow cone. At the bottom of the furnace, or greater basins of the frustum, is a circular grate, or iron plate. This plate is covered with a coat of clay and horse-dung, to defend it from the action of the fire; and pierced with holes, through which the smoke and flame pass. The crucibles stand upon the circular plate, forming a circular row, with one in the middle. The fuel is placed between the crucibles, and is thrown into the furnace at the upper part of it, or the lesser basins of the frustum. To this upper part or mouth of the furnace is fitted a cover made of bricks or clay, kept together with bars of iron, and pierced with holes. This cover serves as a register. When the heat is to be increased, the cover must be partly or entirely taken off, and a free draught is permitted to the external air, which puffs along a vault under-ground to the air-hole, through which the air in the circular grate or plate, betwixt the crucibles, and through the upper mouth, along with the smoke and flame, into an area where the workmen stand, which is covered with a large dome or chimney, through which the smoke and air ascend. When the heat is to be diminished, the mouth of the furnace is closed with the lid; through the holes of which the air, smoke, and flame pass. The crucibles are to be kept red-hot during eight or ten hours; and in some places much longer, even several days, according to the nature of the calamine. During this time, the zinc rises in vapour from the calamine, unites with the copper, and renders that metal considerably more fusible than it is by itself. To render the metal very fluid, that it may flow into one uniform mass at the bottom, the fire is to be increased a little before the crucibles are taken out, for pouring off the fluid metal into moulds. From 60 pounds of good calamine, and 40 of copper, 60 pounds of brazes may be obtained, notwithstanding a considerable quantity of the zinc is dissipated in the operation. The quantity of brazes obtained has been considerably augmented since the introduction of the method now commonly practised, of granulating the copper; by which means a larger surface of this metal is exposed to the vapour of zinc, and consequently less of that vapour escapes. To make the finer and more malleable kinds of brazes, besides the choice of pure calamine and pure copper,
C H E M I S T R Y.

Iron.

Iron is a metal of a greyish colour; soon tarnishing in the air into a dusky blackish hue; and in a short time contracting a yellowish, or reddish rust. It is the hardest of all metals: the most elastic; and, excepting platinum, the most difficult to be fused.

Next to tenacity of gold, iron has the greatest tenacity of parts; an iron wire, the diameter of which is the tenth part of an inch, being capable of sustaining 450 pounds. Next to tin, it is the lightest of all the metals, losing between a seventh and eighth part of its weight when immersed in water. When very pure, it may be drawn into wire as fine as horse-hair; but is much less capable of being beaten into thin leaves than the other metals, excepting only lead.

Iron grows red-hot much sooner than any other metal; and this, not only from the application of actual fire, but likewise from strong hammering, friction, or other mechanical violence. It nevertheless melts the most difficulty of all metals except manganese and platinum; requiring, in its most fusible state, an intense, bright, white heat. When perfectly malleable, it is not fusible at all by the heat of furnaces, without the addition of the immediate contact of burning fuel; and, when melted, loose its malleability: all the common operations which communicate one of these qualities deprive it at the same time of the other, as its fusibility and malleability were in this metal incompatible. When exposed to the focus of a large burning mirror, however, it quickly fused, boiled, and emitted an ardent flame, the lower part of which was a true flame. At length it was changed into a blackish vitrified scoria.

From the great waste occasioned by exposing iron to a red but especially to a white heat, this metal appears to be a combustible substance. This combustion is maintained, like that of all other combustible substances, by contact of air. Dr. Hook, having heated a bar of iron to that degree called white heat, he placed it upon an anvil, and blew air upon it by means of bellows, by which it burnt brighter and hotter. Exposed to a white heat, it contracts a fémivitréous coat, which bursts at times, and flies off in sparkles. No other metallic body exhibits any such appearance. On continuing the fire, it changes by degrees into a dark red calx, which does not melt in the most vehement heat producable by furnaces, and, if brought into fusion by additions, yields an opaque black glass. When strongly heated, it appears covered on the surface with a soft vitreous matter like varnish. In this state, pieces of it cohere; and, on being
being hammered together, weld or unite, without discovering a juncture. As iron is the only metal which exhibits this appearance in the fire, so it is the only one capable of being welded. Those operations which prevent the superficial scoriification, deprive it likewise of this valuable property; which may be restored again, by suffering the iron to resume its vitreous aspect; and, in some measure, by the interposition of foreign vitreous matters, whilst none of the other metals will unite in the smallest degree, even with its own incrustation.

Iron expands the heat of all metals by heat. In the act of fusion, instead of continuing to expand, like the other metals, it shrinks; and thus becomes so much more dense, as to throw up such part as is unmeasured to the surface; whilst pieces of gold, silver, copper, lead, or tin, put into the respective metals in fusion, sink freely to the bottom. In its return to a consistent state, instead of shrinking like the other metals, it expands; sensibly rising in the vessel, and assuming a convex surface, while the others become concave. This property, first observed by Raumer, excellently fits it for receiving impregnations from moulds. By the increase of bulk which the metal receives in congelation, it is forced into the minutest cavities, so as to take the impregnation far more exactly than the other metals which shrink.

Iron is dissolved by all the metals made fluid, except lead and mercury. Though none of them act so powerfully upon it as gold; but, as Cramer observes, if the iron contains any portion of sulphur, it can scarcely be made to unite at all with gold.

Among the semimetallic bodies, it is averse to an union with mercury; no method of amalgamating these two having yet been discovered; though quicksilver, in certain circumstances, forms in some small degree to act upon it. A plate of tough iron, kept immersed in mercury for some days, becomes brittle; and mercury will often adhere to and coat the ends of iron petals used in triturating certain amalgams with saline lepidites. Mr. Jones has also discovered that by plunging iron, while heated to an intense white heat, into mercury, the latter will adhere to the surface of the iron, and completely filter it over.

Next to mercury, zinc is the most difficultly combined with iron; not from any natural indisposition to unite, but from the zinc being difficultly made to sublimate the heat requisite. The mixture is hard, somewhat malleable, of a white colour approaching to that of silver. Regulus of antimony, as soon as it melts, begins to act on iron, and dissolves a considerable quantity. If the regulus be fitted with a iron rod, it will melt off a part of it. Arsenic likewise easily mingles with iron, and has a strong attraction for it, foraking all the other metals to unite with this. It renders the iron white, very hard, and brittle.

This metal is the basis of the fine blue pigment, called, from the place where it was first discovered, Berlin or Prussian blue. This colour was accidentally discovered about the beginning of the present century, by a chemist of Berlin, who, having successfully thrown upon the ground several liquors from his laboratory, was much surprized to see it suddenly stained with a beautiful blue colour. Recollecting what liquors he had thrown out, and observing the same effects from a similar mixture, he prepared the blue for the use of painters; who found that it might be substituted to ultramarine, and accordingly have used it ever since.

Several chemists immediately endeavoured to discover the composition of this pigment; and in the year 1724 Dr. Woodward published the following process, in the Philosophical Transactions, for making it. Place together four ounces of nitre, and as much tartar as is directed for charcoal (no 779). Mix this alkaline well with four ounces of dried balloon blood; and put the whole in a crucible covered with a lid, in which there is a small hole. Calcine with a moderate heat, till the blood be reduced to a perfect coal; that is, till it emits no more smoke or flame capable of blackening any white bodies that are exposed to it. Increase the fire towards the end, so that the whole matter contained in the crucible shall be moderately, but sensibly, red.

"Throw into two pints of water the matter contained in the crucible, while yet red, and gave it half an hour's boiling: decant this first water; and pour more upon the black charry coal, till it becomes almost insipid. Mix together all these waters; and reduce them, by boiling, to about two pints.

"Dissolve also two ounces of martial vitriol, and eight ounces of alum, in two pints of boiling water. Mix this solution when hot with the preceding lixivium also hot. A great effervescence will then be made: the liquors will be rendered turbid; and will become of a green colour, more or less blue; and a precipitate will be formed of the same colour. Filtrate, in order to separate this precipitate; upon which pour the spirit of salt, and mix them well together; by which means the precipitate will become of a fine blue colour. It is necessary to add rather too much of the salt than too little, and till it no longer increases the beauty of the precipitate. The next day wash this blue, till the water comes off from it insipid; and then gently dry it."

Mr. Geoffroy was the first who gave any plausible theory of this procels, or any rational means of improving it. He observes, that the Prussian blue is no other than the iron of the vitriol rendered by the inflammable matter of the alkaline lixivium, and perhaps a little brightened by the earth of alum; that the green colour proceeds from a part of the yellow ferruginous clax, or ochre, unreceived, mixing with the blue; and that the spirit of salt dissolves this ochre more readily than the blue part; though it will dissolve that also by long standing, or if used in too large quantity. From these principles, he was led to increase the quantity of inflammable matter; that there might be enough to revive the whole of the ferruginous ochre, and produce a blue colour at once, without the use of the acid spirit. In this he perfectly succeeded; and found, at the same time, that the colour might be rendered of any degree of depth and lightness, at pleasure. If the alkali is calcined with twice its weight of dried blood, and the lixivium obtained from it poured into a solution of one part of vitriol to six of alum, the liquor acquires a very pale blue colour, and deposits as pale a precipitate. On adding more and more of a fresh solution of vitriol, the colour becomes deeper and deeper, almost to blackness.

He imagines, with great probability, that the blue pigment, thus prepared, will prove more durable in the air, mingle more perfectly with other colours, and be
CHURCH

An amusing phenomenon in the preparation.

Mr Macquer's theory.

By a more particular examination, he found, that the alkali might become perfectly saturated with the colouring matter; so that, when boiled on Prussian blue, it extracted none of its colour. When the salt was thus perfectly saturated, it seemed no longer to possess any alkaline qualities. If poured into a solution of iron in any acid, a fingle, homogeneous, and perfect precipitate, was formed; not green, as in Dr Woodward's processes, but a perfect Prussian blue; which needed no acid to brighten its colour. A pure acid added to the alkali was not in the least neutralized, nor in the least precipitated the colouring matter. From hence Mr Macquer concludes, that in the making of Prussian blue, vitriol is decomposed; because the iron has a strong attraction for the colouring matter, as well as the acid for the alkali; and the sum of the attraction of the acid to the alkali, joined to that of the iron for the colouring matter, is greater than the single attraction of the acid to the metal.

Another very important phenomenon is, that earths have not the same attraction for this colouring matter that metallic substances have. Hence, if an alkali saturated with this colouring matter be poured into a solution of alum, no decomposition is effected, nor any precipitate formed. The alum continues to form, and the alkali remains unchanged. From this experiment Mr Macquer concludes that alum does not directly contribute to the formation of the Prussian blue. The purpose he think it answers is as follows. Fixed alkaline salts can never be perfectly saturated with phlogistic matter by calculation; alkalis, therefore, though calcined with inflammable substances, so as to make a proper lixivium for Prussian blue, remain still alkaline. Hence, when mixed with a solution of green vitriol, they form, by their purely alkaline part, a yellow precipitate, so much more copious, as the alkali is less saturated with phlogiston. But nothing is more capable of spoiling the fine colour of the Prussian blue, than an admixture of this yellow precipitate; it is therefore necessary to add a quantity of alum, which will take up the greatest part of the purely alkaline salt, and of consequence the quantity of yellow feruginous precipitate is much diminished. But the earth of alum, being of a fine shining white, does not in the least alter the purity of the blue colour, but is rather necessary to dilute it. From all this it follows, that it is a matter of indifference whether the green precipitate is to be again dissolved by an acid, or the alkali part of the lixivium saturated with alum or with an acid, before the precipitate is formed. The latter indeed seems to be the most eligible method.

Most alkalies obtained from the ashes of vegetables, blue precipitate, being combined, by their combustion, with a portion durable of inflammable matter, are capable of furnishing a quantity of Prussian blue, proportional to the quantity of colouring matter they contain, even without the necessity of mixing them with a solution of iron; because they always contain a little of this metal dissolved, some of which may be found in almost all vegetables; therefore it is sufficient to saturate them with an acid. Hencel observed the precipitation of this blue in the faturation of the sullie alkali, and recommended to chemists to inquire into its nature.

The theories of Geoffroy, Macquer, &c. however, with respect to Prussian blue, have now given place to discoveries of Mr Scheele, who has examined the substance with the utmost care, and found the colouring matter to consist of an extremely volatile substance, capable of uniting with and neutralizing alkalies, but easily expelled from them by any other acid, even by that of fixed air. He begins his dissertation on this subject by observing, that the solution of alkali calcined with vitriol is deprived of all the green matter, which he calls lixivium fanguinis, by exposure to the air, loses its property of precipitating the iron of a blue colour; and that the precipitate thus obtained is entirely soluble in the acid. In order to determine whether the air had thus undergone any change, he put some newly prepared lixivium into a flas of vitriol well sealed with rosin; but after some time finding no change on the lixivium, or on the air contained in the vessel, he began to think that this might be occasioned by the absence of fixed air, which always abounds in the open atmosphere, though not in any confined portion of it, at least in an equal proportion. Having therefore filled a glass vessel with fixed air, he poured into it a little lixivium fanguinis; and next day found, that it threw down from green vitriol a precipitate entirely soluble in acids. With other acids he obtained no precipitate.

On inverting the experiment, and mixing some green vitriol with lixivium fanguinis, the mixture grew yellow; and he found this addition capable of fixing the colouring matter so that neither the acid of fixed air nor any other could expel it from the alkali. For having poured the mixture abovementioned into a solution of green vitriol, and afterwards super saturated the
the lixivium with acid, he obtained a considerable quantity of blue. To the same lixivium sanguinis, in which a small quantity of green vitriol was dissolved, he afterwards added of the other acids somewhat more than was necessary for its saturation; and though this was done, a considerable quantity of Prussian blue was afterwards obtained. Again, having precipitated a solution of green vitriol with alkali, and boiled the precipitate for some minutes in lixivium sanguinis, part of it was dissolved; the filtered lixivium underwent no change when exposed to the open air or to the aerial acid, and precipitated the solution of vitriol of a blue; and though the lixivium was supersaturated with acid, and some green vitriol added, a very beautiful Prussian blue was obtained. This, however, will not hold when a perfectly dephlogisticitated calx of iron is employed, of which none can be dissolved by the lixivium sanguinis; nor will any Prussian blue be obtained by precipitating with lixivium sanguinis a perfectly dephlogisticitated solution of iron in nitrous acid.

To determine what had become of the colouring matter in those experiments where it seemed to have been dissipated, some lixivium sanguinis was poured into a vessel filled with aerial acid. It was kept well corked during the night, and next day a piece of paper dipped in a solution of green vitriol was fixed to the cork, pencilling it over with two drops of a solution of alkali in water. The paper was thus soon covered with precipitated iron; and on being taken out two hours afterwards, and dipped in muriatic acid, became covered with most beautiful Prussian blue. The same thing happened when lixivium sanguinis supersaturated with vitriolic acid was employed; for in this case also the air was filled with the colouring matter capable of being in like manner absorbed by the calx of iron. But though from these experiments it is plain that acids expel this colouring substance from the lixivium, a given quantity of air is only capable of receiving a certain quantity of it; for the same mixture removed into another vessel imparts the colouring property to the air it contains according to its quantity. On putting perfectly dephlogisticitated calx of iron in water, no Prussian blue was formed; but the muriatic acid dissolved the calx in the water.

Our author having now assured himself that acids really attract the alkali more than the colouring matter, proceeded to try the effects of distillation. Having therefore supersaturated some lixivium sanguinis with vitriolic acid, he distilled the mixture in a glass retort with a gentle fire. When about one-third had passed over, he changed the receiver, and continued the operation till one-half was distilled. The first product had a peculiar taste and smell; the air in the receiver was filled with colouring matter, and the aqueous fluid was also strongly impregnated with it, as appeared by its forming a fine Prussian blue with phlogisticated calx of iron. Part of it being exposed to the open air for some hours, entirely lost its power, and the product of the second operation was no other than water mixed with a little vitriolic acid.

The next step was to procure, if possible, the colouring matter by itself; and this he attempted to obtain from the Prussian blue, rather than the lixivium sanguinis, as he would thus not only avoid the troublesome calculation of the alkali and blood, but obtain the colouring matter in much larger quantity than could be done from the lixivium. On examining several kinds of this pigment, he found in them evident marks of sulphur, volatile alkali, vitriolic acid, and volatile sulphureous acid; all of which substances are to be found in the lixivium sanguinis as well as in that of foot-leaves; and adhere to the precipitate in the preparation of Prussian blue. Finding, however, that he could not obtain his purpose by any kind of analysis of these by fire alone, he had recourse to a neutral salt used by chemists for discovering iron in mineral waters. This salt is formed by digesting caustic fixed alkali on Prussian blue, which effectually extracts the colour from it even in the cold, in a very short time, and being neutralized, may easily be reduced into a dry form. But it is not entirely to be depended upon for this purpose; for it always contains some iron which, indeed, is the medium of its connection with the alkali. The lixivium sanguinis is preferable, though even this contains some iron, as well as the lixivium of foot-leaves; our author’s experiments, however, were made with the neutral salt, for the reason already mentioned.

An ounce of the salt was dissolved in a glass retort in four ounces of water, afterwards adding three drachms of concentrated vitriolic acid; and the mixture was distilled with a gentle fire. The mass grew thicker as soon as it began to boil; from a great quantity of Prussian blue, a quantity of the colouring matter appeared by the smell to penetrate the lixivium; and part of it was absorbed by the air in the receiver, as in former experiments. The distillation was continued till about an ounce had passed into the receiver. The blue mass remaining in the retort was put into a filter, and a piece of green vitriol put into the liquid which passed through; but by this left no Prussian blue was produced. The blue which remained in the filter was again treated with lixivium tartar: the solution freed from its ochre by filtration, and the clear liquor committed a second time to distillation with vitriolic acid. Prussian blue was again separated, though in smaller quantity than before, and the colouring matter came over into the receiver. After one third of the matter had passed over, that which had been obtained in the first distillation with the salt was now added to it, the Prussian blue was separated from the lixivium in the retort, and extracted a third time. Some Prussian blue was formed again, though in much smaller quantity; whence it is apparent that Prussian blue may at last be totally decomposed by means of alkali. Lime, or terra pondersa, likewise extracts the blue colour, and shews the same phenomena as alkali.

With volatile alkali a compound, consisting of the colouring matter, iron, and colouring matter, is formed, which shows the same phenomena with that formed with fixed alkali. By distillation per se after it has been volatile alkali. By distillation per se after it has been volatile alkali. By distillation per se after it has been volatile alkali. By distillation per se after it has been volatile alkali. By distillation per se after it has been volatile alkali.
As in all the operations with vitriolic acid hitherto mentioned he made on metals, and which we are now about to describe, it was found necessary to deprive the colouring matter, of that vitriolic taint.

The precipitating liquor abovementioned, poured on metallic solutions, produces the following appearances by means of double elective attraction. 1. Gold precipitated by acerated alkali becomes white. 2. The fixed air is difengaged from a precipitate of silver with a flight effervescence. 3. Calx of mercury is dissolved, and yields crystals by gentle evaporation. 4. The calx of copper precipitated by acerated alkali effervesces, and assumes a faint citron colour. 5. Calx of iron precipitated from its solution in the vitriolic acid by the same alkali, effervesces, and assumes a dark blue colour. 6. Precipitated cobalt shows some signs of effervescence, and changes into a yellowish brown colour. The other calces are not acted upon.

The precipitating liquor abovementioned, poured on metallic solutions, produces the following appearances by means of double elective attraction. 1. Gold precipitated by a white colour, but by adding a superabundant quantity of the precipitating liquor the calx is redissolved. The second solution is colourless as water. 2. Silver is precipitated in form of a white substance of the consistence of cheese; by adding more of the liquor the precipitate is redissolved, and the solution is not decomposed either by sal-ammoniac or marine acid. 3. Corrosive sublimate apparently undergoes no change, though it is in reality decomposed; the calx being dissolved in the colouring matter. Mercury dissolved in the nitrous acid without heat, is precipitated in form of a black powder. 4. The solutions of tin and bismuth are precipitated, but the calx is not acted upon by the colouring matter. 5. The same effects are produced on the solution of butter of antimony, as well as on that of well digested calx of iron. 6. Blue vitriol is precipitated of a yellow citron colour; if more of the precipitating liquor be added, the precipitate is redissolved into a colourless liquid and a colourless solution of the same calx is likewise obtained by volatile alkali. On adding more of the solution of blue vitriol, the solution likewise disappears, and the liquor assumes a green colour. Acids dissolve a portion of this precipitate, and the remainder is white. The nitrate of mercury dissolves the precipitate completely, but lets it fall again on the addition of water. 7. The solution of white vitriol yields a white precipitate, which is not redissolved by addition of the precipitating liquor, but is soluble in acids. These solutions, like the colouring matter, which may be separated from them by distillation. 8. Green vitriol is precipitated first of a yellowish brown colour, which soon changes to green, and then becomes blue on the surface. Some hours afterwards the precipitate subides to the bottom of the vesicles, and then the whole mixture turns blue; but on adding any acid the precipitate becomes instantly blue. If a very small quantity of green vitriol be put into the precipitating liquor, the
Investigation of the constituent parts of the colouring matter itself; and in this he succeeded in such a manner as must do honour to his memory, at the same time that it promises to be a real and lasting improvement to science, by showing a method of preparing this valuable pigment without that nauseous and horrid ingredient, blood, which is now used in great quantities for that purpose. — His first hint concerning this matter seems to have been taken from an observation of the air in his receiver accidentally taking fire from the neighbourhood of a candle. It burned without any explosion, and he was able to inflame it several times successively. Wishing to know whether any fixed air was contained in the colouring matter, he filled a retort half full of the liquor containing the colouring matter, and applying a receiver immediately after, gave the retort a brisk heat. As soon as the receiver was filled with thick vapours of the colouring matter, he disjoined it, and, inflaming the vapour by a little burning sulphur introduced into the cavity, found that the air which remained threw down a precipitate from lime-water. Hence (says he) it may be concluded, that the aerial acid and phlogiston exist in this colouring matter."

It has been ascertained by several chemists, that Prussian blue by distillation always yields volatile alkali. To determine this, Mr. Scheele prepared some exceeding pure from the precipitating liquor abovementioned and green vitriol; distilling it afterwards in a flask retort, to which he adapted a receiver containing a little distilled water. The operation was continued till the retort became red-hot. In the receiver was found the colouring matter and volatile alkali, but no oil; the air in the receiver was impregnated with aerial acid, and the same colouring matter; the residuum was very black, and obeyed the magnet. On sublimating, instead of the Prussian blue, the precipitates of other metallic substances precipitated by the Prussian alkali, the results were:

1. The yellowish brown precipitate of cobalt yielded the same products with Prussian blue itself; the residuum in the retort was black.

2. The yellow precipitate of copper took fire, and emitted, from time to time, sparks during the distillation. It produced little colouring matter, but a greater quantity of aerial acid and volatile alkali than had been obtained by the former precipitates. A sublimate arose in the neck of the retort, but in too small a quantity to make any experiment; the residuum was reduced copper.

3. The precipitate of zinc yielded the same with Prussian blue.

4. That of silver yielded likewise volatile alkali and fixed air, but chiefly colouring matter; a sublimate containing some silver arose into the neck of the retort; the residuum was reduced silver.

5. Calx of mercury crystallized by means of the colouring matter, yielded some of that matter, but scarce any mark of volatile alkali. Some mercury, with a portion of the original compound, arose in the neck of the retort.

From these experiments Mr. Scheele concluded, that the colouring matter of Prussian blue was composed of volatile alkali and an oily matter. He was confirmed in his conjecture, by obtaining Prussian blue from green vitriol and spirit of hartshorn recently distilled on the addition of muriatic acid. The same product was obtained by means of the volatile spirit drawn from ox's blood; so that nothing now remained, but to imitate these natural processes by artificially combining the two ingredients together. For Unsuccessful this purpose he distilled a mixture of volatile fat alkali and unctuous oil; a mixture of the same alkali with animal fat, and with oil of turpentine; a mixture of quick-lime, sal ammoniac, and a mixture with others of a similar kind; but in vain. He began therefore to conclude, that as long as the volatile alkali contained any water, it could not enter into an union sufficiently intimate with the other principles to form the colouring matter; and finding also that the coal of blood, mixed with salt of tartar, yielded very good lixivium sanguinis, he concluded that no oily matter was necessary for the success of the experiment. Thus was our author led to make the following decisive trials, which on accomplishing his design and purpose, and showed the truth of the principles he had formed it assumed. Three table-spoonfuls of charcoal powder were mixed with an equal quantity of salt of tartar, and the mixture put into a crucible. A similar mixture was put into another crucible, and both put into a fire, and kept red-hot for about a quarter of an hour. One of them was then taken out, and the contents thrown, while perfectly red-hot, into eight ounces of water. At the same time he put into the other quantity an ounce of sal ammoniac in small pieces, agitating the whole briskly together, and taking care at the same time to push the sal ammoniac down towards the bottom of the crucible, which he replaced in the fire. Observing in two minutes afterwards, that no ammoniacal vapours arose, the whole mass was thrown, when red-hot, into eight ounces of water. The former lixivium, into which no sal ammoniac had been put, yielded no Prussian blue; but the latter showed the same phenomena with the best lixivium sanguinis, and produced a great quantity of blue. By mixing plumbago with the alkali instead of charcoal, a tolerable lixivium was obtained.

"From these experiments (says Mr. Scheele), it appears, that the volatile alkali is capable of uniting with the carbonaceous matter, after it has been converted into the strongest heat; that it thus acquires the remarkable property of combining so firmly with salt of tartar as to be able to sustain the most violent degree of heat; and when this lixivium is dissolved in water, there is obtained lixivium sanguinis, as it is called. It is now easy to explain what happens in the distillation."

(A) This reasoning seems not to be sufficiently conclusive; for late experiments have shown that inflammation is generally attended with the production of fixed air, which could not be proved to have an existence either in the materials or common atmosphere before.
Iron: 1203
Appearance.
In the diffilution of Prussian blue, for instance, the calx of iron attracts a portion of phlogiston from the colouring matter. The aerial acid being thus difengaged, must go over into the receiver with the volatile alkali, which is not free at the flame, but as the calx of iron in the heat of this diffilution cannot unite with more phlogiston, a portion of the colouring matter, not decomposed, must likewise arise. If the calx of iron could combine with the whole of the phlogiston, there would come nothing over into the receiver but aerial acid and volatile alkali. In order to prove this, I distilled a mixture of six parts of manganese finely powdered, and one part of pulverized Prussian blue, and obtained nothing but aerated volatile alkali, without the least mark of colouring matter.

Coloured matter kept from rising by manganese. The colouring matter may probably be obtained in an aerial form, though he had not been able to do so. It is also worth notice, that, excepting the solutions of silver and mercury in nitrous acid, the colouring matter of Prussian blue is not able to decompose any other by a single elective attraction. Now, as we know that Prussian blue is not soluble in acids, it naturally follows, that the colouring matter has a greater affinity with iron than acids have; notwithstanding there is no precipitation perceived when this matter is mixed with the solution of vitriol of iron. "It may not be easy (says Mr Scheele) to give a satisfactory explanation of this phenomenon."

Nitric acid.
Iron dephlogitizes with nitric acid, and renders the salt alkaline and caustic. A part of the iron is thus rendered soluble, along with the alkalized salt. A mixture of equal parts of iron fillings and nitric acid, injected into a strongly heated crucible, and, after the detonation, thrown into water, tinges the liquor of a violet or purplish blue colour. This solution, however, is not permanent. Though the liquor at first pales through a filter, without any separation of the iron; yet, on standing for a few hours, the metal falls to the bottom, in form of a brick-coloured powder. Volatile alkalies instantly precipitate the iron from this fixed alkaline solution.

Iron filings and sulphur take fire spontaneously.
Iron readily unites with sulphur; and when combined with it, proves much easier of fusion than by itself. A mixture of iron filings and sulphur, moistened with water, and pressed down close, in a few hours swells and grows hot; and, if the quantity is large, bursts into flame.

By cementation with inflammable matters, iron imbibles a larger quantity of phlogiston; and becomes much harder, less malleable, and more fusible. It is then called lead. See Metallurgy, and Steel.

§ 5. Lead.

Lead is a pale or livid-white metal, soon losing its brightness in the air, and contrasting a blackish or greyish ash-colour. It is the softest and most flexible of all metallic bodies; but not ductile to any great degree, either in the form of wire or leaf; coming far short, in this respect, of all other metals. It has also the least tenacity of all metallic bodies; a leaden wire of \( \frac{y}{4} \) of an inch diameter being capable of supporting only 29\( \frac{1}{4} \) pounds. Lead has, however, a considerable specific gravity; losing, when immersed in water, between \( \sqrt{3} \) and \( \sqrt{5} \) of its weight. It is of all metals the most fusible, excepting only tin and bismuth. The sheen lead. plumbers cast thin sheets of lead upon a table or mould, covered with a woollen, and above this with a linen cloth, without burning or scorching the cloths. The melted lead is received in a wooden cauld without a bottom; which being drawn down the sloping table by a man on each side, leaves a sheet of its own width, and more or less thin according to the greater or less celerity of its defect. For thick plates, the table is covered over with moistened sand, and the liquid metal conducted evenly over it, by a wooden strike, which bears on a ledge at each side.

Some have preferred, for mechanic ufe, the milled Advanta-lead, or flatted sheets, to the cauld; as being more equal, eqs of milled lead smooth, and solid. But whatever advantage of this kind the milled form may appear to have at first, they are not found to be very durable. When the lead is stretched between the rollers, its cavities must necessarily be enlarged. The particles of metal that may be squeezeed into them can have no union or adhesion with the contiguous particles; and of consequence, must be liable, from bending, blows, jars, &c. to start out again, and leave the mafs spongy and porous.

Lead yields the dulcet and weakb least found of all mætallic bodies. Reaumer observes, that it is rendered fo-sonorous by casting a small quantity into a spherical or elliptical segment, as in the bottom of an iron-ladle; from hence he conjectures, that the sound of the fonorous metals might be improved for the bells of clocks, &c. by giving them a familiar form.

Though this metal very soon lofes its lucre, and tarnishes in the air, it refists much longer than iron or copper the combined action of air and water, before it is decomposed or destroyed; and hence it is exceedingly useful for many purposes to which these metals can by no means be applied. When jult become fluid, Calcined. lead looks bright like quicksilver; but immediately contracts a variously coloured pellicle on the surface. If this is taken off, and the fire continued, a fresh pellicle will always be formed, till the metal is by degrees changed into a dusty powder or calx. The injection of a little fat, charcoal-powder, or other inflammable matter, prevents this change, and readily revives the calx into lead again. It is said, that lead, recovered from its cakcs, proves somewhat harder and whiter than at first, as well as less subject to tarnish in the air.

The blackish calx or ashes of lead become of a very Minium. different appearance if the calcination is continued with a fire to moderate as not to melt them, and particularly if exposed to flame. By this treatment it is said that they become fift yellow; then they are called mafficot or yellow lead. This colour becomes gradually more and more intense, till at last the calx is of a deep red; and then is called minium or red lead; but it is certain, that by proper management this calx never becomes yellow, assuming a reddish colour from the beginning. Too great a heat makes it irrecoverably yellow. It can be more easily prepared without exposure
Practice.

Lead. Exposure to the flame. The degree of heat necessary for converting it into unison is between 600 and 700 of Fahrenheit.

Litharge. If instead of keeping this calx in a continued moderate heat, it be suddenly put in the matter then takes on a solid appearance, changing to a dull kind of brick-colour when powdered, and is then called litharge. Most of this substance is produced by refining silver with lead (see Refining); and is of two kinds, white and red. These two are distinguished by the names of litharge of gold, and litharge of silver. The most perfect is that called litharge of gold: the pale fort contains a considerable proportion of lead in its metallic state; and even the highest coloured litharge is seldom free from a little metallic lead, discoverable and separable by melting the mass in a crucible; when the lead subsides to the bottom.

Lead mingles in fusion with all the metals except iron, with which it refuses any degree of union as long as the lead preserves its metallic form. On continuing the fire, the lead, scorifying or calcining, absorbs the phlogistic principle of the iron, and consequently promotes the calcination of that metal; both being at length reduced to calces. The fusible calx of lead easily unites with the calx of iron, and both melt together into an opaque brown or blackish glass. Copper does not unite with melted lead till the fire is raised so high as to make the lead smoke and boil, and of a bright red heat. Pieces of copper, now thrown in, soon dissolve and disappear in the lead: the mixture, when cold, is brittle, and of a granulated texture. The union of these two metals is remarkably slight. If a mixture of copper and lead and is exposed to a fire no greater than that in which lead melts, the lead almost entirely runs off by itself; a separation of which no other example is known. What little lead is retained in the pores of the copper, may be scorified, and melted out, by a fire considerableness less than is sufficient to fuse copper. If any of the copper is carried off by the lead, it swins unmelted on the surface.

Gold and silver are both dissolved by lead in a flight red heat. They are both rendered extremely brittle by the minutest quantity of this metal; though lead is rendered more ductile by a small quantity of either of them. In copellation, a portion of lead is retained by gold, but silver parts with it all. On the other hand, in its elusion from copper, if the copper contains any of the precious metals, the silver will totally melt out with the lead, but the gold will not. The attraction of lead to copper, however slight, is greater than that of copper to iron: a mixture of copper and iron being boiled in melted lead, the copper is imbibed by the lead, and the iron thrown up to the top. Silver is in like manner imbibed from iron by lead; whilst tin, on the contrary, is imbibed from lead by iron. If two mixtures, one of lead and tin, and another of iron and silver, are melted together, the result will be two new combinations, one of the tin with the iron at the top, the other with the lead and silver at the bottom: how carefully forever the matter be stirred and mixed in fusion, the two compounds, when grown cold, are found distinct, so as to be parted with a blow. This metal is soluble in alkaline liquor and expref-

CHEMISTRY.

Tin. Soluble in alkalies and oils.

§ 6. Tin.

The colour of this metal resembles silver, but is somewhat darker. It is fusible, less elastic, and sonorous, than any other metal except lead. When bent backwards and forwards, it occasions a crackling sound, as if torn asunder. It is the lightest of all the malleable metals, being lighter than very few times specifically heavier than water. The tenacity of its parts also is not very considerable; a tin wire of of an inch diameter being able to support only 142 pounds.

Tin is commonly reckoned the least ductile of all metals except lead; and certainly is so, in regard to ductility into wire, but not in regard to extensibility into leaves. These two properties seem not to be so much connected with one another as is generally imagined. Iron and steel may be drawn into very fine wire, but cannot be beat into leaves. Tin, on the other hand, may be beat into very thin leaves, but cannot be drawn into wire: gold and silver possess both properties in a very eminent degree; whilst lead, notwithstanding its flexibility and softness, can not be drawn into fine wire, or beat into thin leaves. It melts the most easily of all the metals; about the 430th degree of Fahrenheit's thermometer. Heated till almost ready to melt, it becomes so brittle that large blocks may be easily beat to pieces by a blow. The purer fort, from its facility of breaking into long shapen pieces, is called grain-tin. Melted, and plainly agitated at the infant of its beginning to congeal, it is reduced into small grains or powder.

With the heat necessary for fusion, it may also be calcined; or at least so far deprived of its phlogiston as to appear in the form of a grey calx, which may be entirely reduced to tin by the addition of inflammable matter. The calcination of tin, like that of lead, begins by the melted metal losing its brightness, and contracting a peculiar tinge on its surface. If the fire is raised to a cherry-red, the pellicle swells and bursts, discharging a small bright flame of an arscenic smell. By longer continuance in the fire, the metal is converted first into a greyish, and then into a perfectly white calx, called putty, which is used for polishing glasses and other hard bodies.

The calx of tin is the most refractory of all others. Even in the focus of a large burning mirror, it only softens a little, and forms crystalline filaments. With

Practice.

Tin. - glafs of bismuth, and the simple and arsenificated glafs of lead, it forms opaque milky compounds. "By this property it is fitted for making the basis of the imperfect glafs called enamels; (see glass and enameled)." The author of the Chemical Dictionary relates, "that having exposed very pure tin, finely to a fire as strong as that of a glafs-house furnace, during two hours, under a muffle, in an uncovered teft, and having then examined it, the metal was found covered with an exceedingly white calx, which appeared to have formed a vegetation; under this matter was a reddish calx, and a hyacinthin glafs; and laftly, at the bottom was a piece of tin unaltered. The experiment was several times repeated with the fame success.

Henckel discovered a method of separating tin, which may possibly arise from its arsenic, by slowly dissolving the tin in eight times its quantity of an aqua-regia made with quicksilver and tin, and forming the solution to evaporate in a gentle warmth: the arsenic begins to crystallize while the liquor continues hot, and more plentifully on its growing cold, into white crystals. M. Margraaf, in the Berlin Memoirs for 1746, has given a more particular account of this process. He observes, that the white sediment which at first separates during the distillation is chiefly arsentic; that Malacca tin, which is accounted one of the purest sorts, yielded less than 7th its weight of arsentic crystals; that some sorts yielded more; but that tin extricated from a particular kind of ore, which contained no arsenic, afforded none. That the crystals were truly arsentic, and appeared from their being totally volatile; from their subliming (a kind of ore, which contained no arsenic, afforded none. That the crystals were truly arsentic, and appeared from their being totally volatile; from their subliming (a kind of ore, which contained no arsenic, afforded none.)

Nitre dissagrates with tin, and hastens the calcination of this as well as of other imperfect metals. The vapours which rise from tin, by whatever method it is calcined, have generally an arsentic smell. Tin melted with arsentic falls in great part into a white calx: the part which remains uncalsced proves very brittle, appears of a white colour, and a sparkling plated texture, greatly resembling zinc. The arsentic is strongly retained by the tin, so as scarcely to be separable by any degree of fire; the tin always discoveries, by its augmentation in weight, that it holds a portion of arsentic, though a very intense fire has been used. Hence, as the tin ores abound in arsentic, the common tin, is found also to participate of that mineral.

Hence, an easy method of purifying silver from tin.

Tin notwithstanding it is, like lead, soon deprived of its lustre by exposure to the air, is nevertheless much less liable to rust than either iron, copper, or lead; and hence is advantageously used for covering over the insides of other metallic vessels. The amalgam of mercury and tin is employed to cover one of the surfaces of looking-glaes; by which they are rendered capable of reflecting the rays of light. The amalgam also, mixed with sulphur and sal ammoniac, and fitted to sublimate, yields a sparkling gold-coloured substance called aurum molaeicum; which is sometimes used as a pigment. This preparation is commonly made from quicksilver and tin, of each two parts, amalgamated together; and then thoroughly mixed with sulphur and sal ammoniac, of one each part and a half. The mercury and sulphur unite into a cinnabar, which sublimes along with the sal ammoniac; and, after sublimation, the aurum molaeicum remains at the bottom.

§ 7. Mercury or quicksilver.

Mercury is a fluid metallic substance, of a bright silver colour, resembling lead or tin when melted; entirely void of taste and smell; extremely divisible; and congealable only in a degree of cold very difficultly produced, in this country, by art (see cold and congealation). It is the most ponderous of all fluids, its density being to that of water nearly as 14 to 1. It is found to be specifically heavier in winter than in summer by 25 grains in 11 ounces.

Neither air nor water, nor the united action of these two, seem to make any impression upon mercury: nor is it more susceptible of rulf than the perfect metals. Its surface, nevertheless, is more quickly tarnished than gold or silver; because the dust which floats in the air, quickly seizes on its surface. The watery vapours also, which float in the air, seem to be attracted by mercury.

From these extraneous matters, which only slightly adhere to it, mercury may be easily cleansed by purifying it through a clean new cloth, and afterwards heating it: but if mixed with any other metals, no separation can be effected without distillation. In this process, a small portion of some of the metals generally arises along with the mercury. Thus, quicksilver
Practice.

Mercury or quicksilver.

Ver distilled from lead, bismuth, or tin, appears less bright than before; stains paper black; sometimes exhibits a film upon the surface; and does not run freely, or into round globules. Mr Boyle relates, that he has observed the weight of mercury sensibly increased by distillation from lead, and this when even a very moderate fire was made use of. By amalgamation with Telluric regula of antimony, and then digested after a few hours digestion, mercury is said to become, by a few repetitions of the process, more ponderous, and more active. The animated, or philosophic mercury of some of the alchemists, are supposed to have been mercury thus prepared. By the same, or similar processes, seem to have been obtained the curious mercury which Boyle declared he was possessed of, and made himself; which were "considerably heavier in specie than common quicksilver, dissolved gold more readily,—grew hot with gold, so as to be offensive to the hand, and elevated gold in distillation." When quicksilver is to be distilled, it is proper to mingle it with a quantity of iron-flings; which have the property of making it much brighter than it can be otherwise obtained, probably by furnishing phlogiston.

By digestion in a strong heat for several months, mercury undergoes a considerable alteration, changing into a powder, at first ash-coloured, afterwards yellow, at length of a bright red colour, and an acrid tafte; and is then called mercurius precipitatus per fe. In this last state it proves similar to the red precipitate, formed in a solution of mercury in nitrous acid. This calx proves less volatile in the fire than the mercury in its fluid state. It supports for some time even a degree of red heat. In the focus of a burning mirror, it is said to melt into glass when laid upon a piece of charcoal, and to revive into running mercury before it exaltes. Evaporated by common fire, it leaves a small portion of a light brown powder; which, Boerhaave relates, bore a blast-heat; swelled into a spongy mass; formed with borax a vitreous friable substance; but vanished in cupellation. By a long continued digestion in a gentle heat, mercury suffers little change. Boerhaave digested it in low degrees of heat, both in open and close vessels, for 15 years together, without obtaining any other reward for his labour than a small quantity of black powder; which, by triturating, was quickly revived into running mercury. Conflant triturum, or agitation, produces a change similar to this in a short time. Both the black and red powders, by bare exposure to a fire sufficient to elevate them, return into fluid mercury. The red powder has been revived by simply grinding it in a glass mortar.

In like manner, quicksilver remains unchanged by distillation. Boerhaave had the patience to distil 18 ounces of mercury upwards of 500 times over, without observing any other change than that its fluidity and specific gravity were a little increased, and that some grains of a fixed matter remained. The vapours of mercury, like those of all other volatile bodies, cause violent explosions if confined. Mr Hellest gives an account of his being present at an experiment of this kind: a person pretending to fix mercury, had enclosed it in an iron box closely walled. When the mercury was heated, it burst the box, and dissipated mercury invisibly into the air.

Mercury dissolves or unites with all metallic bodies, except three, viz. iron, arsenic, and nickel: in some cases it will absorb metals, particularly gold and silver, amalgamated with their solutions in acids or alkalies; but does not act upon any metal when combined with sulphur, nor precipitates made by alkalis, nor on calces by fire. Whatever metal it is united with, it constantly preserves its own white colour. It unites with any proportion of those metallic substances with which it is capable of being combined; forming, with different quantities, amalgams of different degrees of consti'cutence. From the fluid ones, greatest part of the quicksilver may be separated by colature. Bismuth is so far attenuated by mercury, as to pass through leather with it in considerable quantity. It also promotes the action of quicksilver upon lead to a great degree; so that mercury united with $\frac{1}{2}$, or $\frac{1}{6}$ of its weight of bismuth, dissolves many of lead in a gentle warmth, without the agitation, triturum, comminution, or melting heat necessary to unite pure mercury with lead. From these properties, this solution of bismuth in mercury becomes a proper solvent for pieces of lead lodged in the human body.

On triturating or digesting amalgams for a length of time, a blackish or dusky-coloured powder arises of the amalgamated metal. Some of the chemists have imagined, that the amalgamated metal was here reduced to its constituent parts; but pure mercury is by itself reducible to a powder of the same kind; and the metallic particles in this process, united with the mercury, are found to be no other than the metal in its entire substance. Some metals separate more difficulty than others; and gold and silver the most so. Boerhaave relates, that if the powder which separates from an amalgam of lead be committed to distillation with vinegar in a tall vessel, the mercury will glide before the vinegar boils, that, by a like artifice, quicksilver may be made to distil in a lesser degree of heat than that of the human body: but Dr Lewis, though he made many trials, was never able to succeed.

By amalgamation with gold, mercury may become exceedingly fixed; so as not to be distillable by the greatest heat. Concerning this, Dr Brandt relates the following curious experiment: "Having amalgamated fine gold with a large proportion of quicksilver, and strained off the superfluous mercury, he digested the amalgam in a close-stopped vessel for two months with such a degree of heat, that a part of the quicksilver sublimed into the neck of the glass. The matter being then ground with twice its weight of sulphur, and urged with a gradual fire in a crucible, a spongy calx remained; which being melted with borax, and afterwards kept in fusion by itself for half an hour, in a very violent fire, still retained so much of the quicksilver as to become brittle under the hammer, and appear internally of a leaden colour. The metal being again amalgamated with fresh mercury, the amalgam again ground with sulphur, and exposed to an intense fire, a spongy calx remained as before. This calx, being digested in two or three fresh parcels of aqua-regia, a small portion of whitish matter remained:}
Mercury or quicksilver. The paper which covered the cylindrical glass wherein the digestion was performed, contrived from the vapours, a deep-green circular spot in the middle, with a smaller one at the side; whereas the aqua-regia digested in the same manner by itself, or with gold, or with mercury, gave no stain. The first solution, on the addition of oil of tartar per deliquitum, grew red as blood; and standing, it deposited, first, a little yellow wax, like aurum fulminans; afterwards, a bright matter like fine gold; and at last, a paler precipitate, inclining to green; its own deep red colour and transparency remaining unchanged. Being now committed to distillation, a colourless liquor arose; and the residuum, perfectly exiccated, yielded, on adulcration, a yellow calx of gold; which the alkaline liquor had been unable to precipitate. The deliquitur, was calcined with twice its weight of sulphur, and afterwards, a bright matter like ground with a pestle, till the amalgam is completed. The mercury was let fall by little and little, through an aperture made in the gun-barrel, with a most intense degree of heat, without obtaining any water; but it being inspected by a by-fander, that the mercury in this experiment came over before it had been sufficiently acted upon by the fire, by reason of the lowness of the neck of the distilling instrument, the experiment was varied in the following manner. Sixteen ounces of mercury were heated in a crucible, in order to evaporate any moisture that might have been accidentally mixed with it; and an iron gun-barrel of four feet in length, being placed perpendicularly in a good furnace, and a gun-head and recipient fitted to its upper part, the mercury was let fall by little and little into the barrel, and the fire urged with bellows. After each injection, the mercury made a considerable noise and ebullition, and arose into the head; where it soon condensed and trickled down, in the common form of running mercury, into the recipient, without the least perceptible appearance of any aqueous humidity.

Mercury is difficultly amalgamated with regulus of antimony and copper; for which some particular manoeuvres are required. Two of Dr Lewis's receipts for uniting quicksilver with copper, we have already given (n 1153); with regulus of antimony, mercury, he says, may be perfectly united, by pouring a small stream of melted regulus into a considerable portion of mercury, made almost boiling hot. Another method directed by Henckel, is to put mercury into an iron mortar along with some water, and let the whole over the fire. When the water boils, a third or fourth part of melted regulus is to be poured in, and the mass ground with a pestle, till the amalgam is completed. The use of the water, as Dr Lewis observes, is to hinder the mercury from flying off by the heat of the regulus; but as the two are by this means not put together in so hot a flame, the union is more difficult, and less perfect. The loss of the mercury, in the first process, may be prevented by using a large vessel, and covering it with a perforated iron-plate, through the hole in which the regulus is to be poured. This method is likewise applicable to the amalgamation of copper.

With sulphur, mercury unites very readily, forming by trituration, or simple fusion, a black powder or mists, called sulphur mineral; which, by careful sublimation, becomes the beautiful red pigment called vermilion. (See Sulphur, sect. iv.)

Preparatory to the employment of one of these metals in medicine, the chemist has rendered it an object to chemists to find out some more simple and more certain method of preparing it with less expence and trouble, and more certainty of its effects, than it can be by the methods hitherto mentioned. This is now accomplished.
the least brittle of any of the semimetals; and when
amply supplied with phlogiston, which may be done
by treating it in close vessels with inflammable
matters, it poises a femiductility, by which it may be
flattened into thin plates. When broken, it appears formed
of many flat shining plates or facets, which are larger
when slowly than when hastily cooled. When heated,
it is very brittle; and cracks like tin, only louder,
when bent. Exposed to the air, it contracts in
length of time a yellowish ruf. Its specific gravity,
Dehagraphe
according to Dr Lewis, is to that of water as 7 1/, to 1. t-ion.
It begins to melt as soon as red-hot; but does not
flow thin till the fire is raised to a white heat. Then
the zinc immediately begins to burn with an
exceedingly bright and beautiful flame. Kept just in
fusion, it calcinates slowly; not only on the upper surface,
but likewise round the sides, and at the bottom of
the crucible. If several pieces are just melted togeth-er,
the mass, when grown cold, may be broken into the
same number; their union being prevented by a yellowish clax,
with which each piece is covered over. M. Malonini relates,
in the French Memoirs for 1742, that a quantity of zinc being melted six
times, and the fusion continued fifteen hours each
time, it proved, on every repetition, harder, more
brittle, less fusible, and less calcinable; that after the
two first fusions, its colour was grey; after the third,
brown; and after the fourth, black; that the fifth
rendered it of a slate-blue; and the sixth of a
clear violet.

So violent is the defagration of zinc, that the whole
flowers of
of its calx was sublimed by it, in the form of light flocks
of wood; which, however, are easily reduced to a
fine powder. These are used in medicine, and reckoned
an excellent remedy in epileptic cafes. When once sublimed, they are by no means capable of
being elevated again by the most violent heat. In a
heat far greater than that in which they frizz arose,
they suffer no alteration; in a very vehement one,
they melt, according to Henckel, into a semiform
green glass. Vitriified with borex, they give a grey,
or brown, or brownish, glass. From the brightness of the flame
of burning zinc, and the garlic smell which it is said
to emit, some have concluded that zinc contained the
phosphorine acid; which, from some other circumstances,
is not altogether improbable.

The flowers of zinc have been thought very difficultly,
or not at all, reducible to their metallic form by an addition of phlogiston. But Dr Lewis observes,
that this difficulty proceeds not from their unfitness to
be restored into the form of zinc, but from the volatility
of the semimetal, which occases its being disseipated
in fumes, if the common methods are made ufe of. All
causes, tofe of iron excepted, require a greater heat
for their fusion than that in which the metal itself
melts; and as a full melting heat is the greatest that
zinc can sustain, it burns and calcines the indium or
its revival, if the air is admitted; and in close vessels
esecrpes, in part at least, through their pores. On
mixing flowers of zinc with powdered charcoal, and
urging them with a strong fire in a crucible, a defagration
and fresh sublimation ensue: sufficient marks
that the zinc has been reduced to its metallic form;
for as long as it remains in the state of calx, neither
of these effects can happen. If the vessel is so con-
trived
Zinc. — trived to exclude the air, and at the same time to allow the reviving semimetal to run off from the vessel in which it is contained. In this way, the zinc will be found to be preserved in its metallic state. It is still more effectually detained by certain metallic bodies, as copper, or iron; with which the zinc, when thus applied, unites more readily and perfectly than if it were allowed to escape. Hence it can be made to do by any other means.

Homberg pretended to obtain an oil from the flowers of zinc, by distilling them in distilled vinegar, and then distilling the solution in a glass retort. At first a quantity of phlegm arose; then the superfluous acid; and at last an empyreumatic oil. This lat, which Homberg imagined to proceed from the flowers of zinc, Newmann very justly attributes to the distilled vinegar.

Another by Mr. Hellot. — An oil of another kind was obtained by Mr. Hellot from the above solution, by distilling the ash-coloured residuum, which remained after the distillation, with the acidulous phlegm which came over, for eight or ten days; distilling the tincture to dryness; and repeating the extraction with the distilled liquor, till the quantity of dry extract thus obtained was very considerable. This resin-like matter, distilled in a retort with a stronger fire, yielded a yellowish liquor, and a white sublimate. The liquor discovered no mark of oil; but, upon being passed upon the sublimate, immediately dissolved it, and then exhibited on the surface several drops of a reddish oil. Some of this oil was taken up on the point of a pencil, and applied to gold and silver-leaf. In twenty-four hours the parts touched appeared, in both, equally dissolved.

Zinc does not unite in fusion with bismuth, or the semimetal called nickel. It unites differently with iron; less so with copper; easier with the other metals. It renders iron or copper more easily fusible; and, like itself, brittle when hot, though considerably malleable when cold. It brightens the colour of iron almost into a silverhue, and changes that of copper into a yellow or gold colour. It greatly debases the colour of gold; and renders it less fusible. It renders arsenic, and other metals; that most volatile metal brittle and untractable. A mixture of equal parts of each is very hard, white, and bears a fine polish; hence it is proposed by Mr. Hellot for making specula. It is not subject to rust or tarnish in the air, like those metals whose basis is copper. It improves the colour and lustre of lead and tin, renders them firmer, and consequently fitter for several mechanic uses. Tin, with a small proportion of zinc, forms a kind of pewter. Lead will bear an equal weight, without losing too much of its malleability. Mauldin observes, that arsenic, which whitens all other metals, renders zinc black and friable; that when the mixture is performed in close vessels, an agreeable aromatic odour is perceived on opening them, that zinc amalgamated with mercury, and afterwards recovered, proves whiter, harder and more brittle than before, and no longer crackles on being bent.

Mixtures of zinc with other metals, exposed to a strong fire, boil and deflagrate more violently than zinc by itself. Some globules of the mixture are usually thrown off during the ebullition, and some part of the metal calcined and volatilized by the burning zinc; hence this substance has been called metallic nitre. Bismuth.

Gold itself does not entirely resist its action. It very difficultly volatilizes copper; and hence the sublimates obtained in the furnaces where brass is made, or mixtures of copper and zinc melted, are rarely found to participate of that metal. On melting copper and zinc separately, and then pouring them together, it cannot be violent detonation immediately ensues, and above united with half the mixture is thrown about in globules.

Zinc does not unite in the least with sulphur, or with crude antimony, which secrete all other substances except gold and platina; nor with compositions of sulphur and fixed alkaline salts, which dissolve gold itself. With nitre it deflagrates violently. Its flowers do not sufficiently deflagrate; yet alkalize double their weight of the salt more readily than the zinc itself. The alkaiine mafs appears externally greenish, nitre alkaline internally of a purple colour. It communicates a fine line by purple water, and a red to vinegar. The accersous tincture infiltrated, leaves a tenacious substance which soon runs in the air into a dark red caufic liquor, the alkahef of some of the pretended adepts.

§ 9. BISMUTH.

This semimetal, called, also tin-glafl, and by some naturalists marcasita officinarum, is somewhat similar to the regulus of antimony. It appears to be composed of cubes formed by the application of plates upon each other. Its colour is less white than that of regulus of antimony; and has a reddish tinge, particularly when it is exposed to the air. In specific gravity it approaches to silver; being nearly ten times heavier than water. It has no degree of malleability; breaking under the hammer, and being reducible by triturating to fine powder. It melts a little later than tin, and seems to flow the thinnest of all metallic substanstes. Bismuth is semifvolatile, like all other semimetals. When exposed to the fire, flowers are evolved from it; it is calcined; and converted into a litharge of nearly as great a proprity as antimony. It may be employed, like that metal, in the purification of gold and silver by cupellation. (See Refining.) When in fusion, it occupies less volume than in its solid state: a property peculiar to iron among the metals, and bismuth among the semimetals. It emits fumes in the fire as long as it participates of that metallic form; when calcined or vitrified, it proves perfectly fixed.

Bismuth mingles in fusion with all the metallic substances, except regulus of cobalt and zinc. The adobe explosion of nickel or regulus of antimony, renders it incapable of the malleable, malleable, and fusible metals; renders it useless in the refinement of the gold of the most of the metals with which it unites. It whitens copper and gold, and improves the colour of some of the white metals; mixed in considerable quantity, it renders them all brittle, and of a flaky structure like its own. If mixed with gold or silver, a heat that is but just sufficient to melt the mixture, will presently vitrify a part of the bismuth; which, having then no action on those perfect metals, separates, and glazes the crucible all round.

§ 10.

Practice.
Regulus of antimony.

This semi-metal, when pure, and well fused, is of a white shining colour, and coniuits of laminae applied to each other. When it has been well melted, and not too hastily cooled, and its surface is not touched by any hard body during the cooling, it exhibits the perfect figure of a star, consisting of many radial issuing from a centre. This proceeds from the disposition that the parts of this semi-metal have to arrange themselves in a regular manner, and is similar to the crystallization of salts.

Regulus of antimony is moderately hard; but, like other semi-metals, it has no ductility, and breaks in small pieces under a hammer. It loses half of its weight in water. The action of air and water destroys its lustre, but does not rust it so effectually as iron or copper. It is fusible with a heat sufficient to make it red hot; but when heated to a certain degree, it fumes continuously, and is diffipated in vapours. These fumes form what are called the argentina flowers of regulus of antimony, and are nothing but the earth of this semi-metal deprived of part of its inflammable principle, and capable of being reduced to its reguline state by an union with this principle.

There are different methods of preparing the regulus of antimony; but all of them consist merely in separating the sulphur which this mineral contains, and which is united with the regulus. It is plain, therefore, that regulus of antimony may be made by an addition of any sulphur to crude antimony in fusion, which has a greater attraction for sulphur than the regulus itself has. For this purpose, alkaline salts have been employed, either previously prepared, or ex tremoraneously produced in the process, by a destillation of tartar and nitre. By this means, the sulphur was indeed absorbed; but the hepar sulphuris, formed by the union of the sulphur and alkali, immediately dissolved the regulus, so that very little, sometimes none at all, was to be obtained distinct from the scoria. Metals are found to answer better than alkaline salts, but the regulus is seldom or never free from a mixture of the metal employed. The way of obtaining a very pure regulus, and in great quantity, is to calcine the antimony in order to dilate its sulphur; then to mix the calc with inflammable matters, such as oil, soft soap, &c. which are capable of reforming the principle of inflammability to it. This method was invented by Kunckel. Another, but more expensive way of procuring a large yield of very pure regulus, is, by digesting antimony in aqua-regis, which dissolved the reguline part, leaving the sulphur untouched, precipitating the solution, and afterwards reviving the precipitate by melting it with inflammable matters.

There are considerable differences observed in the regulus of antimony, according to the different substances made use of to absorb the sulphur. When prepared by the common methods, it is found to be very difficulty amalgamated with mercury; but Mr. Pott has discovered, that a regulus prepared with two or five parts of iron, four of antimony, and one of chalk, readily unites with mercury into an hard amalgam, by bare triturating with water. Marble and quicklime fuse equally well with chalk; but clay, gypsum, or regulus of other earths, have no effect.

One earthy substance, found in lead-mines, and commonly called cawk, has a very remarkable effect upon antimony. This is found in whitish, moderately com rocacious roact and ponderous masses; it is commonly tipped off with a spar; but differs from bodies of this kind, in not be ing acted upon by acids, (see n^1 1668). If a lump of cawk, of an ounce or two, be thrown red hot into 16 ounces of melted antimony, the fusion continued for two minutes, and the fluid matter poured off. "you will have 13 ounces like polished steel, and as the most refined quicksilver." Phil. Trans. n° 110. Dr. Lewis mentions his having repeated this experiment several times with success: but having once varied it by mixing the cawk and antimony together at the first, a part of the antimony was converted into a very dark black vitreous matter, and part seemed to have suffered little change; on the surface of the mass some yellow flowers appeared.

Regulus of antimony enters into the compositions for metallic speculations for telecopies, and for printing-presses. It is also the basis of a number of medicinal preparations; but many of them, which were formerly much esteemed, are found to be either inert, uncertain, or dangerous in their operations. When taken in substances, it is emetic and purgative, but uncertain in its operation; because it only acts in proportion to the quantity of solvent matter it meets with in the stomach; and if it meets with nothing capable of acting upon it there, the regulus will be quite inactive. For these reasons, the only two preparations of antimony now retained, at least by skilful practitioners, are the infusion of gla s of antimony in wine and emetic tar.

For making the glasses of antimony we have the following process. "Take a pound of antimony; reduce it to fine powder, and set it over a gentle fire; calcine it in an unglazed earthen pan, till it comes to be of an ash-colour, and ceases to fume: you must keep it continually flirring; and if it should run into lumps, you must powder them again, and then proceed to finish the calcination. When that is done, put the calcined antimony into a crucible; set it upon a tile in a wind-furnace; put a thin tile on the top; and cover it all over with coals. When it is brought into fusion, keep it so in a strong fire for an hour; then put into it an iron rod; and when the melted antimony, which adheres to it, is transparent, pour it upon a smooth, hot, marble; and when it is cold, put it up for use. This is vitrum antimonii, or fibrium."

This preparation is more violent in its effects than the pure regulus itself; because it contains less phlogiston, consequently is similar to a regulus partially calcined, and so more soluble. Hence it is the most proper for infusion in wine, or for making the tartar emetic. It is obviously, however, liable to great uncertainties in point of strength; for as the antimony is more or less strongly calcined, the glass will turn out stronger or weaker in its operation, and consequently all the preparations of it must be liable to much uncertainty. This uncertainty is very apparent in the difference of strength of different parcels of emetic tartar; accord ingly Mr. Geoffroy found by examination of different parcels of emetic tartars, that an ounce of the weakest contain
CHEMISTRY.

Practice.

**Regulus of antimony.**

From 30 to 90 grains of regulus; an ounce of moderate strength contained about 108 grains; and an ounce of the strongest kind contained 154 grains. For these reasons, the author of the Chemical Dictionary recommends the pulvis algaroth as the most proper material for making emetic tartar; being perfectly soluble, and always of an equal degree of strength. Emetic tartar, as he judiciously observes, ought to be a metallic salt composed of cream of tartar saturated with the regulus of antimony; and M. Bauné has shown such a saturation to be possible, and that the neutral salt crystallizes in the form of pyramids. They are transparent while moist; but by exposure to the dry air, they lose the water of their crystallization and become opaque. The preparation of this salt, according to M. Bauné, consists in mixing together equal parts of cream of tartar, and levigated glafs of antimony: these are to be thrown gradually into boiling water; and the boiling continued till there is no longer any effervescence, and the acid is entirely saturated. The liquor is to be filtered; and upon the filter is observed a certain quantity of fulphureous matter along with some undissolved parts of the glafs of antimony. When the filtered liquor is cooled, fine crystals will be formed in it, which are a soluble tartar perfectly satured with glafs of antimony. He observes, that the diffolution is soon over if the glafs is well levigated, but requires a long time if it is only grossly pounded.

The trouble of levigating glafs of antimony, as well as the uncertainty of diffolving it, would render pulvis algaroth much preferable, were it not on account of its price; which would be a temptation to those in use to prepare medicines, to sublimate a cheaper antimonial preparation in its place. This objection, however, is now in a great measure removed by Mr Scheele; who demonstrated that the pulvis algaroth is no other than regulus of antimony half calcined by the dephlogisticated marine acid in the corrodive sublimations made use of for preparing the antimonial caustic. If therefore we can fall upon any other method of dephlogisticating the regulus, we shall then be able to combine the marine acid with it; and by separating them afterwards, may have the powder of algaroth as good as from the butter of antimony itself. One of the methods of dephlogisticating the regulus is by nitre. Our author therefore gives the following receipt for the powder in question.

"Take of powdered crude antimony one pound, powdered nitre, one pound and a half; which, after being well dried and mixed, are to be detonated in an iron mortar. The hepar obtained in this manner is to be powdered, and a pound of it to be put into a glafs vessel, on which first a mixture of three pounds of water and 15 ounces of vitriolic acid is to be poured, and afterwards 15 ounces of powdered common salt are to be added; the glafs vessel is then to be put in a fand-bath, and kept in digestion for 12 hours, during which period the mafs is to be contantly stirred. The solution, when cool, is to be strained through linen. On the residuum one third of the above menstruum is to be added, and the mixture digested and strained. From this solution, when it is diluted with boiling water, the pulvis algaroth precipitates, which is to be well edulcorated and dried."

As regulus of antimony, like other metallic sub-

flances, is soluble in liver of sulphur, it happens, that, on boiling antimony in an alkaline ley, the salt, uniting with the sulphur contained in that mineral, forms an heparr sulphur, which dissolves some of the reguline part. If the liquor is filtered, and saturated with an acid, and the regulus and sulphur will fall together in form of a kermes mineral. If the ley is suffered to cool, a like precipitation of a red powder happens. This last is called kermes mineral.

Nitre deffagrates violently with antimony, confumine not only its sulphureous part, but also the phlogifon of the regulus; and thus reduces the whole to an inert fly.

**§ II. ARSENIC.**

Arsenic. Found naturally in a metallic form.

Reguline arsenic, whether found naturally or prepared by art, very readily parts with as much of its phlogifon as is sufficient to make it fly off in a white smoke; but this still retains a very considerible quantity of phlogistic matter, as evident from its producing nitrous air by the affusion of nitrous acid, and from the experiments already related of the preparation of the acid of arsenic. This caulis indeed is the form in which arsenic is most commonly met with. It is less volatile than the regulus; and by sublimation in a glafs vessel assumes an opaque crystaline appearance from becoming white on the surface; but that which crystalizes in the bowels of the earth does not appear to be subject to any such change.

White arsenic, though a true metallic caulis, may be white ar-

mixed in fusion with the same metals which will unite with the regulus. This seems contrary to the general rule of other calces, which cannot be united with any metal.
Practice.

CHEMISTRY.

Arsenic.

Metal in its metallic state; but it must be remembered, that by this operation the arsine calx is reduced to a regulus by the phlogiston of the metal: whence, in all fusions of this kind, some fome rise to the top, consisting of the calcined metal and part of the white arsenie. The parts of distilled water diffuse, by means of moderate heat, one part of calcined arsenie, and by boiling may be made to take up 1.5. The solution changes syrup of violet green, but the tincture of turfuole red. It is not changed by neutral salts, but slowly precipitates the solutons of metals, the arsenie united to the metallic calx falling to the bottom.——

"It may be asked (says Mr Bergman), whether the whole of the arsenie, or only the arsine acid, unites with the metallic calx, yielding the phlogiston to the menstruum of the other metal?" Certainly such a mutual commutation of principles does not appear improbable, if we consider only those cafes in which the menstruum is vitriolic or nitrous acid: but as iron, for example, united with malac acid (while does not attract the phlogiston of white arsenic), as well as when it is joined to the nitrous acid, is precipitated, it would appear that the whole of the arsenic is united, at least in certain cafes, to the metallic calxes.

One part of arsenic is dissolved by 70 or 80 of boiling spirit of wine.

Arsenic dissolves partially in concentratd vitriolic acid, but concentrates in the form of crystalline grains on cooling. These dissolve in water with much greater difficulty than the arsenic itself. On the blow-pipe they emit a white smoke, but form into a globule by fublimation, which at first bubbles, but soon grows quiet, and is but slowly consumed even in a white heat. This fixity is occasioned by the acid carrying off the phlogiston of the arsenic, and thus leaving a greater proportion of its peculiar acid than what it naturally contains; and therefore the more frequently the operation is repeated, the more fixed the arsenic becomes, though it is scarce possible to dissipate the arsinephlogiston as perfectly with this acid as with the nitrous; the effects of which have been already particularly mentioned.

The marine acid, which naturally contains phlogiston, dissolves about one-third of its weight of arsenic, a great part of which separates spontaneously on cooling in a state of saturation with the acid. This falt, which may be had in a crystalline form, is much more volatile than the former, readily subliming in a clofe vessel with a moderate heat; but is soluble with difficulty in boiling water. It is of a fine yellow colour, and yearly differs from butter of arsenic, except in its degree of concentration. The nature of marine acid prevents it from disengaging the arsine acid from the phlogiston of the femimetal, as will easily appear from what has been said concerning that acid. The arsine acid, however, is easily made to appear by the addition of that of nitre, as will be understood from the directions given by Mr Scheele for the preparation of the acid of arsenic.

Arsenic is not precipitated from its solution in vitriolic and nitrous acids by the phlogisticated alkali, which yet very readily precipitates all other metals.

From the marine acid, however, it is precipitated by its means of a white colour; but unless the solution be very acid, the addition of more water will throw down a precipitate of the same colour.

Dephlogisticated marine acid deprives arsenic of its inflammable principle; so that in the distilled vessel we find water, acid of arsenic, and marine acid, rege nerated.

Arsenic is dissolved by its own acid, and forms crystalline grains with it as well as with that of flour and borax. Salaccharine acid dissolves it likewise, and unites with other acids.

Solution of fixed alkali dissolve arsenic; and, when loaded with it, form a brown tenazulic mass, called liver of arsenic. The arsenic is partly precipitated by mineral acids, though part of it gradually loses its phlogiston, and adheres more tenaciously. Solution made with volatile alkali seems to effect this decomposition more readily, as no precipitation is made by acids. Limpid solution of saline hepatic, dropped into a solution of white arsenic, floats upon the surface in form of a grey stratum, which at length disturbs the whole liquor.

By the sufficience of heat solutions of arsenic attack effusions on some of the metals, particularly copper, iron, and zinc metals...and the solutions of the two last yielding crystals by evaporation. No alteration is made on these compounds by alkaline salts or by acids: volatile alkali does not discover the copper by changing the colour of the solution blue, nor does the phlogisticated alkali throw down any blue precipitate from the solution of iron. The reason of this is the superabundance of phlogiston in the solutions; for the arsine acid takes up all metals: when united with copper, it shows a blue colour with volatile alkali; and when united with iron, it lets fall a Prouiana blue in the usual way; but the quantity of phlogiston which converts the acid into white arsenic, prevents the appearance of these phenomena when the latter is made use of.

Arsenic, either in its calcined or regular state, may be united with sulphur; in which case it appears golden with either of a red or yellow colour, according to the sulphur. Quantity of sulphur with which it is united. These compounds are spontaneously produced by nature; both of them sometimes pellicid and crystalline; with this difference, however, that the yellow seems to affect a lamellated, and the red a crystalline, form. These are called red and yellow orpiment, or realgar and orpiment; the specific gravity of realgar being about 3.225; of orpiment, 5.315. Both of these sublimes totally with a moderate heat, unless when they happen to be mixed with other substances. They readily unite with those metals which form an union with the arsenic and sulphur of which they are composed. Silver mineralized by fublimation with orpiment, forms a substance similar to that which is called the red ore of that metal. Iron, in conjunction with orpiment, assumes a white, polished, and metallic appearance, similar to that of the white or arsine pyrites; and by various combinations of these substances with metals of different kinds, many of the natural metallic ores may be produced.

Nitre, when treated with mineralized arsenic, decomposes it, and combines with it to form nitrates of arsenic.
CHEMISTRY.

Arfenic. tonates partly with the sulphur, and partly with the phlogiston of the arfenic; the alkaline basis of the salt either forming fat polychreft with the acid of the sulphur, or uniting with the alkali, and forming the neutral arfencial salt. By the addition of fixed alkali in proper quantity, either to orpiment or realgar, and then exposing the mixture to a subliming heat, nitre retains the sulphur, but lets go the greatest part of the arfenic; the hepatic mafs, however, retains a small quantity of the latter; and if there is much alkali, scarce any of the arfenic arises.

On distilling orpiment with twice or thrice its quantity of corrosive sublimate, two liquids arife which refuse to unite; and at length, on augmenting the heat, a cinnabar arfices. A butter of arfenic is found at the bottom of the receiver, of a ferruginous brown colour, but pellucid: in the open air it first emits a copious fume of a white colour, and then gradually attracts the moisture of the atmosphere, by which it is precipitated. It is remarkable that it unites so slowly with marine acid, that they form a repelant mixture; nor can they be made to unite beyond a certain degree. By the effusion of distilled water, a white powder will be precipitated, which, though ever so well washed, retains some acidity; for a portion of butter of antimony is produced by distillation, as is likewise true of the pulvis algaroth. The smoke has a peculiar penetrating smell, somewhat similar to that of phlogilized vitriolic acid, and lets fall white flowers.

The liquor which flows above, and which, by chemical authors, has been compared to oil, is yellowish and pellucid, separating a white arfencial powder by the addition of water and spirit of wine. It is not affected by the stronger acids; but effervesces, and lets fall a precipitate, with alkalies. On keeping it with a cucumber with a long neck unfiptopped, white flowers gradually concrete round the orifice, which are lax, and sometimes approaching to a crystalline form. And lastly, by spontaneous evaporation, pellucid crystals appear at the bottom of the liquor, which are soluble in water with great difficulty; but when disolved, precipitate silver from nitrous acid, and let fall some arfenic on the addition of an alkali. When put into lime-water, a cloudy flow surrounds them; on being exposed to the fire, they totally sublimate without any arfencial smell, without decrepitation, or losing their transparency; but if ignited, phlogilic matter comes in contact with them, the arfencial smell faintly appears. No traces of mercury are to be found in this liquor by treating it either with alkali or copper; not the slightest precipitation is made by it on being dropped into a solution of terra pondersota in the marine acid; from all which it appears, that this liquor is only a very dilute butter of arfenic, containing less of the mercury on account of the quantity of water it has. The butter contains the acs in its most concentrated state, and is therefore loaded with a larger quantity of arfenic: the former liquor will therefore be obtained in much larger quantity, by setting the mixture of corrosive sublimate and arfenic to stand a night in a cellar, or moistened with water, before it is subjected to distillation. As the common marine acid can dissolve only a determined quantity of the butter, it naturally follows, that what remains after complete saturation should totally refuse to mix. The acida, however, when too much diluted, precipitates the butter; but in proportion to its strength it dissolves a greater quantity.

Arfenic mineralized by sulphur is not dissolvd by Arfenic mifwater, but is affected by the different acids, according nerIALIZED to the particular circumstances of each. Nitrous acid and aqua-regia act most powerfully; the former soon destroys the red colour of the realgar, and converts it into yellow orpiment; its primary action being to calcine the arfenic, without affecting the yellowness of the sulphur. It makes no change on the colour of orpiment. Aqua-regia, by long digestion, takes up the arfenic, and leaves the sulphur at the bottom; and hence we may find out the proportions of the two ingredients. Some dexterity, however, is necessary in performing this operation with accuracy; for if, on the one hand, the menstrum be too weak, part of the arfenic will remain undissolved; and if, on the other, it be too strong, part of the sulphur will be decomposed; for strong nitrous acid is capable of decomposing sulphur by long digestion, having a greater attraction for phlogiston than the vitriolic acid itself. The colour of the residuum ought to be grey; for as long as any yellow particles remain, it is a sign that some of the arfenic also remains. If any iron be present in the compound, it is all dissolvd, by reason of the superior attraction of the acid for it, before any of the arfenic is taken up, unlefs it shall have been calcined either by the access of air and heat employed in the operation, or by the too great power of the menstrum.

The pure regulus of arfenic may be obtained artificially from white arfenic, either by sublimation with mercury, black flux, or other phlogilic materials; or by melting it with double its weight of soap and potash; or lastly, by precipitation by means of some other metal, from orpiment or sandarack melted with sulphur and fixed alkali. By the first of these methods it is obtained in a crystalline form, ochohedral, pyramidal, or even prismatic. Mr Bergman mentions a natural regulus of arfenic, named mispickel, which along with mispickel, some sulphur contains a large quantity of iron united with the regulus into a metallic compound; but the iron sometimes amounts to ½ or even ⅓ of the whole, it neverthelcss remains untouched by the magnet. When ignited, it sends forth an arfencial smell, and soon becomes obedient to the magnet, even though the operation be performed on a tile without any additional phlogiston; it melts easily in an open fire, and in close vessels the greater part of the regulus sublimes, leaving the iron at the bottom.

The pure regulus of arfenic is vastly more volatile than any other metal, and therefore cannot be melted, uthility of this it begins to send forth a visible fmoke in 180° of the Swedish thermometer, and is capable of inflammation; but in order to inflame it, it must be thrown into a vesel previously heated to a sufficient degree, otherwise it will be sublimed. The flame is of an obscure whitish blue, diffusing a white smoke and garlic smell. In close vessels it retains its metallic form, and may be sublimed of any figure we please.

Regulus of arfenic unites with many of the metals, but destroys the malleability of those with which it enters into fusion. It renders those more easy of fusion on which are melted with difficulty by themselves; but tin, the most easily fusible of all the metals, becomes
Regulus of arfelic,

This metal acquires a permanent and shining whiteness by its union with regulus of arfelic, and is able to retain half its own weight of the arfentical metal. The other white metals become grey by fusion with this femimental, platina only excepted. Gold fusfed in a clofe vefsel with regulus of arfelic, scarcely takes up $\frac{1}{2}$ of its weight; silver $\frac{1}{2}$ lead $\frac{1}{2}$ copper $\frac{1}{2}$ and iron more than its own weight. The magnetic property of this latent metal is destroyed by a large quantity of regulus, though the exact proportion which destroys it can scarcely be determined, as some of the iron is always taken up by the fcoria; but according to Mr Bergman, less than an equal quantity is certainly sufficient. Bifmutn retains $\frac{1}{2}$ of its weight; zinc $\frac{1}{2}$ regulus of antimony $\frac{1}{2}$; and manganese an equal quantity. Nickel and regulus of cobalt take up a large quantity; but how much cannot be determined, as it is next to impossible to procure any of those metals in a flare of perfect purity. In a fufficient degree of heat, and by a triotte of feveral hours, regulus of arfelic takes up about $\frac{1}{2}$ of its own weight of mercury, forming an amalgam of a grey colour.

Regulus of arfelic, by reafon of its volatility, may be expelled from all the metals with which it is united; but, in flying off, it generally carries along with it some of the metals with which it is united, gold and silver not excepted, if the degree of heat be great and very suddenly applied. Platina, however, perfectly refists the volatilization; and by reafon of its refractory nature, even retains a portion of the arfenic. This femimental cannot be united by fusion with alkaline falls until the phlogifon is confiderably diminished, and the regulus approaches to the nature of pure arfenical metal. By adding regulus therefore to nitre in fusion, a detonation enfues, the phlogifon of the former is totally destroyed, and the acid uniting with the alkali of the nitre forms a neutral arfenical salt, similar to that made with white arfenic and nitre. By difillation with dry acid of arfenic, the regulus fublinges before it can be acted upon by the acid; but when thrown into the acid in folution, foon takes fire, and fends forth a white fmoke; for the acid, being in this infuance deprived of its phlogifon, feparates that principle from the regulus, and fublimes it with it in fuch quantity as to regenerate white arfenic; while on the other hand, the regulus, by this operation, is fo far deprived of its phlogifon as to appear in the form of a cafl. By difillation with corrosive fublimare, a fmoaking butter, and fmall quantity of mercurius dulfis and running mercury, are procured; which happens in confequencc of a dolfble elcclive attraction; the regulus of arfenic yielding its phlogifon to the base of the corrosive fublimare, which being thus really calcined, reduces the former to perfect mercury, while the marine acid takes up the cafl of arfenic. The regulus of arfenic readily unites with sulphur, and forms the fame red and yellow compounds that have already been mentioned when fpeaking of white arfenic; it is difoluble in hepaf sulphuris, but may be precipitated by every other metal which can unite with the hepaf.

Regulus of arfenic is not affected by the vitriolic acid, unless when concenfrated and affifted by heat. The inflammable part of the regulus which phlogifonizes cooks the acid flies off, fo that the remainder affumes the nature of white arfenic, and exhibits the fame propertics with menilina as any other metallic cafl: the fame holds good with nitrous acid, except that it attaracts the phlogifon more vehemently. Marine acid has little or no effect except when boiling.

Regulus of arfenic precipitates certain metals diffolved in acids, fuch as gold and platina, difolved in aqua regulis on metallic solution.

§ 12. Cobalt.

Regulus of cobalt, or more properly pure cobalt itself (what we have under the name of cobalt being only a cafl of the regulus), is a femimental of a redhifh white colour, clofe-grained, fo as to be easily reducible to powder, about 7.7 of specific gravitiy, and forming itself into mafles of a needle-like texture, placed upon one another. It is feldom or never found native, but always calculated and united with arfenic, the arfenical acid, sulphur, iron, &c. The zaffire used in commerce is an impure and grey cafl of cobalt. When mixed with three times its weight of pulverized flints, and exposed to a ftrong fire, it melts into glafs of a dark blue colour, called fmalts, used in tinging other glafes, and in painting. With three times its weight of black flux, a small quantity of tallow and marine falt, it affords the femimetal known by the improper name of regulus of cobalt; but the reduction is very difficult. For this purpose a large quantity of flux must be made of, and the crucible kept a confiderable length of time in a white-red heat, that the matter may become quite difolved. So- Regulus of cobalt, when cooled, becomes covered with a dull pellicle, and undergoes a spontaneouf calcification; but it may easily be calcined in the air.
Cobalt. in any quantity by exposing it in powder in a shallow vessel, under the muffle of a cupelling furnace, and fritting it now and then to expose fresh surfaces to the air. After being kept red hot for some time, this powder loses its splendor, increases in weight, and becomes black, the calx being convertible, by a most violent heat, into a blue glass. By fusion it combines with vitriofulceur earths, forming with them a beautiful blue glass extremely fixed in the fire; whence it is of the greatest use in enamelpainting, porcelain-painting, &c. The action of terra ponderosa, magnesia, and lime, on cobalt, is not known. Alkalies manifestly alter it; but in what respect is not known.

Cobalt dissolves in concentrated vitriolic acid, when its calx forms a beautiful blue glass. Its calx, with vitriofulceur earths, entirely dissolves in the vitriolic acid. Phenomena with vitriofulceur earths, when the vitriolic acid is boiled with the heat, the acid evaporating almost entirely in the form of sulphurous gas. The residue is then to be washed; a portion of it dissolves in the water, and communicates a greenish colour to it when warm, which changes to a rosy colour when cold. M. Beauné affirms, that by sufficiently evaporating the vitriolic solution of cobalt, two sorts of crystals are obtained; one white, small, and cubical; the other greenish, quadrangular, fissiles in length, and four in breadth. These last he only considers as the true vitriol of cobalt; the former being produced by certain foreign matters united to it. The crystals most commonly obtained have the form of small needles, and may be decomposed by fire, leaving a calx of cobalt not reducible by itself. They may likewise be decomposed by all the alkalies, by terra ponderosa, magnesia, and lime. According to Fourcroy, 100 grains of cobalt, dissolved in the vitriolic acid, afford, by precipitation with pure mineral alkali, 140 grains of precipitate; by the same alkali aerated, 160 grains. Diluted vitriolic acid acts on zaffre, and dissolves a part, with which it forms the salt already described.

Nitrous acid acts upon the femimetal with that violence which is its general characteristic; and the solution, when nearly faturated, appears either of a rosy brown or bright green colour. By strong evaporation it yields a salt in small needles joined together; which is very deliquescent, boils upon hot coals without denotation, and leaves a calx of a deep red colour. It is decomposed by the same substances as the former, and by excess of alkali the precipitate disappears.

Muriatic acid, affixed by heat, dissolves cobalt in part, but has no effect upon it in the cold. It acts more strongly on zaffre, forming a solution of a reddish brown, which becomes green by being heated. By evaporation it yields a very deliquescent salt in small needles, which becomes green when heated, and is soon after decomposed. Aqua-regia dissolves the metal more easily than the marine acid, but less so than the nitrous. The solution has been long known as a sympathetic ink.

Cobalt is not dissolved directly by the acid of borax; but when a solution of this salt is mixed with a solution of cobalt in any of the mineral acids, a double decomposition takes place; the alkaline basis of the borax uniting with the acid which held the cobalt in solution; and the calx, combining with the sedative salt, falls to the bottom in form of an insoluble precipitate.

This femimetal is calcined by being heated to ignition with nitre. One part of cobalt, and two or three of dry nitre, well powdered and mixed, when thrown into a red-hot crucible; produce small incandescences; a portion of the cobalt being converted into a calx of a red colour, more or less deep, and sometimes of a green. Sal ammoniac is not decomposed, by reason of the slight attraction there is between the metal and muriatic ammoniac acid. M. Busquet, who made the experiment with great care, could not obtain a particle of volatile alkali. Sulphur does not unite with it but very difficultly, and the combination is promoted by liver of sulphur. Thus a kind of artificial one may be produced, the grain of which will be finer or closer, and its colour whiter or yellower, in proportion to the quantity of sulphur in the mixture. M. Beauné observes, that this compound cannot be decomposed by acids, and that fire cannot destroy all the sulphur.

This was first discovered to be a femimetal of a peculiar kind by Cronstedt, in the years 1751 and 1754, by Mr. Voss, who procured it in the form of regulus from its ore, but Cronstedt, without being able to reduce it to a sufficient degree of purity; which indeed has not yet been done by any chemist. M. Bergman has laboured most in this way, though even he has not reduced it to the purity of other metallic substances. His experiments were made with some regulus made by M. Cronstedt, and whose specific gravity was to that of water exactly as 7.421 to 1. His attempts to purify it were made.

I. By Calcination and Scorification.

Nine ounces of powdered nickel were exposed for 3000 hours, in several portions, to a most violent heat, under the dome of an assaying furnace. Thus the arsenic was first diffipated with a fetid smell, after which the odour of sulphur became perceptible; after this a white smoke arose without any smell of garlic, and which, according to our author, arose probably from the muriatic substances. His experiments were made with some regulus made by M. Cronstedt, and whose specific gravity was to that of water exactly as 7.421 to 1. His attempts to purify it were made.
Nickel.

green colour. Nearly the same phenomenon appeared after reduction in a fourth operation.

On performing the reduction with lime and borax, the regulus, when full melted, lost much of its ferruginous nature, which adhered to the black incorius; it soon acquired an hyacinthine colour, without any remarkable mixture of cobalt, was little obedient to the magnet, and its specific gravity was somewhat diminished, being now only 7.0828.

By a fifth calculation, gradually adding a quantity of powdered charcoal while the matter continued red hot, a prodigious quantity of arsenic, imperceptible before, flew off in the form of vapour; the arfenical acid being thus furnished with as much phlogiston as was necessary to make it rise in fume. The regulus was treated in this manner until no more arfenical smoke could be perceived; it was now of a lamella ted and tenacious texture when reduced, but still diffused the arfenical odour on being removed from the fire. The roasting was therefore repeated a sixth time, and continued for ten hours; the addition of powdered charcoal continued to diffuse the arsenic in invisible vapours which yet were perceptible by the smell; the colour of the metallic calx was obscurely ferruginous, with a mixture of green scarcely visible. On reducing the regulus with equal parts of white flux, lime and borax, a semiducile regulus was obtained, highly magnetic, and soluble in nitrous acid, to which it communicates a deep green colour; a blackish mass remained, which afterwards became white, and when laid on a burning coal, flies off without any remarkable arfenical smell. The regulus being then six times fused with lime and borax, the scorius resembled the hyacinth in colour, and the metallic part was surrounded with a green calx. The regulus, as before, was magnetic and semiducile. Lastly, it was exposed for four hours to a very strong heat; when the powdered charcoal was added by degrees without any dilution of arsenic or loss of weight; the colour of the roasted powder was ferruginous, with a very slight tinge of green. On reduction, a very small globe, still magnetic, was found among the scorius.

II. By Sulphur.

Eight hundred parts of Crofts's regulus of nickel, fused with sulphur and a small quantity of borax, yielded a mineralized mass of a reddish yellow, whole weight amounted to 1700. On exposing one half of this to the fire, it began to grow black; on which the heat was augmented until vegetations appeared; the remaining calx weighed 652. Melting this part with borax, and the other which had not been exposed to the fire, a sulphurated regulus of a whitish yellow colour was obtained, weighing 1102. The same regulus, calcined for four hours, was still covered with vegetations, and then, on the addition of powdered charcoal, diffused an arfenical odour; the metallic calx was green, and weighed 1058. A whitish yellow regulus was obtained semiducile, highly magnetic, and extremely refractory, weighing 504. By fusion with sulphur a second time, it weighed 816; one half of which roasted to greenness, united by means of fire to the other half still sulphurated, weighed 509, and was almost deprived of its magnetic quality. A calcination of four hours, during which phlogiston was ad-

ded, diffused a considerable quantity of arsenic; the powder put on an ashen-colour, somewhat greenish, in weight 569; and by reduction yielded a regulus whose surface was red, and when breaking, appeared of a white ashen-colour, very friable, and weighing 432; the specific gravity 7.173.

On mineralizing the regulus a third time with sulphur, adding charcoal as long as any vestige of arsenic remained, which required a violent calcination of 12 hours, the remaining powder was of an ashen-colour, and weighed 364; but the regulus obtained by means of a reduction effected by the most violent heat in a forge for three quarters of an hour, was so refractory that it only adhered imperfectly to the scorius, which were of a distinct hyacinthine colour; nor could it be reduced to a globule by means of borax, though urged by the flame vehement of fire. The absolute gravity of this regulus was 180; its specific gravity 8.666. Its magnetic virtue was very remarkable; for it not only adhered strongly to the magnet, but to any other piece of iron; and the small pieces of it attracted one another. It had a considerable ductility, was of a whitish colour, mixed with a kind of glittering red; dissolved in volatile alkali, yielding a blue solution, and a green one in nitrous acid.

An hundred parts of the same regulus, beaten out into thin plates, were covered by a calcination of four hours, with a crust apparently martial, having under it a green powder, and within it a nucleus consisting of reguline particles still unchanged; the weight maintained unchanged by 5. The frangible mass, reduced to powder, put on a brownish-green colour; and after a calcination of four hours more, concreted at the bottom in form of a friable black crust, strongly magnetic, and weighing 100: No vestiges of arsenic were discovered by a succeeding operation, in which charcoal was added; nor was the magnetic powder destroyed, but the weight was increased to 105, and the colour somewhat changed. By fusing for an hour with lime and borax, this powder yielded a regulus of an angular structure, red, semiducile, and altogether magnetic, the specific gravity being 8.975. The same globule dissolved in aqua regia, was precipitated by green vitriol, as if it had been bathed with gold; but the precipitate was readily soluble in nitrous acid. Most of the reguli showed no signs of precipitation with green vitriol.

III. With Hepar Sulphuris.

Fifty-eight parts of regulus of nickel, which had been sulphurated before, being fused with 1200 parts of salinum hepar sulphuris, then dissolved in warm water, filtered through paper, and precipitated by an acid, yielded a powder, which, by calcination till the sulphur was driven off, appeared of an ashen-colour, and weighed 35. The infoluble residuum, deprived of its sulphur by means of fire, was likewise of an ashen-colour, and weighed 334. On reducing this regulus by means of the black flux, a friable regulus was obtained, which had a very weak magnetic property; but, on fusion with borax, this quality was augmented. On mixing and melting together equal parts of calx of nickel, gypsum, colophony, and white flux, a powdery, fictitious, and reguline mass was produced; which, by fusion with borax, afforded a regulus possessing the properties...
C H E M I S T R Y.

Nickel.

Properties of nickel, but not entirely definite of cobalt, which obeyed the magnet, and did not part with its iron even after two solutions in the nitrous acid, and various reductions by fusion with borax; the sulphur was also retained with great obstinacy.

On dissolving regulus of nickel by fusion, in hepatic sulphur made with fixed alkali, adding a quantity of nitre sufficient only to destroy a small part of the hepatic sulphur, the regular which had been fuperseded by it was separated, and fell to the bottom. On examining this regulus, it appeared more pure, and generally deprived of cobalt, but still containing iron. In like manner nickel is always very distinctly precipitated by regulus of cobalt, as this latter is attracted more powerfully by the hepatic sulphur. When dissolving by fusion with hepatic sulphur, this femimetal may be precipitated by adding iron, copper, tin, or lead, and even by cobalt: the regulus obtained is indeed scarcely ever attracted by the magnet; but we are not from thence to conclude that it does not contain any iron; for when the heterogeneous matters, which impede its action, are properly removed, it then acknowledges the power of the magnet very plainly.

IV. By Nitre.

One part of Cronstedt's regulus was added to twelve of nitre ignited in a crucible, and kept red-hot for about an hour. Some weak families appeared first; then a large quantity of arsenic was emitted; and, lastly, the sides were covered with a blue crust occasioned by the cobalt, a green matter remaining at bottom. This fused again for an hour, with twelve parts of nitre, tinged the internal sides of the vessel of a green colour; and, lastly, a brownish green mass, much less in quantity than in the former operation, was left at the bottom. This green matter, treated in the same way for two hours a third time, left a grey foetia at the bottom, which yielded no regulus with black flux.

Another portion of the same regulus, treated in the same way with nitre, was dissolved, and became green; yet, on being freed by abrasion from the alkaline salt, it yielded no regulus with black flux, but only foetia of a hyacinthine colour mixed with blue, tinged nitrous acid of a green colour, crucinating, and on evaporation leaving a greenish calx behind.

Another portion of Cronstedt's regulus was kept some hours in the crucible with 16 parts of nitre, by which means all the arsenic was first separated; then the phlogisticated nitrous acid; and, lastly, the sides of the vessel were penetrated by a kind of green efflorescences. The mass, after being washed with water, was of a dilute green colour, and tinged borax of a greenish brown. A green powder was still yielded, after treating this in the same manner with 12 parts of nitre; and on reducing it with one-half black flux, one-eighth borax, and as much lime, a yellowish white regulus, both magnetic and malleable, was obtained, possessing all the properties of nickel. Its specific gravity was 9.039; the phlogistic ingredient was used in small quantity, that the iron might, if possible, enter the foetia.

It having appeared from this and some other experiments, that nitre was capable of discovering the smallest quantity of cobalt contained in nickel the products of the former operations were now subjected to its action. The regulus produced by repeated foecification thus became a little blue; that dissolved in volatile alkali (to be afterwards particularly mentioned) discovered a considerable quantity of cobalt; nor was there any one which did not thus discover more or less of that ingredient by this trial.

V. By Sal Ammoniac.

A calx of nickel, so much freed from cobalt that it Effects of did not tinge borax in the leash, mixed with twice its weight of sal ammoniac, yielded by sublimation with a strong red heat, two kinds of flowers; one, which rose higher than the other, was of an ash colour; the other white. The bottom of the glass was stained of a deep hyacinthine colour; the residuum was divided into two strata; the upper one yellow, scaly, and shining like mosaical gold. With borax it afforded an hyacinthine glass, but not regulus; and in a few days liquefied in the air, acquiring a green colour and the confidence of butter. The residuum showed the same properties with calx of nickel; and the green solution flowed no veigles of iron with galls, but became blue with volatile alkali; which was also the case with the flowers. The lower stratum contained a calx, blackish on the upper part, but of a ferruginous brown in the under, with a friable and scarcely magnetic regulus, of a reddish white. The blackish calx yielded an hyacinthine glass with borax. Part of this stratum sublimed with twice its quantity of sal ammoniac; and with the same degree of heat as before, yielded flowers of a very fine white, with a residuum of ferruginous brown, greenish on the upper part towards the sides of the vessel, the bottom being stained of an hyacinthine colour as before. Twenty parts of sal ammoniac being added to a part of the interior stratum reduced, the whole was sublimed in a retort; a blackish powder remained, which became green by calcination, and of an hyacinthine colour by foecification, as did also the bottom of the containing vessel. The sublimation being twice repeated, using a double quantity of sal ammoniac each time, the calx became at length very green, dissolving with the same colour in the nitrous acid, and yielding by reduction a white, brittle, and very little magnetic regulus. In all the sublimations, it was observed, that the volatile alkali rofe first; then sal ammoniac; and lastly, a part of the marine acid was forced over by the violence of the heat.

VI. With Nitrous acid.

Having obtained a salt by crystallization from nickel Effects of of dissolving in nitrous acid, part of this was calcined with antimony charcoal doft in a proper vessel, and during the operation a large quantity of arsenic was dissipated; a grey, femidulcite, and magnetic regulus being obtained after reduction. A brittle regulus was obtained after a second solution, precipitation, and reduction; but by a third operation it became again femidulcite and magnetic. By repeating this process a fourth and fifth time, the quantity became to much diminished that it could no longer be tried. In all these solutions a blackish residuum appeared; which, when suffered to remain in the acid, grew white by degrees; but when edulcorated and laid on a burning coal, exhaled a sulphurous smoke, and left a black powder soluble in the nitrous acid.

Volatile alkali.

Four hundred and eighty-seven parts of a calx of nickel, produced by diffusing Crofiedt's regulus in nitrous acid, and precipitating the solution by a fixed alkali, being immerfed for 24 hours in a quantity of volatile alkali, yielded a residuum of fifty, having a blackish green colour. The solution, which was blue, by filtration and infpiration yielded a powder of a light blue, weighing 282; which, reduced with black flux, produced a white, feminidite, and highly magnetic regulus, weighing 35, whose specific gravity was 7.000. The icoria were of a light red; but when mixed with borax, put on a hyacinthine colour, and yielded a regular weighing 30. The two regulns united together proved very refractory; so that the mafs could not be melted by the blow-pipe, even with the addition of borax. It lent forth neither an arfencical nor sulphureous smell on the addition of charcoal dust; but, on a succeeding reduction, yielded by hyacinthine icor; and the remaining fuccelli, diffolved in nitrous acid, affording a very green solution, which, on the addition of volatile alkali, yielded a powder of the fame colour.

From 50 parts of the blackish-green residuum, 13 of a clear white, brittle, squamous, and little magnetic regulus, were obtained, the specific gravity of which was 9.333. At the bottom of the vessel was found a fcoria of an obscurely blue colour, with the upper part hyacinthine. It was easily fufed; and tinged borax, first blue, then of a hyacinth colour, upon which it became more strongly magnetic. By the addition of heat it diffolved in nitrous acid, forming a solution of a beautiful blue colour. A black powder at first floatd in the liquor, but became white, and fell to the bottom. After eduction it was for the most part diffipated, with a sulphureous smell, on being exposed to the fire; a little brown-coloured mafs, soluble in volatile alkali, remaining at bottom. This solution was precipitated by phlogificated alkali, and a powder thrown down of the colour of calx of nickel, which soon grew blue with volatile alkali.

From all these experiments it appears, that nickel cannot be obtained in a state of purity by any means hitherto known. From every other substance, indeed, it may be separated, except iron; but this refisits all the operations hitherto defcribed, and cannot be diminished beyond certain limits. The magnet not only readily discovers its preence, but some portions of the regulus itself becomes magnetic; but the tenacity and difficulty of fution, which increafes the more in proportion to the number of operations, plainly show that there is no hope of separating the whole quantity, unless we fuppose the regulus of nickel itself to be attracted by the magnet; and there is certainly a pofibility that one other substance besides iron may be attracted by the magnet. The great difficulty, or rather impoffibility, of obtaining it in a state of purity, naturally rafes a fupicion of its not being a diftinct semimetal, but a mixture of others blended together; and on this fubjeét our author agrees in opinion with those who fuppose it to be a compound of other metals. Indeed, Mr BERGMAN is of opinion, that "nickel, cobalt, and manganese, are perhaps no other than modifications of iron." And in order to aecertain this, he made the following experiments.

1. Equal parts of copper, of the gravity of 9.324, and iron of 8.5676, united by fusinon with black flux, yielded a red mafs, whose specific gravity was 8.5441; compose and which tinged nitrous acid first blue, then green, nickel artificially.

2. Two parts of copper and one of iron had a specific gravity of 8.4634; the mixture yielding first a blue, and then a green solution. 3. Equal parts of copper and iron, of the specific gravities already mentioned, with another part of cobalt whose gravity was 8.1500, yielded a metal of the gravity of 8.0300, imparting a brown colour to the solution. 4. Two parts of arsene of 4.000, added to one of copper and another of iron, gave a brittle metal of 8.0468, which formed a blue solution. 5. One part of copper, one of iron, two of cobalt, and two of white arfene, gave a brittle regulus of 8.4186; the solution of which was brownish, and separated in part spontaneously. 6. One part of copper, one of iron, four of cobalt, and two of white arfene, formed a mafs of 8.7174. The solution was somewhat more red than the former; and a similar effect took place on repeating the experiment, only that the specific gravity of the metal was now 8.2941. 8. One part of iron and four of white arfene formed a metal which diffolved with a yellow colour; and, on the addition of Pruffian alkali, immediately let fall a blue sediment. 9. One part of copper, eight of iron, sixteen of white arfene, and four of sulphur, united by fire, on the addition of black flux, yielded a mafs which, though frequently calcined and reduced, produced nothing but brown or ferruginous calces. It acquired a greenish with nitrous acid; but on the addition of phlogifticated alkali deposited a Pruffian blue. 10. One part of iron was diffolved in fix of the nitrous acid, and likewise separated by one part of copper and one of the calcined ore of cobalt, in the fame quantity of the fame acid. The whole of the solution of iron was then mixed with five parts of the solution of copper, whence a green and faturated nickel colour was produced; which, however, on the addition of three parts of the folution of cobalt, became evidently occluded. The alkaline lixivium dropped into this, which formed a ferruginous brown sediment, the folution still remaining green: afterwards all the blue was precipitated; by which at first all colour was deftroyed, but afterwards a red appeared, occasioned by the cobalt diffolved in the alkaline falt. The fediment, when reduced, yielded a regulus similar to copper, and at the fame time duc­tile, which tinged both glafs and nitrous acid of a blue colour. If a faturated folution of nickel be mixed with half its quantity of folution of cobalt, the green colour is much occluded; but four parts of the former, on the addition of three of the latter, put off all appearances of nickel. See the article Nickel.

§ 14. OF PLATINA.

The properties of this metal have not as yet been The hear­thoroughly investigated by chemists, and there is there­viat of all fore some disagreement concerning them. Formerly metals, it was fupposed to be inferior in specific gravity to 4 A gold;
Platina.

Gold; but now is generally allowed to be superior in that respect by little less than a fourth part; being to water in the proportion of 23 to 1 when perfectly freed from all heterogeneous matters. Mr. Bergman says that its colour is that of the purest silver. They are not affected by the magnet in the least, nor can they be dissolved in any simple menstruum excepting dephlogisticated marine acid. As it is commonly met with, however, platina has the form of small grains, its plates of a bluish black, whose colour is intermediate between those of gold and silver. These grains are mixed with many foreign substances, as particles of gold, mercury, and blackish ferruginous, sandy grains, which by the magnifier appear coriaceous. The grains themselves, when examined by a magnifying glass, appear sometimes regular, sometimes round and flat, like a kind of button. When beat on the anvil, most of them are flattened and appear dull; some break in pieces, and on being narrowly examined appear to be hollow, and particles of iron and a white powder have been found within them; and to these we must attribute the attraction of platina by the magnet; since, as we have already observed, pure platina is not attracted by it.

Mr. Bergman, who carefully examined this metal, dissolved it first in aqua-regia composed of the nitrous and marine acid. The solution at first exhibits a yellow colour, but on approaching to saturation became red, and the reddness increases as the liquor becomes more loaded with metal. Crystals are produced by evaporation of a deep red colour, generally in small angular and irregular grains, whose true shape cannot be discovered. Their appearance is sometimes opaque and sometimes pellucid. After these are once formed, they are extremely difficult of solution, requiring much more water than even gypsum itself for this purpose. — The solution is not precipitated by vegetable fixed alkali, nor does the latter affect the crystals, except very faintly by digestion with them in a caustic frit. Acetated mineral alkali takes them up and grows yellow, but without depositing anything, though it decomposes them at last by evaporating to dryness.

On the addition of a small quantity of vegetable fixed alkali, either mild or caustic, small red crystals soluble in water, and sometimes of an octahedral figure, are deposited. They are decomposed with difficulty by the mineral alkali, but not at all by the vegetable. If a larger quantity of falt is added at first, an infusible spongy matter of a yellow colour is precipitated. Crystalline particles of the same kind are thrown down by an alkali faturated either with the vitriolic, nitrous, marine, or acceous acids, though all the platina cannot thus be separated from the menstruum.

Aqua-regia, composed of nitrous acid and common salt, dissolved the metal with equal facility as the former; only the solution was more dilute, and a yellow powder floated on the surface, a larger quantity being found at the bottom. On adding vegetable fixed alkali to the clear solution, a copious yellow powder, soluble in a large quantity of water, was deposited. A powder, of a similar kind, was precipitated, tho' more slowly, and more of a crystalline nature; but mineral alkali, though used in much larger quantity, did not make any alteration. The collected powder was yellow, and agreed in property with that separated independently in a former experiment.

On repeating the experiment with nitre and depurate spirit of salt, instead of nitrous acid and sea-falt, the platina was dissolved into gold-coloured liquor, a green-coloured granulated matter falling to the bottom, and the finer part of the same rising to the top. After faturating the superaerious acid, a metallic calx, insoluble in water, was thrown down by the vegetable alkali. The green powder is soluble in water, and is of the same nature with the precipitate thrown down by the vegetable alkali.

Platina precipitated from aqua-regia by a sufficient quantity of mineral alkali, the precipitate washed and precipitated by vegetable alkali immediately lets fall a crystalline powder, as it does also with nitre and other salts, having the vegetable alkali at the same time dilutes them with dilute solutions of platina, dissolved in vitriolic acid. Nitrous acid also dissolves the calx in marine acid; — The above phenomena are likewise produced by the precipitate thrown down by the vegetable alkali after the saline powder has been deposited.
The volatile alkali first throws down this metal in a saline form; the grains sometimes distinctly octahedral. Their color is red when that of the solution is so, but yellow when the solution is more dilute. After faturating the superabundant acid, the same alkali precipitates the platina truly calcined. This precipitate is dissolved in water, though with difficulty, and may be reduced to more regular crystallites by evaporation. These are dissolved by the mineral alkali; but hardly any signs of decomposition are to be observed, unless the yellow solution, evaporated to dryness, be again dissolved in water; for then the metallic calx reverts at the bottom, and the solution is deprived of its yellow color. The vegetable alkali has scarce any effect in this way; for, after repeated exsolution, the solution remains clear and yellow: but here probably the fixed alkali takes the place of the volatile; for in larger quantities, and especially when the caustic vegetable alkali is made use of, the mixture filments of volatile alkali.

The volatile alkali, faturated with any acid, precipitates the platina in the same manner as the vegetable alkali in combination with acids: but these neutral salts precipitate only a determined quantity of platina; for after their effect has ceased, the liquor lets fall a pure calx of platina on the addition of vegetable or volatile alkali.

Platina, partly precipitated by neutral salts.

The caust of platina precipitated by mineral alkali, and then dissolved in any simple acid, shows nearly the same phenomena with volatile alkali as with the vegetable alkali. "Whence (says Mr Bergman) we may conclude, that platina dissolved in acids forms at first, both with the volatile and fixed vegetable alkali, a triple salt, difficult of solution, and which therefore almost always falls to the bottom unless the quantity of water be very large." Calcareaeous earth, whether aerated or caustic, produces the same phenomena as the vegetable alkali, without any crystalline appearance.

Platina has been remarkable ever since its first discovery for being the most insubfluent substance in the world. Meissr Macquer and Beaumé kept it in the most violent heat of a glafs-house furnace for several days without perceiving any other alteration than that its grains adhered slightly to each other; but the adhesion was so slight that they separated even by touching. In these experiments the color of the platina became brilliant by a white heat, but acquired a dull grey colour after it had been heated for a long time. They observed also, that its weight was constantly increased; which undoubtedly arose from the calculation of the iron it contained. Dr. Lewis, after various attempts to fuse platina, found himself unable to succeed even in a fire which vitrified bits of glafs-house pots and Heffian crucibles. Meissr Macquer and Beaumé first melted this refractory metal with a large burning-gla$s, 22 inches diameter and 28 inches focus. The power of this speculum was almost incredible, and far exceeded what is related of the lens of Téhirnhausen or the mirror of Villette. Its general effects are related under the article BURNING-CrEss.

And as platina refilts this intense heat more than six times as long as the most insubfluent substances formerly known, it appears to require a fire as many times stronger to melt it. It has been found, however, capable not only of fussion but of vitrification by the electric fire; and that it may also be melted by fire excited by defphlogistificated air: but M. de Lisle was the first who was able to melt it with the heat of a common forge when exposed to the blast of a double belows in a double crucible. Thus its real specific gravity must be observed in a common forge. Its precipitate is fusible, in a common forge.

Platina, most insubfluent substance in the world.

Though Dr Lewis could not accomplish the fusion alloyed by platina by the methods he attempted, he was not able to alloy it with other metals. Equal with other parts of gold and platina may be melted together by metals, a violent fire, and the mixed metal forms, however, an ingot by pouring it into a mould. It is whifht, hard, and may be broken by a violent blow; but when carefully annealed, is capable of considerable extension under the hammer. Four parts of gold with one of platina form a compound much more fusible than the former, and likewise more malleable; so that it may be extended into very thin plates without being broken or even split at the edges. Dr Lewis remarks also, that though in this case it is alloyed with such a quantity of white metal, it neverthele$s appears no paler than guinea usually are, which contain only one-twelfth of silver.

Equal parts of silver and platina melted together with gold, with a violent fire, form a much harder and darker metal, colored mafs than silver, which has also a large grain, though it preserves some ductility. Seven parts of silver with one of platina form a compound much more resembling silver than the other; but still coarser-grained and less white. From the experiments made on silver, however, it appears that no perfect union is formed.
formed between the two; for after the mixture has been kept in fusion for a considerable time, most of the platina separates and falls to the bottom. Lewis observed that silver melted with platina was thrown up with an explosion against the sides of the crucible.

Silver did not appear to be in any degree meliorated by its union with this metal, excepting by the superior hardness communicated to it; but copper seemed to be considerably improved. A large proportion of platina, indeed, as two-thirds or equal parts, produced an hard, brittle, and coarse-grained compound; but when a smaller quantity of platina is added, as from 1 to 9, or even less, a golden-coloured copper is produced, very malleable, harder, susceptible of a finer polish, smoother-grained, and much less subject to calcination and rust than pure copper.

Of all metallic matters, however, zinc most readily unites with platina, and is most effectually dissolved by fusion. When the proportion of platina is considerable, the metal is of a bluish colour, the grain clover, without tarnishing or changing colour in the air, and they have not even the malleability of the femi-metal.

Platina unites readily with the compound metals, braifs formed of copper and zinc, and bronze made of copper and tin. In the latter it was remarkable, that the compound metal took up more platina than both its ingredients separately can do. This compound was hard and capable of receiving a fine polish, but is subject to tarnish.

Equal parts of braifs and platina formed a compound very hard, brittle, capable of receiving a fine polish, and not subject to tarnish. It is possible therefore that it might be used to advantage as a material for speculums; all materials for which, hitherto discovered, have the great inconvenience of tarnishing in the air, and that very quickly.

Platina amalgamates with mercury, but with much greater difficulty than gold, which will also separate the quicksilver after it has been united with the platina. The amalgamation of platina does not succeed but by very long trituration of the metals with water, as for instance a week; but if the trituration be performed with a mixed metal composed of gold and platina, the mercury feizes the gold, and leaves the platina untouched. Dr Lewis proposes this as a method of separating gold from platina; and it is that used in Peru, where gold and platina are sometimes naturally mixed in the ore; but we do not know whether this separation be quite complete.

Mr Morveau succeeded in uniting iron with platina, though Dr Lewis could not accomplish this. The latter succeeded, however, in uniting it with cast iron. The compound was much harder and less subject to rust than pure iron. It was also susceptible of a much finer polish.

Platina may be alloyed with tin, lead, or bismuth, but without any advantage. To lead and tin it gives the property of affaining blue, violet, or purple colours, by being exposed to the atmosphere.

‘Dr Lewis could not succeed in uniting platina with arfenic; but M. Scheffer affirms, that if only one twentieth of arfenic be added to platina when red hot in a crucible, the two substances will be perfectly fused and united into a brittle grey mass. This experiment did not succeed with Mr Margraf, for he, having exposed to a violent fire during an hour a mixture of an ounce of platina with a fusible glass, composed of eight ounces of minium, two ounces of plints, and one ounce of white arfenic, obtained a regulus of platina well united and fused, weighing an ounce and 32 grains; the surface of which was smooth, white, and shining, and the internal parts grey; but which nevertheless appeared sufficiently white when filed. The experiment succeeded imperfectly also in the hands of Dr Lewis; but M. Fourcroy informs us, that ‘it has since been repeated, and that platina is in fact very fusible with arfenic, but that it remains brittle. In proportion as the arfenic is driven off by the continuance of the heat, the metal becomes more fusible; and by this process it is that M. Acharut and M. de Morveau succeeded in making crucibles of platina by melting it a second time in moulds.’

M. Fourcroy seems to deny that platina can be united with mercury, contrary to what is mentioned above. ‘Platina (says he) does not unite with mercury, though triturated for several hours with that metallic fluid. It is likewise known, that platina refits the mercury used in America to separate the gold. Many intermediums, such as water, used by Lewis and Beaumé, and aqua-regia by Scheffer, have not been found to facilitate the union of these two metals. In this respect platina seems to resemble iron, to whose colour and hardness it likewise in some measure approaches.’

This last sentence, however, seems very little to agree with what he himself had before told us of M. Macquer’s experiment of melting platina. ‘The melted portions (says he) were of a white brilliant colour, in the form of a button; they could be cut to pieces with a knife.’ This surely was a very small approach to the hardness of iron; and gives us an idea rather of the consistence of tin or lead. ‘One of these masses was flattened on the anvil, and converted into a thin plate without cracking or breaking, but it became hard under the hammer.’ In another experiment indeed the button of platina was brittle, and sufficiently hard to make deep traces in gold, copper, and even iron; but this was obtained from precipitated platina urged for 33 minutes by a strong blast furnace. In an experiment of this kind M. Beaumé even succeeded in melting the precipitate along with certain fluxes, into a vitrifrom substance by two different processes. The precipitate of platina, mixed with calcined borax, and a very fusible white glass, was exposed, for 36 hours, in the hottest part of a potter’s furnace; and afforded a greenish glass, inclining to yellow, without globules of reduced metal. This glass, treated a second time with cream of tartar, gypsium, and vegetable alkali, was completely melted, and exhibited globules of platina dispersed through its substance. M. Beaumé separated them by washing, and found them fusible. The same chemist afterwards, together

(a) For a particular account of this process see before no 587.
Platina.

Platina, together with M. Macquer, exposed precipitate of platina to the same burning mirror with which they had fused the metal: the precipitate exhaled a very thick and luminous fume, with a strong smell of aqua-regia: it lost its red color, returned that of platina, and melted into a perfect brilliant button, which was found to be an opaque vitreous substance, of an hyacinthine colour at its surface, and blackish within; and may be considered as a true glass of platina. It may however be observed, that the saline matters with which it was impregnated contributed doubts to its vitrification.

"The orange-coloured precipitate obtained by pouring a solution of sal ammoniac into a solution of platina, appears to be a saline substance entirely soluble in water. This precipitate has a valuable property, discovered by M. de l'Ile, viz. that it is fusible without addition in a good furnace or common forge-heat. The platina melted by this process is a brilliant, dense, and close-grained button; but it is not fusible unless it has been exposed to a very strong heat. Macquer thinks that this fusion, like that of the grains of platina alone, exposed to the action of a violent fire, confines only in the agglutination of the softened particles; which being exceedingly more divided and minute than the grains of platina, adhere to and touch each other in a greater number of points than the grains; and in that manner render the texture of the metal much more dense, though no true fusion may have taken place. It seems, however, that if platina in grains be capable of fusion by the burning glafs, and of becoming considerably ductile, the precipitate of this metal, formed by sal ammoniac may likewise be fused on account of its extreme division; and that its not being as ductile as the button of platina fused by the solar heat, may perhaps depend on its retaining a part of the matter it carried down with it in precipitation, of which it may be possible to deprive it by fire."

Attempts to purify platina by cupellation

It being so extremely difficult to bring platina itself into fusion, one of the first attempts to purify it was by cupellation with lead. Thus the better metals would be purified, and, running through the crucible along with the lead, leave the platina in as great purity as though it had been melted by itself. This operation, however, was found almost equally difficult with the fusion of the metal by itself. Lewis failed in the experiment, though he applied the most violent heat of the ordinary cupelling furnaces. The vitrification and absorption of the lead indeed took place as usual; but in a short time the platinum became fixed, and could not by any means be reduced fluid. Melfrs Macquer and Beaumé succeeded by exposing an ounce of platina with two ounces of lead in the hottest part of a porcelain furnace, where the fire is continued for 50 hours without interruption. At the end of the operation the platina was flattened in the cupel; its upper surface was dull and rough, and easily separated; but its under surface was brilliant, and it was found easily to extend under the hammer; and on every chemical trial was found to be perfectly pure, without any mixture of lead. M. de Moreau likewise succeeded in cupelling a mixture of one drachm of platina and two drachms of lead in M. Macquer's wind-furnace. The operation lasted eleven or twelve hours, and a button of platina was obtained which did not adhere to the cupel, was uniform, though rather rough, and of a colour resembling tin. It weighed exactly one drachm, and was not at all acted upon by the magnet. Thus it appears that platina may be obtained in plates or laminae, which may be forged, and consequently may be employed in making very valuable utensils; and this the more especially as Mr. Beaumé has observed that different pieces of it may be welded and forged like iron. After having heated two pieces of pure cupelled platina to whitlness, he placed them one upon the other, and striking them briskly with a hammer, found that they united together as quickly and firmly as two pieces of iron would have done.

The great specific gravity of platina has rendered it a very desirable matter for such as would adulterate the precious metal, and can procure the platina easily, adulterating gold with platina. This, however, can only be done in South America, where platina is met with in plenty. In Europe the scarcity of platina renders it a more valuable object than even the gold itself. Fears of this fraud, however, have undoubtedly given occasion to the prohibition of exporting it. There are great differences among chemists concerning the quantity of platina that can be mixed with gold without destroying the colour of the latter. Dr. Lewis, as has already been observed, informs us, that four parts of platina may be mixed with one of gold, and yet the mixture be no paler than that for guineas; while Fourcroy afferts, that "it greatly alters the colour of the metal, unless its quantity be very small: thus, for example, a 47th part of platina, and all the proportions below that, do not greatly affect the colour of the gold." But whether this be the case or not, chemistry has afforded various ways of separating even the smallest proportion of platina from gold so that there is now no reason to prohibit the importation of it to Europe, more than that of any other metal with which gold can be alloyed. The following are the methods by which the platina may be most readily discovered: 1. By amalgamating the suspected metal with mercury, this fraud and grinding the mixture for a considerable time with it should water; by which the platina will be left, and the gold be pradically amalgamated. 2. By dissolving a little of it in aqua-regia, and precipitating with alkaline salt; the remaining liquor, in case the metal has been adulterated with platina, will be so yellow, that it is supposed a mixture of one thousandth part would thus be found out. 3. By precipitation with sal ammoniac, which throws down the platina but not the gold. If mineral alkali be used, the gold will be precipitated, but not the platina, unless the precipitant is in very large quantity. 4. By precipitation with green vitriol, which throws down the gold, and leaves the platina united with the crucible.

Platina.

All these methods, however, are not only attended with a considerable deal of trouble, but in some cases, for instance in suspected coin, it might not be eligible to use them. The hydraulic balance, alone affords a certain method of discovering mixtures of metals without hurting the texture of their parts. The great specific gravity of platina would very easily discover it if mixed with gold in any moderate quantity; and even in the smallest, the gravity of the mass could never be less than that of the pure gold: which circumstance
Manganese

compliance, as gold is never worked without alloy, would be sufficient to create a just suspicion; after which some of the methods already mentioned might be tried. It is possible, however, that the hardness and ductility of platinum might render it more proper for alloying gold than even copper or silver, usually made use of for this purpose.

§ 15. Of Manganese.

This substance is now discovered to afford a semi-metal different from all others, and likewise to posses some other properties of a very singular kind. Mr Scheele has investigated its nature with the utmost care; and the results of his inquiries are as follows:

1. Two drachms of levigated manganese, digested for several days in a diluted vitriolic acid, did not appear to be dissolved or diminished in quantity; nevertheless a yellowish white precipitate was procured by saturating the acid with fixed alkali. The remaining manganese was not acted upon by more of the same acid, but the addition of another half ounce nearly destroyed the acidity of the menstruum when boiled upon it.

2. With concentrated vitriolic acid an ounce of manganese was reduced to a mass like honey, and then exposed to the fire in a retort till it became red-hot. Some vitriolic acid came over into the receiver; and after breaking the retort, a mass was found in it weighing 12; drachms, hard and white in the inside, but red on the outside. A great part of it dissolved in distilled water, on the effusion of which at first it became very hot. The residuum after evaporation weighed a drachm and an half, and was of a grey colour. Being calcined in a crucible with concentrated vitriolic acid till no more vapours arose, it was all dissolved by water excepting one drachm; which being again calcined with the same acid, an insoluble residuum of a white colour, and weighing only half a drachm, remained. This white residuum effervesced with borax, and melted into a transparent brown glass; it likewise effervesced with fixed alkali, changing into a brown mass, which yielded an hepatic smell with acids, and became at the same time gelsinous. The solution obtained by calcination was evaporated and set to crystallize. A few small crystals of felenite were first deposited, and afterwards some very fine large crystals of an oblique paralleloiped form, whose number increased as long as there was any liquid left. They tafted like Epson salt, and Mr Weffield supposes them to be alum; but according to Mr Scheele, they have no other resemblance to alum than that they contain the vitriolic acid.

3. By phlogificated vitriolic acid the manganese was entirely dissolved. To procure this acid in purity, Mr Scheele dipped some rags in a solution of alkali of tartar, and after saturating them with the fomes of burning brimstone, put them into a retort, pouring on them some dissolved acid of tartar, luting on a receiver which contained levigated manganese and water. After a warm digestion of only one day, the liquid of the receiver had become as clear as water, and a little fine powder, confluting principally of siliceous earth, fell to the bottom.

4. Two drachms of levigated manganese, digested for several days with an ounce of pure colourless acid of nitre, did not appear to have deprived the menstruum of its acidity, or to have been affected by it in any degree. The liquor being distilled off, and the product of the distillation poured back on the residuum, a small quantity of it was dissolved. By a third distillation, and pouring back the liquor on the residuum, a complete solution was effected; and this quantity of acid appeared capable of dissolving nine drachms of the powder.

5. The solution of manganese thus saturated, was precipitated and divided into two equal portions. Into one and crystals obtained of these some drops of vitriolic acid were poured, by which a fine white powder was thrown down, which however, did not settle to the bottom for some hours. It was soluble neither in boiling water nor in acids. The limpid solution, by evaporation, yielded some small crystals of felenite or gypsum.

6. From the other half of this solution, after evaporation by a gentle heat, about ten grains of small shining crystals of a bitter taste were obtained. By pouring some drops of vitriolic acid into the solution impregnated by gentle heat, no precipitation, excepting of a little felenite, ensued; but as soon as it was impregnated to the consistence of honey, some fine acicular crystals, verging towards the fame centre, began to form, but grew foit, and deliquesced in a few days after.

7. Phlogificated nitrous acid dissolves manganese as readily as the phlogificated vitriolic. A little lead was dissolved by phlogificated vitriolic nitrous acid.

8. An ounce of purified muriatic acid was poured upon half an ounce of levigated manganese; which, it on spirit after standing about an hour, assumed a dark brown of salt colour. A portion of it was digested with heat in an open glass vessel, and smelled like warm aqua regia. In a quarter of an hour the f mell was gone, and the solution became clear and colourless. The reft of the brown solution being digested, to see whether the muriatic acid would be saturated with manganese, an effervescence ensued, with a strong f mell of aqua regia, which lasted till next day, when the solution was found to be saturated. Another ounce of acid was poured upon the residuum, which was followed by the same dissolving phenomenon, and the manganese was entirely dissolved, by this a small quantity of siliceous earth only remaining.

The solution, which was yellow, being now divided into two portions, some drops of vitriolic acid were poured into the one, by which it instantly became white, and a fine powder, insoluble in water, was precipitated. Some small crystals of felenite were formed by evaporation, and the residuum exhibited the fame phenomenon with those abovementioned with nitrous acid.
The following experiments Mr. Scheele concludes, that manganiferous acid has a strong elecive attraction for all phlogistic substances; and that this attraction becomes stronger, if there be present a menstruum which can unite with the phlogificated manganiferous acid. Thus it attracts phlogiston more powerfully than even the nitrous acid itself in the moist state. By saturation with phlogiston, manganiferous acid has the property of losing its black colour, and assuming a white one, which is unusual, the phlogiston generally communicating a black or dark colour to the substances with which it was united.

That manganiferous acid naturally contains some phlogiston, though in small quantity, appears from evaporating a solution of it in vitriolic acid to dryness, and then distilling the mala in a glass retort in an open fire. When the retort begins to melt, the acid parts fly off from the manganiferous acid, forming a black colour. By distilling the mala remaining after evaporation of the nitrous folution, a green vitriolic acid remains, and the black calx of manganiferous acid remains as before. A solution of this mineral in vitriolic or nitrous acid, precipitated by fixed alkali, retains its colour; but when calcined in the open fire, again becomes black.

By loosing its phlogiston, manganiferous acid becomes insoluble in pure acids; and therefore the residue of the above-mentioned folution cannot be dissolved by adding more of the vitriolic or nitrous acids: but if that which has come over into the receiver be poured back into the retort, a folution will again take place by reason of the manganiferous acid remaining in the acid.

On this principle our author explains the reason of Partial Solution of this mineral abovementioned. Part of it is dissolved, for instance, in the vitriolic acid, while the remainder is found insoluble. This happens (says he), "because the undissolved portion has parted with the little phlogiston it naturally possesses, to that portion of manganiferous acid which is taken up by the vitriolic acid during the firit dissolution; for without that principle it is insoluble."

Manganiferous acid attracts phlogiston more strongly when combined with some acid than by itself, as appears from the following experiments. 1. Levigated manganiferous acid, digested or boiled with a strong solution of sugar, honey, gum arabic, harthorn jelly, &c. remains unchanged, but on mixing the pounded manganiferous acid with vitriolic acid during the decomposition of the mineral, the whole is dissolved, the black colour vanishes by degrees, and the solution becomes as limpid as water. So strongly is the attraction of manganiferous acid for phlogiston in these circumstances, that metals, the noble ones excepted, render it soluble in these acids in a limpid form.

"It would be difficult to conceive how the concentrated acid of manganiferous acid might dissolve metals without affecting the phlogiston. Quicksilver and silver, when dissolved in the pure vitriolic acid, really lose their phlogiston, which is a constituent part of these metals. This appears from the red vapours in which the acid arises, and the dissolved metallic earth cannot be again reduced to its metallic form, till it has acquired the loth phlogiston, which is effected either by precipitation with complete metals or by heat alone. Thus manganiferous acid attracts phlogiston in a limpid form, and it is not probable that the concentrated acid undergoes a dissolution of this degree of fire; for if you saturate half an ounce of this acid with alkali of calx, and afterwards calcine a retort, with a receiver applied, an ounce and a half of powdered manganiferous acid, with an equal quantity of the same vitriolic acid, then dissolve the calcined mass in distilled water, and likewise wash well the receiver, which contains some drops of vitriolic acid, which are also to be added to the solution, and lastly, add the same quantity of alkali, there will be no mark of superabundant acid or alkali. Thence it may be concluded, that the phlogiston in the vitriolic acid, if there really exists any in it, contributes nothing to the solution. But the manganiferous acid precipitated by alkali, contains a considerable quantity of it; in consequence of which it is afterwards entirely soluble in acids without any addition."

The effects of volatile sulphureous acid on manganiferous acid, clearly prove what has been asserted. The manganiferous acid attracts the phlogiston contained in this acid, phlegmatically, which is the cause of its great volatility, and which renders it.

"Volatile acid dif-"
Manganese renders the former soluble in the new pure vitriolic acid. If this solution be mixed with concentrated vitriolic acid and distilled, no volatile sulphureous acid is obtained; and if it be precipitated by means of fixed vegetable alkali, vitriolated tartar is obtained; which proves that manganese has a stronger attraction than vitriolic acid for phlogiston in the most way.

"The effects of nitrous acid on this substance are similar to those of vitriolic acid. Could spirit of nitre sustain as great a degree of heat as the concentrated vitriolic acid, it would also entirely disfolve the manganese by means of the phlogiston attracted by heat; but as this is not the case, it is necessary to add phlogiston in the manner abovementioned. The manganese decomposes phlogificated nitrous acid, for the same reason that it does the volatile sulphureous acid; and that the phlogiston of this acid really combines with manganese, is manifest from this, that the effusion of vegetable acid destroys no smell of aquafortis by displacing the phlogificated acid of nitre. By distillation with pure vitriolic acid also, the nitrous acid is expelled, not in a smoking state, and of a yellow colour, but pure and colourless.

"In the solution of manganese by means of gum arabic or fugar, a very considerable effervescence takes place, owing to the extrication, or probably rather the production, of fixed air from the mixture; but with phlogificated acid of nitre no such phenomenon takes place, because the manganese is combined with pure phlogiston; and if this should be again separated, there is no cause for the production of fixed air. This mineral is also distilled without effervescence, by uniting it with nitrous acid and metals, arsenic or oil of turpentine."

As muriatic acid disfolves manganese without addition, Mr. Scheele is of opinion that this proves the existence of phlogiston in that acid, as has already been taken notice of. The manganese digested in the cold with spirit of salt assumes a dark brown colour; for it is a property of this substance that it cannot be dissolved into a colourless liquor without phlogiston, but has always a red or blue colour; but with spirit of salt the solution is more brown than red, on account of the fine particles of the manganese floating in the liquid. Here the mineral adheres but loyally to the acid, so that it may be precipitated by water.

The effects of acid of tartar and acid of lemons upon manganese are likewise explained on the principle already laid down, viz. the extreme attraction this substance has for phlogiston. Thus it attracts part of that naturally contained in these acids, decomposing one part of them, and being dissolved by the other. This destruction of the acid is similar to that of the sugar, gum arabic, &c. which render it soluble in nitrous acid; for if a proper quantity of these are added, the manganese will be dissolved, without a possibility of recovering the smallest particle of the vegetable substance employed; and if the solution be slowly evaporated and calcined, there will not remain the smallest mark of burned sugar or gum. During this decomposition, a pungent vapour arises, which, being collected, appears to be true vinegar. It is obtained in its purest state from diluted vitriolic acid, sugar, and manganese.

Flour acid disfolves but very little manganese, owing to its precipitating salt which envelopes the particles of manganese, and prevents the further action of the manganese. In all precipitations of manganese, however, by means of mild fixed alkalis, the full quantity is not procured; because the fixed air, detached from the mineral, disfolves part of it.

Though manganese contains nitre, yet this effects of does not happen till the mixture becomes red hot. If manganese phlogificated manganese be mixed with an equal quantity of nitre, and distilled in a glass retort, the mixture begins to grow black before the retort becomes red-hot, but no nitrous acid goes over. By lixiviation, no mark of uncombined alkali is met with; but phlogificated nitrous acid is extricated by the application of tamarinds, or any vegetable acid. Three parts of phlogificated manganese, mixed with one part of finely pounded nitre, yields no nitrous acid, though the nitre is alkalized as soon as the mixture becomes black in the retort.

Mr. Scheele proceeds now to another set of experiments upon manganese united with phlogiston. In order to procure it in this state, the best method is to disfolve in distilled water, and crystallize the salt obtained by solution of manganese in vitriolic acid, and then precipitate it with vegetable fixed alkali. In this state it is white like chalk; but by calculation in an open fire, the superfusious phlogiston flies off, and the calx regains its usual black colour. This change of colour likewise happens when the precipitation is made with caustic alkalis, whether fixed or volatile. The precipitate, indeed, in this case, is white when kept close from the air, but assumes a brown colour when exposed to it for any time; but when the precipitation is made by mild alkali, the white colour is preserved by the fixed air, which in this case it also contains. By diluting the solution with a considerable quantity of water, and precipitating with caustic alkali, the precipitate is brown from the very beginning, owing to the air in the liquid attracting the phlogiston from the manganese. The precipitate formed by lime-water is also brown; but on adding more of a strong solution of manganese, and afterwards precipitating with caustic alkali, the powder falls of a white colour; because the air, being already saturated with phlogiston, cannot take up any more. The results of Mr. Scheele's experiments on this phlogificated manganese are:

1. An ounce of this substance distilled by itself in a glass retort, with a strong fire, yielded a great quantity of fixed air with some drops of water. The residuum poured warm out of the retort grew red-hot, and set the paper on fire.

2. On repeating the experiment with only a drachm of phlogificated manganese, and tying a bladder to the neck of a retort, three ounce-measures of air came over: the residuum was of a light grey colour; dissolved in acids without addition of any more phlogiston; and took fire in that degree of heat in which sulphur smokes, but does not burn. From these experiments, says Mr. Scheele, it is evident, that phlogiston does not separate from manganese if the access of air be prevented.

3. One part of finely powdered manganese boiled in Beid with four of oil-olive, effervesced violently, and dissolved oil olive, into a kind of saline.

4. On distilling a mixture of finely powdered manganese and charcoal, with an empty bladder tied to the mouth of the retort, a quantity of fixed air was extricated.
Manganese.

5. On distilling half an ounce of powdered manganese with two drachms of sulphur, the latter partly rose into the neck of the retort, and some volatile acid vapours penetrated through the lute. The distillation was continued till the retort began to melt; and, on cooling, the residuum was found to weigh 3 drachms. It was of a yellowish-grey colour; and distilled in spirit of vitriol with effervescence, yielded an hepatic smell, some sulphur being also precipitated at the same time. By calcination in the open air, the sulphur was dissolved; but great part of the mass was rendered soluble on account of its having been penetrated by the acid vapour, and shot into crystals as though it had been formally dissolved in volatile sulphurous acid; and by repeating the calculation with more sulphur, the whole became at last entirely soluble, and was reduced to crystals.

7. By the addition of finely powdered manganese, triturated with nitre and strongly calcined in a crucible, unites with the alkali of the nitre, while the acid is dissipated in the air. The mass formed by the union of the manganese and alkali is of a dark green colour, and soluble in water, communicating also a green colour to the liquid; but in a short time a fine yellow powder (an ochre of iron) falls to the bottom, leaving the liquor of a blue colour. By the addition of water, this solution first assumes a violet colour, grows afterwards red, and a precipitation of the manganese takes place, which refumes its natural colour as soon as it has fallen. The same precipitation takes place on the addition of a few drops of acid, or by exposure for some days to the open air. As for the dark red colour affirmed by the solution when the precipitate is about to fall, Mr. Scheele conjectures that the particles of manganese may naturally have a red colour, which becomes visible when the substance is dispersed through a menstruum without being perfectly dissolved.

8. Half an ounce of phlogisticated manganese, distilled in a retort with an equal quantity of powdered sal ammoniac, yielded first a concrete volatile salt, after which some sal ammoniac undecomposed arose in the neck of the retort. Half an ounce of pure dephlogisticated manganese, mixed with two drachms of powdered sal ammoniac, yielded alkali in its caustic state. Both residua were soluble in water; which shows that manganese attracts phlogiston from the volatile alkali.

9. On digesting finely powdered manganese for some weeks with pure nitrous acid and some volatile alkali, a great number of air-bubbles rise to the top, and the volatile alkali is entirely decomposed: for though the mixture be afterwards distilled in a retort with the addition of quicklime, not the least urinous smell can be perceived. This decomposition is effected by the manganese attracting the phlogiston of the volatile alkali; for that the nitrous acid has no share in this, is proved by the following experiment.

10. An ounce of well triturated manganese was distilled with half an ounce of sal ammoniac; and a liquid alkali, such as that obtained from sal ammoniac and quicklime, was procured. On repeating this experiment, with the variation only of a bladder instead of a receiver, the same kind of air was obtained as that which rises to the top of the nitrous mixture. Though the emission of this air indicated a destruction of the volatile alkali, our author explains the reason of its being still obtained in a caustic state by the phlogiston taken from the alkali being more than sufficient to render the alkali soluble in natrium acid; in consequence of which, the superfluous quantity combines with the manganese, and enables it to decompose the sal ammoniac in the ordinary way. It must be owned, however, that his reasoning on this subject is not entirely satisfactory, nor does the account he gives of his experiments seem entirely consistent with itself. See Scheele's Chem. Essays, Essay V. xxxix.

11. Powdered manganese, distilled with an equal quantity of white arsenic, underwent no change, with the addition of arsenic flying off in its proper form; but with an equal quantity of yellow orpiment, some volatile sulphurous acid came over first, then a yellow sublimate, and at last a little red sublimate arose. On augmenting the fire by degrees, the orpiment remained obstinately attached to it. Similar effects ensued on treating manganese with an equal quantity of antimony; which likewise yielded a pungent sulphurous acid, but no sublimate. By calculation in the open air these compounds are decomposed; and the manganese, united with vitriolic acid, becomes soluble in water.

12. On distilling manganese with an equal quantity of finely pounded cinnabar, a volatile sulphurous acid came over first, then a little cinnabar was sublimed into the neck of the retort; and at last the quicksilver, which had been the basis of the cinnabar, began to distil: the residuum, being a combination of manganese and sulphur, was similar to the compounds already described.

13. With an equal quantity of corrosive sublimate, manganese underwent no change; but when sublimed with an equal quantity of mercurius dulcis, a corrosive sublimate, and then mercurius dulcis, arose into the neck of the retort. The reason of this is, that the mercurius dulcis contains a portion of phlogiston; by being deprived of which it ceases to be mercurius dulcis, and becomes corrosive sublimate: but by reason of the strong attraction of manganese for phlogiston, the mercurius dulcis parts with that portion which is necessary to keep it in its mild state, and thus is converted into corrosive mercury.

Sect. IV. Inflammable Substances.

These may be divided into the following classes: General

4. Resins. 5. Bitumens; and, 6. Charcoal.

Vol. IV.
CHEMISTRY.

§ 1. SULPHURE.

1. Common sulphur. For the extraction of this substance from its ores, see Sulphur. The artificial composition of it we have already related, n° 715; and have now only to take notice of a few of its properties, which come more properly under this section.

Sulphur, as commonly used in commerce and the arts, is of a pale yellow colour, of a disagreeable and peculiar smell, which is rendered more sensible when it is heated or rubbed. By rubbing, it receives very curious electrical qualities; (See ELEcTRIcITY.) Its specific gravity is considerably greater than that of water, though less than earth or stones. In clofe vessels, sulphur is incapable of receiving any alteration.

It melts with a very gentle heat; and then is sublimed, adhering to the capital in small, very fine, needle-like crystals, called flowers of sulphur. It may thus be sublimed many times without alteration. If sulphur is exposed to a heat barely sufficient to melt it, and very slowly cooled, it crystallizes in form of many needles crossing one another. Some of these pointed crystals may also be observed in the interior parts of the lumps of sulphur which have been melted, and cast into cylindrical moulds, as they are commonly sold; because the centre of these cylindrical rolls is more slowly cooled than the surface. Sulphur also gives this needle-like form to cinnabar, antimony, and many other minerals containing it. Sulphur may be decomposed in several ways. The most simple is by burning; which we have already taken notice of, n° 623. It may also be very effectually decomposed by mixing it with iron filings and water. In this case the phosphigen is disublimated, and the acid uniting with the iron forms a green vitriol.

It is very remarkable, that though sulphur is composed of vitriolic acid and phosphigen, yet the addition of more inflammable matter, so far from making the union stronger, weakens it to a great degree: and hence we have another method of decomposing this substance; namely, by combining it with a large quantity of oil, and distilling the compound. Sulphur is capable of being easily dissolved in expressed oils, but very difficult in effential ones. These compositions are called balsams of sulphur; and are sometimes employed in medicine, but are found to be of a very heating nature. They are much used by farriers. According to Mr Beaumé, sulphur cannot be disublimed in oil, without a heat sufficient to melt it. A larger quantity is kept disublimed when the mixture is hot, than when cold; and consequently the sulphur, especially if it has been disublimed in a thin effential oil, crytallizes on cooling the mixture. The sulphur, thus separated from the oil, is found not to be altered in any respect from what it formerly was; but if the mixture is exposed to a degree of heat capable of entirely decomposing the oil, the sulphur is decomposed along with it, and the same products are obtained by distilling this mixture to dryness, as if a mixture of pure oil of vitriol and oil were distilled. These products are, first a portion of oil, when an effential oil was made use of in the composition of the balsam; then some volatile sulphureous acid, which is at first watery, and afterwards becomes stronger; along with this acid more oil arises, which becomes more and more thick towards the end of the distillation; and lastly, when the resort has been made red hot, nothing remains but a fixed coal.

In this process we find, that both the sulphur and oil are decomposed. The acid of the sulphur seems to attack the watery principle of the oil, while its phlogiston remains confounded with that of the oil, or is disublimed in vapours. Hence, though the vitriolic acid in sulphur is concentrated to the utmost degree, and perfectly free from water, what rifes in this distillation is very aqueous, by reason of the water which it attracts from the oil.

Spirit of wine does not sensibly act upon sulphur in its liquid state; but if both the spirit of wine and sulphur meet in the state of vapour, they will then unite, and a perfect solution will take place. By methods of this kind, many combinations might be effected, which have been hitherto thought impossible.

Pure sulphur unites easily with all metals; gold, its union platina, and zinc, excepted. The compounds, except with metals that with mercury, poofs a metallic lustre without any dulness. The sulphur may be separated by expelling the mixture into a strong fire. (See MetalurGy,) or by dissolving the metallic part in acids. The sulphur, however, defends several of the metals from the action of acids; so that this dissolution succeeds but imperfectly. The reguline part of antimony is more easily separated from sulphur by means of acids than by any other metallic substance. Alkali salts will separate the sulphur from all metals in fusio, but they unite with it themselves, and form a compound equally capable of dissolving the metal.

Sulphur united with quicksilver forms the beautiful pigment called cinnabar, or vermilion; which is so much used in painting, that the making of it is become a distinct trade. Neumann relates, that in the making of cinnabar by the Dutch method, six or eight parts of quicksilver are made use of to one of sulphur. The sulphur is first melted, and then the quicksilver is filtered into it; upon which they unite into a black mass. In this part of the process the mixture is very apt to take fire; of which it gives notice by swelling up to a great degree. The vessel must then be immediately covered. The mass being beaten to powder, is afterwards to be sublimed in large earthen jars almost of an equal width from end to end; these are hung in a furnace by a strong rim of iron. When the matter is put in, the mouth of the vessel is covered, the fire increased by degrees, and continued for several hours, till all the cinnabar has sublimed; care being taken to introduce at times an iron rod to keep the middle clear; other wise the cinnabar concreting there, andMopping up the passageway would infallibly burst the vessels.

The quantity of sulphur directed in the common receipts for making cinnabar is greatly larger than the above; being no less than one-third of the quantity of quicksilver employed: accordingly it has been found, that the sublimate, with such a large quantity of sulphur, turned out of a blackish colour, and required to be several times sublimed before it became perfectly red; but we cannot help thinking, that by one gentle sublimation
divides the matter among six retorts, so that if any accident happens to one, the whole matter is not lost. The retorts ought to be well luted to a receiver of a moderate size, pierced with a small hole, and half full of water; and a small wall of bricks must be raised between the furnace and receiver, in order to guard this vessel against heat as much as possible. The retorts are to be heated by slow degrees for an hour and an half; then the heat is to be increased till the vesels are red hot, when the phosphorus ascends in luminous vapours. When the retort is heated till between a red and white, the phosphorus falls in drops, which fall and congeal in the water at the bottom of the receiver. This degree of heat is to be continued till no more comes over. When a retort contains eight-pints or more, this operation continues about five hours.

In the first distillation, phosphorus never passes pure, Redistillation is always of a blackish colour, by reason of its carrying along with it some part of the coal. From this, phosphorus however, it may be purified by redistillation in a small glass-retort, to which is luted a receiver half full of water. A very gentle heat is sufficient; because phosphorus, once formed, is very volatile; and as the fuliginous matter was raised probably by the fixed air emitted by the charcoal in the instanteous union with the phosphoric acid, none of it can arise in a second distillation.

The phosphorus is then to be divided into small cylindrical rolls, which is done by putting it in glass-tubes immersed in warm water; so the phosphorus is almost as fusible as fus. It takes the form of the glass-tubes; from which it may be taken out, when it is cold and hardened. All this must be done under water, lest the phosphorus should take fire.

This concrete continually appears luminous in a dark place; and by a very slight heat takes fire, and burns sometimes far more vehemently than any other known substance. Hence it is necessary to be very cautious in the distillation of it; for if the receiver should happen to break while the phosphorus is distilling, and a little flaming phosphorus fall upon the operator's legs or hands, it would burn its way to the bone in less than three minutes. In this case, according to Mr Heliot, nothing but urine will stop its progress.

Though phosphorus takes fire very readily by itself, it does not inflame at all when grinding with other inflammable bodies, as camphor, gun-powder, or essential oils. In grinding it with nitre, some luminous flashes are observed; but the mixture never burns unless the quantity of phosphorus be large in proportion to the nitre: rubbed pretty hard on a piece of paper or linen, it sets them on fire if they are rough, but not if they are smooth. It fires written paper more readily than such as is white, probably from the former having more aperities. On grinding with iron-slings, it presently takes fire.

Oils ground with phosphorus appear, like itself; Liquid luminous in a temperately warm place; and thus become phosphoric oil, which may be rubbed on the hands, &c. without danger. Phosphorus is commonly prepared by grinding a little of the solid phosphorus with oil of cloves, or rubbing it first with camphor, and this mixture with the oil. A luminous amalgam, as it is called, may be obtained, by digesting...

SULPHUR.

Experiments on phosphorus with spirit of wine.

Rectified spirit of wine, digested on phosphorus, extracts a part of it, as to emit luminous flames on being dropped into water. It is computed that one part of phosphorus will communicate this property to 60,000 parts of spirit. The liquor is never observed to become luminous of itself, nor in any other circumstance except that above-mentioned. By digestion for some months, the undissolved phosphorus is reduced to a transparent oil, which neither emits light nor concretes in the cold. By washing with water, it is in some measure revived; acquiring a thicker consistence, and becoming again luminous, though in a less degree than at first. During this digestion, the glass is very apt to burst.

Phosphorus is partially dissolved by express'd oils; and totally, or almost so, in essential oils and ether. When essential oils are satu rated with it by heat, a part of the phosphorus separates, on standing in the cold, in a crystalline form. Concentrated spirit of salt has no action on it. In distillation, the spirit rises first, and the phosphorus after it unchanged. Spirit of nitre dissolves it, and the distillation is attended with great heat and copious red fumes; so that great part of the spirit distills without the application of any external heat, and the phosphorus at last takes fire, explodes, and bursts the vessel. Oil of vitriol likewise dissolves phosphorus, but not without a heat sufficient to make the acid diftil. The distilled liquor is white, thick, and turbid; the residuum is a whitish tenacious mass, which deliquesces, but not totally, in the air. Phosphorus itself is resolved into an acid liquor on being exposed two or three weeks to the air, its inflammable principle seeming by degrees to be diffipated.

Phosphorus has been reported to produce extraordinary effects in the resolution of metallic bodies: but from the experiments that have been made with this view, it does not appear to have any remarkable action on them; at least on the precious ones, gold and silver, for the resolution or subtilization of which it has been chiefly recommended. The following experiments were made by Mr Margraff.

1. A scruple of filings of gold were digested with a drachm of phosphorus for a month, and then committed to distillation. Part of the phosphorus arose, and part remained above the gold, in appearance resembling glafs: this grew moist on the admission of air, and dissolved in water, leaving the gold unaltered. Half a drachm of fine silver, precipitated by copper, being digested with a drachm of phosphorus for three hours, and the fire then increased to distillation, a great part of the phosphorus arose pure, and the silver remained unchanged. Copper filings being treated in the same manner, and with the same quantity of phosphorus, the phosphorus sublimed as before; but the remaining copper was found to have lost its metallic brightness, and to take fire on the contact of flame. Iron filings suffered no change. Tin filings run into granules, which appeared to be perfect tin. Filings of lead did the same.

2. Sulphur, precipitated per fo, treated in the same manner, was totally converted into running quicksilver.

3. Rectified spirit of wine, digested on phosphorus, extracts a part of it, as to emit luminous flames on being dropped into water. It is computed that one part of phosphorus will communicate this property to 60,000 parts of spirit. The liquor is never observed to become luminous of itself, nor in any other circumstance except that above-mentioned. By digestion for some months, the undissolved phosphorus is reduced to a transparent oil, which neither emits light nor concretes in the cold. By washing with water, it is in some measure revived; acquiring a thicker consistence, and becoming again luminous, though in a less degree than at first. During this digestion, the glass is very apt to burst.

4. Phosphorus of Homberg. This substance, which in Homberg's experiments with metals.

1. Mr. Canton's phospheus. This is a composition of quicklime and common sulphur. The receipt for ton's phosphorus is as follows: 'Calcine some common oyster shells, by keeping them in a good coal fire for half an hour; let the purest part of the calx be pulverized and sifted. Mix with three parts of this powder one part of flowers of sulphur. Let this mixture be rammed into a crucible of about an inch and a half in depth till it be almost full; and let it be placed in the middle of the fire, where it must be kept red hot for an hour at least, and then set by to cool: when cold, turn it out of the crucible; and breaking or breaking it to pieces, scrape off, upon trial, the brightest parts; which, if good phosphorus, will be a white powder. This kind of phosphorus shines on being exposed to the light of the sun, or on receiving an electrical stroke.

2. Phosphorus of Homberg. This substance, which in Homberg's experiments with metals.
Practice.

CHEMISTRY

be bruised into powder; and then it must be put into a glafs matraf, the mouth of which is rather strait than wide, and seven or eight inches long. This matraf is to be placed in a crucible, or other earthen vefsel, large enough to contain the belly of the matraf, with about a space equal to that of a finger all round the vefsel. This space is to be filled with sand, so that the matraf shall not touch the earthen vefsel. The apparatus is then to be put into a furnace, and the whole to be made red hot. The fire must be applied gradually, that any oily or fuliginous matter may be expelled; after which, when the matraf is made red hot, fulphurous vapours exhale; this degree of heat is to be continued till a truly fulphurous flame, which appears at the end of the operation, has been seen nearly a quarter of an hour: the fire is then to be extinguished, and the materias left to cool, without taking it out of the crucible; when it ceases to be red hot, it must be stopped with a cork. Before the materias is perfectly cold, it must be taken out of the crucible, and the powder it contains poured as quickly as possible into a very dry glass phial, with a glass stopper. If you would preserve this phosphorus a long time, the bottle containing it must be sealed as feldom as possible. Sometimes it kindles while it is pouring into the glass phial; but it may be then extinguished by closing the phial expeditiously. A small quantity of this pyrophorus laid on paper, and exposed to the air, immediately takes fire, becomes red like burning coals, and emits a strong fulphurous vapour greatly resembling that which arises on decomposing liver of sulphur.

It has been generally alleged, that the common black phosphorus is impaired by being exposed to the light; but Mr Cavallo has discovered the fallacy of this supposition by the following experiment. Some portions of the same pyrophorus were inclosed in three glass tubes, and immediately sealed up hermetically. On the 22th of May 1779, two of them were suspended from a nail out of a window, and the third was wrapped up in paper and inclosed in a box, where not the least glimmering of light could enter. In this situation they were left for more than a year; after which one of those that had been kept out of the window was broke, along with that which had been kept in the dark, in the presence of Mr Kirwan; when the pyrophorus seemed to be equally good in each tube, taking fire in about half a minute after it was taken out of the tubes, and exposed to the air on a piece of paper.

There are many different kinds of pyrophor; some of the most remarkable of which are described under the article PYROPHORUS. Many theories have been invented to solve the phenomenon of their accension on the contact of air. This has been thought owing to the conversion of the earth of alum into lime, or to a remainder of the vitriolic acid attracting moisture from the atmosphere; but the formation of pyrophorus, without either alum or vitriolic acid, shows that neither of these opinions can be just. It is more probable, therefore, that the heat is occasioned by the total distillation of that aqueous part which is essential, to the constitution of terrestrial substances. In consequence of this, the water contained in the atmosphere is not only attracted with avidity, but decomposed by the matter reduced to such a state of extreme dryness. By these operations it gives out the latent heat contained in it, and this produces the accension in question.

§ 2. ARDENT SPIRITS.

See Fermentation and Distillation.

§ 3. OILS.

1. Essential Oils. Those oils are called essential which have evidently the smell of the vegetable from which oils, they are drawn. For the method of procuring them, see Distillation. They are distinguished from all others by their superior volatility, which is so great as to cause them rise with the heat of boiling water. All these have a strong aromatic smell, and an acid, caustic tafe; in which respect also they differ from other oils. This tafe is thought to proceed from a copious and disengaged acid, with which they are all penetrated. The presence of this disengaged acid in essential oils, appears from the impression they make upon the corks of bottles in which they are kept. These corks are always stained of a yellow colour, and a little corroded, nearly as they are by nitrous acid. The vapour of these oils also reddens blue paper, and converts alkalies into neutral salts.

This acid is likewise supposed to be the cause of their solubility in spirit of wine. They are not all equally soluble in this menstruum, because they do not all contain an equal quantity of acid. As this acid is much more volatile than the other volatile concrete, they lose a great deal of it by repeated distillations, and therefore they become less and less soluble on being frequently distilled. By evaporation they lose their volatile and thin part, in which the specific smell of the vegetable from which they are extracted resides; by which losses they become thicker, and acquire the smell and consistence of turpentine, and even of resins. In this state they are no longer volatile with the heat of boiling water; and, if distilled with a stronger fire, they give over an oil which has neither smell nor tafe of the vegetable whence they were extracted, but is entirely empyreumatic, and similar to those oils procured by distilling vegetable or animal substances with a strong fire. See Distillation.

To the class of essential oils, the volatile concrete called camphor seems most properly to belong. With them it agrees in its properties of inflammability, solubility in spirit of wine, and a strong aromatic flavour. The only differences between them are, that camphor is always in a solid state, and is incapable of decomposition by any number of sublimations. It has, however, been found possible to decompose it by distillation with certain additions. By distilling it several times along with bole, we obtain a fluid having the properties of an essential oil, soluble in water, and separating again on the addition of spirit of wine. On distilling it eight times with decomposed nitrous acid, we obtain a salt having the form of a paralipoped, of an acid and bitter tafe, and changing the juice of violets and turnsole red. This has the properties of a true acid; combines with fixed and volatile alkalies into neutral salts capable of being crystallized; diffuses copper, iron, bismuth, arsenic and cobalt.
Oils.

With magnesia it forms regular crystals, in some measure resembling balsap. It is distinguished from the acid of sugar by not precipitating lime from its solution in marine acid, and by forming with magnesia a white powder soluble in water.

According to Neumann, all the camphor made use of is the produce of two species of trees; the one growing in Sumatra and Borneo, the other in Japan. Of the Japanese kind is the only one brought into Europe. The tree is about the size of a large lime, the flowers white, and the fruit a small red berry. All parts of the tree are impregnated with camphor; but the resinous part, and therefore are chiefly made use of for the preparation of this commodity: though, in want of them, the wood and leaves are sometimes mixed.

The camphor is extracted by distillation with water in large iron pots filled with earthen heads stuffed with straw; greatest part of the camphor concretes among the straw, but passes down into the receiver among the water. In this state it is found in small bits like grey salt-petre, or common bay-leaf; and requires to be purified either by a second sublimation, or by distillation in spirit of wine, filtration, and expression. If the first method is followed, there will be some difficulty in giving it the form of a perfect transparent cake. A difficulty of this kind indeed always occurs in sublimations; and the only way is to keep the upper part of the glass to such a degree of heat as may keep the sublimate in a half-melted state. Dr Lewis recommends the repetition of camphor by spirit of wine, and then melting it into a cake in the bottom of a glass.

Camphor possesses considerable antiseptic virtues; and is a good diaphoretic, without heating the constitution; with which intention it is often used in medicine. It is likewise employed in fire-works and several other arts, particularly in making varnishes. See Varnish.

This substance dissolves easily and plentifully in various spirits and in oils; four ounces of spirit of wine will dissolve three of camphor. On distilled the mixture, the spirit rife first, very little camphor coming over with it. This shows that camphor, however volatile it may seem by its smell, is very far from having the volatility of ether, and consequently is improperly clasped with substances of that kind.

2. Empyreumatic Oils. Under this name are comprehended all those oils, from whatever substance obtained, which require a greater heat for their distillation than that of boiling water. These are partially soluble in spirit of wine, and becomes more and more fo by repeated distillations. The empyreumatic oils obtained from animal substances are at first more fetid than those procured from vegetables but by repeated distillations, they become exceedingly attenuated and volatile, becoming almost as white, thin, and volatile, as ether. They then acquire a property of taking upon the brain and nervous system, and of allaying its irregular movements, which is common to them with all other inflammable matters when highly attenuated and very volatile; but this kind of oil is particularly recommended in epileptic and convulsive affections. It is given from 4 to 10 or 11 drops: but, though prepared with the utmost care, it is very susceptible of losing its whiteness, and even its thinness, by a short exposure to air; which proceeds from the almost instantaneous evaporation of its more thin and volatile parts, and from the property which the less volatile remains has of acquiring colour. To avoid this inconvenience, it must be put, as soon as it is made, into very clean glass bottles with glass stoppers, and exposed to the air as little as possible.

The most important observations concerning the method of making the pure animal oils are, first to change the vessel at each distillation, or at least to make them perfectly clean; for a very small quantity of the thicker and less volatile part is sufficient to spoil a large quantity of that which is more rectified. In the second place the Br. Beauné has observed, that this operation may be greatly abridged, by taking care to receive none but the most volatile part in each distillation, and to leave a large residuum, which is to be neglected, and only the more volatile part to be further rectified. By this method a considerable quantity of fine oil may be obtained at three or four distillations, which could not otherwise be obtained at fifty or sixty.

Animal Fats. Though these differ considerably from one another in their external appearance, and probably in their medicinal qualities, they afford, on a chemical analysis, products similar in quality, and differing but inconsiderably in quantity. They all yield a larger portion of oil, and no volatile part; in which respect they differ from all other animal substances. Two ounces of hog's lard yielded, according to Neumann, two drachms of an empyreumatic liquor, and one ounce five drachms and 50 grains of a clear brown-coloured oil of a volatile smell, somewhat like horse-radish. The caput mortuum was of a shining black colour, and weighed ro grains.

Tallow being distilled in the same manner, two Tallow drachms of empyreumatic liquor were obtained from two ounces of it; of a clear brown oil, smelling like horse-radish, one ounce six drachms and 12 grains. The remaining coal was of a shining black colour, and weighed 18 grains. A particular kind of acid is now found to be contained in it.

The marrow of bones differs a little from fats, Marrow. when chemically examined. Four ounces of fresh marrow, distilled in the usual manner, gave over three drachms and a scruple of a liquor which smelled like tallow; two scruples and an half of liquor which had more of an empyreumatic and a fourth smell; two ounces and an half of a yellowish-brown, butyryceous oil, which smelled like horse-radish; and six drachms and an half of a blackish-brown oil of the same smell. The caput mortuum weighed four scruples.

All animal fats, when perfectly pure, burn totally away without leaving any ashes, and have no particular smell. In the state in which we commonly find them, however, they are exceedingly apt to turn rancid, and emit a most disagreeable and noxious smell; and to this they are peculiarly liable, when long kept in a gentle degree of heat. In this state, too, an inflammable vapour arises from them, which when on fire is capable of producing explosions. Hence, in those works where large bellows are used, they have been often suddenly burst by the inflammable vapours arising from the rancid oil employed for softening the leather.
**Chemistry.**

**Resins and Balsams.**

These are commonly reckoned to be composed of an essential oil thickened by an acid; as the essential oils themselves are found to be convertible into a similar substance, by the exhaustion of their more volatile parts. True resins are generally transparent in a considerable degree, soluble in spirit of wine, and possess of a considerate degree of flavour.

Resins are originally produced by infusing the natural juices which flow from incisions made in the stems of growing vegetables, and are in that state called balsams. The balsams may be considered as essential oils thickened by loosing some of their odoriferous principle, and of their finest and most volatile parts. There are several kinds of balsams, which, however, differ from each other only in the fineness and degree of consistence; and therefore all yield similar products on distillation. An analysis of turpentine therefore will be sufficient as an example of the analysis and natural properties of all the rest.

The true turpentine-tree is found in Spain and the southern parts of France, as well as in the island of Chio and in the Indies. It is a middling-sized evergreen-tree, with leaves like those of the bay, bearing purplish, imperfect flowers; and on separate pedicles hard unctuous berries like those of juniper. It is extremely resinous; and unless the resin is discharged, decays, produces fungous excrescences, swells, bursts, and dies; the prevention of which consists wholly in plentiful bleeding, both in the trunk and branches. The juice is the Chio or Cyprus turpentine of the shops. This fort is quite of a thick consistence, of a greenish white colour, clear and transparent, and of scarcely any taste or smell.

The kind now called Venice turpentine, is no other than a mixture of eight parts of common yellow or black rosin with five parts of oil of turpentine. What was originally Venice turpentine is now unknown. Neumann relates, that the Venice turpentine sold in his country was no other than that prepared from the larix tree, which grows plentifully in some parts of France, as also in Austria, Tyrol, Italy, Spain, &c. Of this there are two kinds: the young trees yielding a thin limpid juice, resembling balsam of copaiba; the older, a yellower and thicker one.

The Strasbourg turpentine is extracted from the silver fir. Dr. Lewis takes notice that some of the exotic firs afford balsams, or resins, superior to those obtained from the native European ones; as particularly that called balm of Gilead fir, which is now naturalized to our own climate. A large quantity of an elegant resinous juice may be collected from the cones of this tree: the leaves also, when rubbed, emit a fragrant smell; and yield, with rectified spirit, an agreeable resinous extract.

The common turpentine is prepared from different sorts of the pine, and is quite thick, white, and opaque. Even this is often counterfeited by mixtures of rosin and common essential oil.

All the turpentine yield a considerable proportion of essential oil. From sixteen ounces of Venice turpentine, Neumann obtained, by distillation with water, four ounces and three drachms of oil. The same quantity distilled, without addition, in the heat of a water-bath, gave but two ounces and an half; and from the residuum treated with water, only an ounce could be obtained. The water remaining in the still is found to have imbied nothing from the turpentine; on the contrary, the turpentine is found to imbibe part of the water; the residuum and the oil amounting to a full ounce on the pound more than the turpentine employed. When turpentine is distilled or boiled with water till it becomes solid, it appears yellowish; when the process is further continued, of a reddish brown colour: in the first state, it is called boiled turpentine; and in the latter, colophony, or rosin.

On distilling sixteen ounces of turpentine in a retort with an open fire, increased by degrees, we obtain first four ounces of a thick colourless oil; then two ounces and two drachms of a yellowish one; four ounces and three drachms of a thicker yellow oil; and two ounces and one drachm of a dark brownish red empyreumatic oil, of the consistence of balsam, and commonly called balsam of turpentine.

The limpid essential oil called spirit of turpentine, is exceedingly difficult of solution in spirit of wine; the turpentine itself dissolves with great ease. One part of the oil may indeed be dissolved in seven parts of rectified spirit; but on standing for some time, the greatest part of the oil sediments to the bottom, a much greater proportion of spirit being requisite to keep it dissolved.

2. Benzoin. This is a very brittle brownish resin, of an exceedingly fragrant smell. The tree which produces benzoin is a native of the East Indies; particularly of Siam and the island of Sumatra. It is never permitted to exceed the fifth year, being, after this time, unfit for producing the benzoin. It is then cut down, and its place supplied by a young tree raised commonly from the fruit. One tree does not yield above three pounds of benzoin.

A tree supposed to be the same with that which affords
Bitumen.  

Forbs benzoin in the East Indies, is plentiful also in Virginia and Carolina; from whence it has been brought into England, where it grows with vigour in the open ground. The bark and the leaves have the smell of benzoin; and yield with rectified spirit a resin of the same smell; but no resin has been observed to issue from it naturally in England, nor has any benzoin been collected from it in America.

Bitumen dissolves totally in spirit of wine, leaving only the impurities, which commonly amount to no more than a scruple on an ounce. To water, it gives out a portion of fulphur matter of a peculiar kind, volatile and sublimable in the fire. See 984 et seq.

The principal use of resins is in the making of lacquers, varnishes, &c. See VARNISH.

§ 5. BITUMENS.

These are inflammable mineral bodies, not sulphurous, or only casually impregnated with sulphur. They are of various degrees of consistence; and seem, in the mineral kingdom, to correspond with the oils and resins in the vegetable.

Concerning the origin of bitumens, chemists are not at all agreed. Some chemical writers, particularly Mr. Macquer, imagine bitumens to be no other than vegetable resins altered in a peculiar manner by the admixture of some of the mineral acids in the earth; but Dr. Lewis is of a contrary opinion, for the following reasons.

"Mineral bitumens are very different in their qualities from vegetable resins; and, in the mineral kingdom, we find a fluid oil very different from vegetable oils. The mineral oil is changed by mineral acids into a substance greatly resembling bitumens; and the vegetable oils are changed by the same acids into substances greatly resembling the natural resins.

"From bitumens we obtain, by distillation, the mineral oil, and from resins the vegetable oil, diitfined in their qualities as at first. Vegetable oils and resins have been treated with all the known mineral acids; but have never yielded anything similar to the mineral bitumens. It seems, therefore, as if the oily products of the two kingdoms were essentially and specifically different. The laws of chemical inquiries at least demand, that we do not look upon them any otherwise, till we are able to produce from one a substancc similar to the other. When this shall be done, and not before, the presumption that nature effects the same changes in the bowels of the earth, will be of some weight."

There is a perfectly fluid, thin bitumen, or mineral oil, called naphtha, clear and colourless as crystal; of a strong smell; extremely subtle; so light as to swim on all known liquors, other perhaps excepted: spreading to a vast surface on water, and exhibiting rainbow colours; highly inflammable: formerly made use of in the composition of the fopposed inextinguishable greek fire.

Next to this in consistence is the oleum petra, or petroleum; which is groffer and thicker than naphtha, of a yellowish, reddish, or brownish colour; but very light, so as to swim even on spirit of wine. By distillation, the petroleum becomes thinner and more subtle, a gros matter being left behind; it does not, however, easily arile, nor does it totally lose its colour by this process, without particular managements or additions.

Both naphtha and petroleum are found plentifully in some parts of Peria, trickling through rocks or swimming on the surface of waters. Kemper gives an account of two springs near Baku; one affording naphtha, which it receives in drops from subterraneous veins; the other, a blackish and more fetid petroleum, which comes from Mount Caucasus. The naphtha is collected for making varnishes; the petroleum is collected in pits, and sent to different places for lamps and torches.

Native petrola are likewise found in many different places, but are not to be had in the shops; what is sold there for petroleum, being generally oil of turpentine coloured with alkanet root. The true naphtha is recommended against disorders of the nerves, pains, cramps, and contractions of the limbs, &c.; but genuine naphtha is rarely or never brought to this country.

There are some bitumens, such as amber, amber-gris, pit-coal, and jet, perfectly solid; others, such as Barbadoes tar, of a middle consistence between fluid and solid. Tarf and pest are likewise thought to belong to this class.

1. Amber. This substance melts, and burns in the fire, emitting a strong peculiar smell. Distilled in a strong heat, it yields a phlegm, an oil, and a particular species of acid salt. The distillation is performed in earthen or glass retorts, frequently with the addition of sand, sea-salt, coals, &c. which may break the phlegm, and light oil, which absores a part of the oil: and changing the paste, ther depuration as well as the nature of this salt, see GRIS. 1447

The most advantageous method of distilling amber, Moft ad- vantageously, is without any addition; and this is the method used in Prussia, where the greatest quantities of coal, and oil of amber are made. At first a phlegmatic liquor distils; then a fluid oil; afterwards one that is thick and more ponderous; and last of all, an oil still more ponderous along with the salt. In order to collect the salt more perfectly, the receiver is frequently changed; and the phlegm, and light oil, which arile at first, are kept by themselves. The salt is purified, by being kept some time on biblious paper, which absorbs a part of the oil: and changing the paper as long as it receives any oily salt. For the further depuration as well as the nature of this salt, see SUCCEINUM.

2. Ambergris. This concretc, which is only used as a perfume, yields, on distillation, products of a grissimilar nature to that of amber, excepting that the volatile salt is in much less quantity. See AMBERGRIS.

3. Pit-coal. See the articles Coal and Lithan. Thrax.
Practice.

**Bitumens.** This substance yields by distillation, according to the translator of the Chemical Dictionary, 1. phlegm, or water; 2. a very acid liquor; 3. a thin oil, like naphtha; 4. a thicker oil, resembling petroleum, which falls to the bottom of the former, and is inflammable with a violent fire; 5. an acid, concrete salt; 6. an inflammable earth (we suppose he means a piece of charred coal, or cinder) remains in the retort. The fluid oil obtained from coals is said to be exceedingly inflammable, so as to burn upon the surface of water like naphtha itself.

**Peat.** There are very considerable differences in this substance, proceeding probably from the admixture of different minerals: for the substance of peat is plainly of vegetable origin; whence it is found to answer for the filling of ores, and the reduction of metallic calces, nearly in the same manner as coals of wood. Some sorts yield, in burning, a very disagreeable smell, which extends to a great distance; whilst others are inoffensive. Some burn into grey or white, and others into red, ferruginous ashes. The ashes yield, on elixation, a small quantity of alkaline, and some neutral salts.

The smoke of peat does not preserve or strengthen like that of wood; and the foot into which it condenses is more apt to liquefy in moist weather. On distilling peat in close vessels, there arises a clear insipid phlegm; an acid liquor, which is succeeded by an alkaline one; and a dark-coloured oil. The oil has a very pungent taste, and an empyreumatic smell; less agreeable than that of mineral bitumens. It liquefies in the cold, into a pitchy mass, which liquefies in a small heat: it readily catches fire from a candle; but burns less vehemently than other oils, and immediately goes out upon removing the external flame. It dissolves almost entirely in rectified spirit of wine, into a dark, brownish-red liquor.

**Charcoal.** This is the form to which all inflammable matters are reducible, by being subjected to the most violent action of fire in close vessels; but though all the coals are nearly similar to one another in appearance, there is nevertheless a very considerable difference among them as to their qualities. Thus the charcoal of vegetable parts with its phlogiston very readily, and is easily reducible to white ashes: charcoal pitch, or, as it is commonly called, coak, much more difficultly; and the coals of burnt animal substances, far more difficulty than either of the two. Mr Macquer acquaints us, that the coal of bullock's blood parts with its phlogiston with the utmost difficulty. He kept it very red, in a shallow crucible surrounded with charcoal, for six hours and more, stirring it constantly that it might be all exposed to the air, without being able to reduce it to white, or even grey ashes. It still remained very black, and full of phlogiston. The coals of pure oils, or concrete oily substances, and foot, which is a kind of coal raised during the inflammation of oils, are as difficultly burnt as animal coals. These coals contain very little saline matter, and their ashes furnish no alkali. These coals, which are so difficultly burnt, are also less capable of inflaming with nitre than others more combustible; and some of them, in a great measure, resist even the action of nitre itself.

Charcoal is the most refractory substance in nature; no_instance having been known of its ever being melted, or showing the least disposition to fusion, either by itself, or with additions: hence, charcoal is found to be the most proper support for such bodies as are to be exposed to the focus of a large burning glafs. The only true solvent of charcoal is niter sulphur. By the violent heat of a burning glafs, however, it is found to be entirely dissipable into inflammable air, without having any residuum. See *Aerology*, n° 129, and CHARCOAL.

The different substances mixed with different coals, render some kinds of charcoal much less fit to be used in reviving metals from their calcines, or in smelting them originally from their ores. The coals of vegetable substances are found to answer best for this purpose. See *Metallurgy*.

**Sect. V. Vegetable and Animal Substances.**

The only substances afforded by vegetables or animals, which we have not yet examined, are the mucilaginous, or gummy; and the colouring parts obtained by infusion, or boiling in water; and the calculous concretions found in the bodies of animals, chiefly in the human bladder. The colouring matter is treated of under the article *Colour-Making*, to which we refer; and in this section shall only consider the nature of the others.

§ 1. Mucilage of Gum.

The mucilage of vegetables is a clear transparent mucilage substance, which has little or no taste or smell, the consistence of which is thick,ropy, and tenacious, when united with a certain quantity of superabundant water. It is entirely and intimately soluble in water, and contains no disengaged acid or alkali.

When mucilage is dissolved in a great quantity of water, it does not sensibly alter the consistence of the liquor; but, by evaporation, the water grows more and more thick; and, at last, the matter acquires the consistence of gum arabic, or glue; and this without losing its transparency, provided a heat not exceeding that of boiling water has been used.

Gums, and solid mucilages, when well dried and very hard, are not liquefied in the fire like refining, but swell, and emit many fumes; which are, at first, watery: then oily, fuliginous, and acid. Diftilled in close vessels, an aqueous acid liquor comes over along with an empyreumatic oil, as from other vegetable substances; a considerable quantity of coal remains, which burns to ashes with difficulty.

Mucilages and gums are not soluble either by oils, spirit of wine, alkalis, or acids, except in so far as they dissolve in theseliquors by means of the water in which the alkali or acid are dissolved. They are, however, the most effectual means of uniting oil with water. Three parts of mucilage, poured upon one part of oil, will incorporate with it by trituration or agitation; and the compound will be soluble in water. Vegetable gums are used in medicine, as well as the mechanic arts; but the particular uses to which each of them is applicable, will be mentioned under the name of each particular gum.

Vol IV.
CHEMISTRY.

§ 2. Of the Human Calculus.

This substance has been repeatedly examined by the most eminent chemists. Mr Scheele, as has been related, has been able to extract an acid from it. His account of it in other respects is to the following purpose.

1. All the calculus examined, whether flat and polished, or rough and angular, were of the same nature, and consisted of the same constituent parts.

2. The diluted vitriolic acid has no effect upon the calculus, but the concentrated acid dissolves it, and by abstraction from it is converted into the sulphureous kind, leaving a black coal behind.

3. Neither diluted nor concentrated spirit of salt had any effect upon it.

4. By means of nitrous acid, a new one was produced, and which is possessed of singular qualities, as already mentioned.

5. The solution of calculus in nitrous acid is not precipitated by ponderous earth, nor are metallic solutions sensibly altered by it.

6. It is not precipitated by alkalis, but grows somewhat yellower by a superabundance of the latter. In a strong digesting heat the liquor becomes red, and tinges the skin of the same colour. It precipitates green vitriol of a black colour; vitriol of copper, green; silver, grey; corrosive sublimate, zinc, and lead, white.

7. The solution is decomposed by lime-water, and lets fall a white precipitate, soluble in the muriatic acid without any effervescence: but though there be an excess of precipitate, the liquor still remains acid; which happens also with animal earth, and that of flour dissolved in the same acids. On evaporation to dryness, the matter will at last take fire; but when heated only to a dull red heat in a close crucible, it grows black, smells like burnt alum, and effervesces with acids; being convertible before the blow-pipe into quicklime.

8. Neither this solution, nor the alkaline mixture, is changed by the acid of sugar.

9. The calculus is not changed by acid of tartar, though it is dissolved even in the cold by alkali, when reduced to such a state of causticity as not to discover the least mark of serial acid. The solution is yellow and tastes sweetish; and is precipitated by all the acids, even by the aerial. It decomposes metallic solutions, but does not precipitate lime-water; and a smell of volatile alkali is produced by a little superabundance of alkali in the solution. Dry volatile alkali has no effect upon the calculus; but caustic volatile alkali dissolves it, though a pretty large quantity is required for this purpose.

10. Calculus is likewise dissolved by digesting in lime-water; and for this purpose four ounces of lime-water are required to twelve grains of the calculus; but the latter is partly precipitated by adding acids to the solution. By this union the lime-water loses its caustic taste.

11. Calculus is also dissolved entirely by pure water; but for this purpose a large quantity of fluid is required. Eight grains of calculus in fine powder will dissolve by boiling for a short time in five ounces of water. The solution reddens tincture of lacmus, but does not precipitate lime-water; and when it grows cold, the greatest part of the calculus separates in fine crystalls.

12. On distilling a drachm of calculus in a glass retort, a volatile liquor was obtained resembling horse-horn, but without any oil; and in the neck of the vessel was a brown sublimate. On heating the retort thoroughly red hot, and then leaving it to cool, a black coal was left, weighing 12 grains, which retained its black colour on a red hot iron in the open air. The sublimate, which had some marks of fusion, weighed 28 grains, and became white by a new sublimation. Its taste was somewhat fourth, but it had no smell; it was soluble both in water and in spirit of wine; but a larger quantity of spirit than of water was requisite for this purpose. It did not precipitate lime-water, and seemed in some respects to agree with the sal finisii.

From these experiments our author concludes, that the human calculus is neither calcareous nor gypseous; but consists of an oily, dry, volatile acid, united with some gelatinous matter. The calculus is an oily salt, in which the acid prevails a little, since it is soluble in pure water; and this solution reddens the tincture of lacmus. That it contains phlogiston, appears from its solution in caustic alkalis and lime-water, but especially from the effect of the nitrous acid, by which it acquires quite different properties than from solution in alkalis; nor can it be precipitated from this solution. The animal gelatinous substance appears on distillation, by which a liquor is obtained resembling spirit of horse-horn, and a fine coal is left behind.

13. Calculus is found dissolved in all urine, even in that of children. On evaporating four kannes of fresh urine to two ounces, a fine powder is deposited as it cools, and a part firmly adheres to the glases. The precipitated powder readily dissolves in a few drops of caustic fixed alkali; and in others respects all the properties of calculus. Of the same nature is the extraordinary sediment deposited by the urine of those who labour under an ague. Mr Scheele suspected at first, that there was in this urine some unknown menstrum which kept such a quantity of powder dissolved, and which might afterwards evaporate by exposure to the air; but altered his opinion on perceiving that the sediment was equally deposited in close vessels.

14. All urine contains some animal earth combined with phlogistic acid; by the superabundance of which acid,
Acid, the earth is kept dissolved; and by reason of this supernumerous acid fresh urine communicates a red colour to lacmus. By saturation with caustic volatile alkali a white powder is precipitated; of which three drachms and an half are obtained from four kanles of urine. In the superabundance of this urine, a white precipitate is formed. On evaporating the superabundance, another remains, which precipitated lime-water; and when mixed with lamp-black, afforded phosphorus by distillation; whence it is evident, that the white powder just mentioned contained lime and phosphoric acid.

15. From these experiments Mr Scheele concludes, that all urine contains, besides the substances already known (viz. salt ammoniac, common salt, digestive salt, Glauber's salt, microscopic salt, fat, perlmutter, and an oily extractive matter), a concrete acid, or that of calculus, and animal earth. It is also remarkable, that the urine of the sick is more acid, and contains more animal earth than that of healthy persons. With regard to the fat perlmutter, it was afterwards discovered by Mr Scheele not to be a peculiar acid, but only a phosphoric acid digested by a small quantity of foal alkali united with it. The analysis is confirmed by synthesis; for, by combining foal alkali with phosphoric acid, our author obtained a true perlmutter.

In a supplement to Mr Scheele's dissertation on the calculus, Mr Bergman observes, that he could not succeed in dissolving it entirely either in pure water or in the nitrous acid, though the undissolved part was the larger proportion in the proportion of the powder to which the calculus was reduced. The undissolved part appears most conspicuous when small pieces, or small calculi of a raw grains weight only, are put into a supernumerous quantity of nitrum potass., and kept in a degree of heat very near to that which makes water boil. Here it will be observed, that the greatest part of the piece is dissolved; but that at the same time some small white powdery particles remain, which are affected by water, spirit of wine, acids, or caustic volatile alkali. If the liquor be made fully to boil, these particles divide into white rare floculi, and become almost imperceptible, but without any entire dissolution. Mr Bergman could not collect a sufficient quantity of them to determine their nature with accuracy; only he observed, that when exposed to a strong heat, they were reduced to a coal which burns slowly to ashes, and is not soluble in diluted nitrous acid.

16. When calculus vesicae (says he) is dissolved in nitrous acid, no precipitation ensues on adding the acid of sugar; whence one is readily induced to conclude, that there is no calcaeous earth present, because this experiment is the surest way to discover it. But I have found, in the variety of experiments concerning elective attractions, that the addition of a third substance, instead of dissolving two already united, often unites both very closely. That the same thing happens here I had the more reason to believe, because the acid of sugar contains some phlogistic matter, though of a subtle nature, that, on being burned, it does not produce any sensible coal; and the event of my experiment has shown, that I was not mistaken in my conjecture. In order to ascertain this point I retained coals of the calculus to ashes, which were quite white, and showed in every respect the same phenomena as lime; cau5ed some effervescence during their solution in acids, united with vitriolic acid into gypsum, were precipitated by the acid of sugar, and were partly soluble in pure water, &c. Notwithstanding this, there remains about one-hundredth part of the ashes insoluble in aquafort; being the remainder of the substance abovementioned, which, together with the concrete acid, constitutes the calculus. If the calculus be dissolved in nitrous acid, the solution filtered and evaporated to dryness, and the dry mass calcinated to white-ness, a calcareous powder is thus likewise obtained. As pure vitriolic acid contains no phlogiston, our author supposed, that by dropping it, in its concentrated state, into a solution of calculus in nitrous acid, the calcaeous earth, if any existed in it, would be discovered. In this he was not disappointed, for when the solution was saturated, some small crystals were thus immediately separated. These, on examination, were found to be gypsum, and, after being dissolved in distilled water, were precipitated by acid of sugar. When the solution of calculus was very much diluted, no change appeared at first on the addition of oil of vitriol; but after a little evaporation, the abovementioned crystals began to appear. Some of the bladder or kidneys at least certainly contain lime, but from more than one half in an hundred parts, or one in 200 parts.

By the assistance of heat, concentrated vitriolic acid dissolves the calculus with effervescence, and the solution is of a dark brown colour. On adding a little water, a kind of coagulation takes place; but by adding more, the liquor again becomes clear, and assumes a yellowish colour. Mr Bergman agrees with Mr Scheele in supposing that the muriatic acid has no effect upon the calculus; but he is in no doubt whether it may not extract some part of the calcaeous earth.

The red colour assumed by the solution of calculus in aquafortis is remarkable. A saturated solution dissolves no smell of nitrous acid, and if evaporated by itself in a large open vessel, the liquor assumes at last a deep red colour, and freely contains any nitrous acid: for, on the one hand, paper tinged with lacmus scarcely shows any redness; and, on the other, the colour is destroyed irrecoverably by the addition of any acid. By quick evaporation the solution at last swells into innumerable bubbles; the foam grows redder and redder, and at last becomes dark red after it is quite dry. This dry mass communicates its colour to a much larger quantity of water than before, and dissolves very readily in all acids, even such as have no action on the calculus; but they entirely destroy the colour, and that the more quickly in proportion to their degree of strength; even alum has this effect on account of the small quantity of loose acid it contains. Caustic alkalis also dissolve the colouring matter, and destroy it, but more slowly.

Our author endeavours to account for this red colour produced by the nitrous acid, from the peculiar nature of that acid and the effect it has upon phlogiston. In order to obtain it, a proportionable quantity of acid must be made use of, and it ought to be diluted, that there may be no danger of going beyond the necessary limit. If too much be used, it will not produce the proper effect; but if a supernumerous, more or less, or even the whole, will be destroyed in proportion to the quantity. By pouring it in an undiluted state on powdered calculus, it is con-
The following hour.

Experiments upon this subject.

Eight hundred and forty grains of dry and well powdered calculus were introduced into a glass retort. It was taken from a laminated stone with a small nucleus, which was likewise laminated. The outer crust appeared very porous, but increased in density towards the centre. By the application of heat, an effafto fluid was first slowly extricated; and which, on examination, appeared to be composed of equal parts of fixed and phlogificated air. The last portions came over very fast, and were attended with an urinous smell; and, by continuing the distillation, it became evident that fixed and alkaline air came over together without forming any union, as they ought, on the common principles of chemistry, to have done; though our author is at a loss to know why they did not unite, unless they were prevented by the small quantity of inflammable air which came over along with them.

From the beginning of the tenth measure, a black, charry, and greasy matter began to line the conical tube and air-vessel adapted to the retort; and as the process went on, the proportion of alkaline air decreased, while that of the inflammable air was augmented, until towards the end, when the last nine measures were all inflammable; after which no more would come over, though the retort was urged with a white heat. On breaking the distilling vessel, a black powder weighing 95 grains was found in it. On digesting this for an hour in ten ounces of distilled water, and then filtering and evaporating it to two ounces, a yellowish powder was precipitated, but no crystals were formed after standing a whole night. This powder was then separated by filtration, and the liquor evaporated to one ounce; during which time more powder was precipitated. It was then filtered a second time, and the liquor evaporated to half an ounce; when the more was depoct by a white powder, and to emit a subacid acrid put not unlike that of vitriolic acid. This white precipitate, when washed and dried, amounted only to one grain, had a shining appearance, and felt very soft, not unlike mica in powdery. It was not, however, looked whiter by exposing it to a fierce heat for ten minutes. It dissolved in distilled water without being precipitated by caustic volatile alkali. Mineral alkali, acid of sugar, and nitrated terra ponderosa, rendered the solution turbid; whence our author inferred, that the powder in question was seifelite.

After the separation of this powder, the remaining solution was evaporated to dryness with a gentle heat. During the evaporation it continued to emit subacid vapours, leaving eleven grains of powder of a dirty yellow colour, having an albuminous taste. To this powder he added as much distilled water as was nearly sufficient to dissolve it; after which it was left by for three weeks. At the expiration of this term several small, transparent, and cubical crystals appeared on the side of the vessel above the surface of the solution; and these likewise had an albuminous taste. The whole was then dissolved in distilled water, and the solution filtered. Acid of sugar produced no change in the liquor for at least five minutes, but an immediate cloudiness took place on a mixture with volatile alkali; and on filtering the liquor it was again rendered turbid by mineral alkali, though the caustic alkali already predominated. Nitrated terra ponderosa threw down a copious precipitate, and Prussian alkali discovered a small quantity of iron. This albuminous solution left a yellow substance on the filter; which, when collected and dried, weighed only half a grain; it dissolved without effervescence in nitrous acid; acid of sugar caused no precipitation, but caustic volatile alkali threw down a precipitate which dissolved in distilled water. This solution was rendered turbid by the acid of sugar and nitrated terra ponderosa, but no effect was produced by caustic volatile alkali or lime-water.

The yellow powder first deposited by the solution weighed two grains and a half, and by exposure to a strong heat acquired a deep orange colour. On digestion with distilled water, the insoluble part was reduced to three-fourths of a grain, and appeared to be iron: while the soluble part was found to be nothing else but gypsum. Our author, however, is of opinion, that this iron is impregnated with a small portion of vitriolic acid, though not in such quantity as to render it soluble.

The charred matter remaining in the retort was reduced by lixiviation with water to 60 grains. These were calcined with a red heat in an open fire, but could not be reduced to a grey powder in less than three quarters of an hour. When thoroughly calcined and cold, it weighed only 21 grains, which communicated to hot distilled water a limy taste, and gave it the property of turning syrup of violets green. Diluted vitriolic acid had no effect upon it, but it was rendered turbid by aerated volatile alkali and acid of sugar. The remainder when well dried weighed 16 grains, which dissolved in nitrous acid at first with a little effervescence; and when this ceased, the solution went on very slowly, until the whole was taken up. Acid of sugar made no change in the liquid, but the whole was precipitated by caustic volatile alkali. Prussian alkali threw down a grain, or perhaps more of blue;
blue; the precipitate digested with distilled vinegar lost a grain and a half, which was thrown down by cautic volatile alkali. The insoluble part being washed and digested in distilled water for half an hour, was partly dissolved; the solution was not affected by cautic volatile alkali, but acid of sugar and nitrate of terra pondersa caused an immediate coagulation. Seven grains and an half of the powder, which was insolu-
ble both in acetic acid and distilled water, were readily taken up by diluted vitriolic acid, and precipitated by cautic volatile alkali: the 16 grains last treated, therefore, appeared to contain, of clay 7; grains of felenite, 6 grains; magnetia, one and a half; and of iron, one grain. The proportions of the different ingredients in the whole calculus, therefore, according to Mr. Higgins, are as follows:

In all 94½

In this experiment, a darkish yellow sublimate adhered to the neck of the retort; the inner part next the retort more compact, but the rest of a lamellar spongy texture. This sublimate, when carefully collected, was found to weigh 425 grains, and readily dissolved in eight ounces of hot distilled water. A coaly sublimate was separated from this solution by filtration, which, when washed and dried, weighed ten grains, and when exposed to a red heat burned with a greenish flame, emitting white fumes, which smelled like vitriolic sal ammoniac: the residue after calcination weighed half a grain, and was of a whitish colour: appearing insoluble in distilled water, but disolving with effervescence in nitrous acid. Acid of sugar caused a very small precipitation, which did not take place until the mixture had stood for some time; but cautic volatile alkali instantly threw down a precipitate, which was taken up, when washed, by acetic acid.

The quantity was too small to be examined with greater accuracy; but it seemed to possess the properties of magnetia. The saline solution had the colour of small beer; and, when evaporated to two ounces, did not deposit any sediment, or yield any crystals. The black matter with which the conical tube and air vessel were lined, weighed 28 grains, and adhered so fast to the glads, that it was impossible to collect the whole from the fragments of the glads. When dissolved in distilled water and filtered, four grains of coals, similar to that obtained from the former, were procured; but no signs of crystallization were observed after evaporation to one ounce, and fusing the liquor to stand all night.

By this treatment the solution acquired the consistence of treacle; so that it was plainly not crystallizable, and therefore its analysis was plainly to be attempted after a different method. It was now put into a tubulated glass retort, together with six ounces of distilled water to wash it down. By distillation in a sand bath three ounces of water were procured, which disprovided in nothing from common distilled water, but in being coloured with a small quantity of the solution from the neck of the retort. On changing the receiver, about half an ounce of liquor of the same kind came over, after which the distillation began to be attended with an urinous smell. This continued barely perceptible for some time; but when about an ounce and a half had passed over, it became so very pungent, that our author could no longer doubt of its being in a cautic state. A small quantity of mild alkali, however, adhered to the lower part of the neck of the retort, some of which was washed down by the distillation; so that the proportions between the two could not be ascertained. The volatile alkaline solution in the retort had the colour of spirit of hartshorn, and like it became darker coloured by the contact of air; on account of the evaporation of part of the alkali, and the ret becoming less capable of suspending the coaly matter mixed with it.

After all the liquor had passed over, and nothing remained in the retort but a small quantity of black matter, the fire was raised; and, as the heat increased, this black substance acquired a white colour, with a kind of arrangement on the surface, which was occasioned by the heat applied to the bottom of the retort being only sufficient to raise the falt to the top of the matter in the retort; but as the falt became nearly red-hot, white fumes began to appear, which condensed on the upper part of the retort, and a little way down the neck. The process lasted until the matter was nearly red-hot, when the fumes ceased, and nothing more passed over. The sublimate, when collected, was found to weigh 72 grains, a black porous brittle sublimate remaining on the bottom of the retort, which weighed 12 grains. This residue, when exposed to a strong heat, emitted white fumes, with a slight alkaline smell; by which process it was reduced, with very little appearance of combustion, to a grey powder weighing three grains, which was accidentally lost.

Five grains of this purified sublimate, mixed with as much quicklime, emitted no smell of volatile alkali; and, when thrown upon a red-hot iron, emitted white fumes. The fume effect was produced by a mixture of equal quantities of vegetable alkali and sublimate. The remainder, consisting of 62 grains, was divided into two equal parts; the one of which was mixed with two ounces of distilled water, and on the other was poured 60 grains of vitriolic acid diluted with half an ounce of water. These two mixtures being suffered to remain for six weeks, seemed to be but little acted upon. That with vitriolic acid was then put into a small matras, and boiled on sand for half an hour with two ounces of distilled water, when the whole was taken up. The solution looked clear, and deposited nothing on standing. Mild mineral alkali had no effect upon it; but mild vegetable alkali threw down a copious sediment in white floculi, which was redissolved by cautic alkali, lime-water, and partly by mild mineral alkali. Phlogistified alkali, acid of sugar, and acid of tartar, had no effect upon it. The other portion of sublimate, which had been mixed with distilled water, was very little disolved; but in pouring it into a matras some small round lumps were observable on the bottom of the glads. These were fix
Calculi, sometimes called gravel, is composed of various mineral substances. The stones which were put into a retort and distilled with nitrous air contained iron in a volatile form. The precipitate was then washed and distilled vinegar poured upon it, which did not dissolve it. On filtering the solution to separate what had been deposited by cooling, no change was produced in the filtered liquor by mineral alkali; but mild vegetable alkali produced a cloudiness, which was instantly taken up on adding mineral alkali and lime-water. Neither Prussian alkali, nor the acids of arsenic, tartar, sulfur, or borax, nor any of the three mineral acids, had any effect upon it.

On filtering the solution to separate what had been deposited by cooling, no change was produced in the filtered liquor by mineral alkali; but mild vegetable alkali produced a cloudiness, which was instantly taken up on adding mineral alkali and lime-water. Neither Prussian alkali, nor the acids of arsenic, tartar, sulfur, or borax, nor any of the three mineral acids, had any effect upon it.

The precipitate was then washed and distilled vinegar poured upon it, which did not dissolve it; but it was dissolved by marine acid. Phlogisticated alkali had no effect upon it; and the acid of sugar occasioned very little cloudiness after standing three or four hours; from which our author supposed that the matter was phosphorated clay.

The solution, being now free from iron and phosphorated clay, had a fibrous taste, and looked clearer, though still retaining a yellow cast. Acid of sugar had no effect upon it; but nitrated terra pannera threw down a precipitate, as did likewise the caustic volatile alkali. Mild vegetable alkali caused no precipitation; which our author attributed to the solution of the manganese and clay by the fixed air extricated from the alkali. Two-thirds of the solution were then put into a small glass retort, and two ounces distilled off, which had no taste, but smelled very agreeably, and not unlike roe-water. After all the liquor had passed over, white fumes appeared in the retort, and there were soon followed by an aerial fluid. On collecting some of this, a candle was found to burn in it with an enlarged flame. Nitrous air did not diminish it in the least; and it seemed to be that species of air into which nitrous ammoniac is convertible. No more than 13 or 14 inches of this kind of air could be obtained; and as soon as it ceased to come over, crystals were observed in the lower part of the neck of the retort. On augmenting the heat, a white falt began to sublime and adhere to the upper part of the retort; the operation was continued until the falt was red-hot; but, on breaking it, the quantity of sublimate was so small, that very little of it could be collected; though, from the small quantity obtained, our author was convinced of its being the same in quality with what was obtained in the former analysis. The falt which crystalized in the neck of the retort was nitrous ammoniac, as appeared from its detonation perpe, &c. A grey powder was left in the bottom of the retort, which hot distilled water partly dissolved; nitrated terra pannera, acid of sugar, and vegetable alkali, rendered this solution turbid; but caustic volatile alkali had no effect upon it. The remaining part of the powder which was left by the distilled water, readily dissolved with effervecence in the marine acid, and was precipitated by caustic volatile alkali; the part soluble in distilled water appearing to be gypsum, and that soluble in marine acid to be magnesium silicate.

From all these experiments, Mr Higgins concludes the composition of the human calculus to be vastly different.
Calculus.

Mr. Scheele or Mr. Bergman have supposed it to be, "it appears (says he), that the calculus was composed of the following different compounds blended together: viz. sebacate, alum, microcosmic salt, mild volatile alkali, lime, and caustic volatile alkali, combined with oil, so as to form a faponaceous mass; calx of iron, magnetite combined with aeral acid, clay enveloped by a faponaceous and oyle matter, and the sublimate already described." Considering this to be the true state of the calculus in the bladder, the small proportions of clay, sebacate, magnetite, iron, which are the most insoluble of the ingredients; the great solubility of microcosmic salt and alum, and the miscibility of lime, volatile alkali, and oil, in water; tend to show, that the sublimate is the cementing ingredient. Indeed, its intollutibility in water, and property of forming nuclei out of the body, as above observed, leave no room to doubt it. The proportion of the other ingredients, and very likely their preference, depend upon chance. Volatile alkali and oil excepted; therefore this sublimate should be the object of our investigation.

Mr. Higgins concludes his dissertation with some practical remarks concerning the remedies proper for dissolving the stone, for counteracting that disposition in the body which tends to produce it, and concerning the regimen proper for those who are to undergo the operation of cutting for it. "The effect of mild mineral alkali (says he) on the sublimate, is well worth the attention of those who may have an opportunity of trying its efficacy. Mild mineral alkali may be taken in large doses, and continued for a length of time with impunity to the most delicate constitutions, only observing a few circumstances: but this alkali, in a caustic state, must very often be attended with mischievous conseqences. Besides, if we consider that it must enter the mafs of blood before any part can reach the bladder, and the small portion of the dose taken secreted with the urine, and, lastly, the action of caustic alkali upon animal substances; we shall be at a loss to know on what principle caustic alkali have been recommended in preference to mild. Soap itself might as well be recommended at once; for soon after caustic alkali is taken, it must be in a faponaceous state. Fixed vegetable alkali should be avoided, and the preference given to the other two alkali. As it is evident that alkali have no real action on the stone in the bladder, though their efficacy has been experienced in alleviating the difafe when timely administered, their mode of action is only explicable in the following manner: They either prevent the generation of the sublimate in the system, or else keep it in solution in the mafs of fluids: and being in the utmost degree of divisibility, its ultimate particles are capable of passing through the most minute emnuncies; by which means it is carried off by other secreotions as well as the urinary. Thus urine, not being satureted with this matter, acts as a solvent on the stone; and as the most soluble parts are first walled away, it falls through time into fragments of irregular surfaces, which by their friction irritate and inflame the bladder, as has been observed by several practitioners.

"Allowing that the sublimate is the cementing subfance in the calculus, and judging, from the effects of alcalies upon it, their modus operandi in the constitutition, it remains now to inquire into the origin of the calculus. Mr. Scheele has found this sublimate in the urine of different persons; and hence inferred, that it was a common secretion; but it still remains to be ascertained, whether there be a greater quantity of it procured from the urine of patients who labour under this disorder than in those who do not? If this should not be the cafe, may not a deficiency of volatile alkali in the constitutition be the cause of the concretions in the kidneys, bladder, &c.; or, which must have the fame effect, too great a proportion of acid, which, uniting with the alkali, may take up that portion which would have kept the sublimate in solution until conveyed out of the system by the urinary and other secreotions; and may not this he the phosphoric acid? If this latter should be the cafe, an increase of microcosmic salt must be found in the urine; but if the former, a decrease of the volatile alkali, and no increase of the neutral salt. The small quantity of phosphoric acid found in the calculus proceeds from the solubility of microcosmic salt. Do not volatile alkali and phosphoric acid constitute a great part of the human frame? and is their not a proces continuallly carried on to generate these in the system? and is not this proces liable to be retarded or checked by intemperance, &c. which may vary their quantities and proportions? and may not a due proportion of these be necessary to a vigorous and sound constitution? If so, no wonder that an increase or deficiency in either or both of these should be productive of several disorders."

On this subject, however, our author has not had sufficient leisure to make the experiments necessary for its elucidation. Indeed, it seems not easy to do so; as, in his opinion, at least 500 would be required for the purpose. "That the urinary sublimate is present in tubercles found in the lungs of persons who die of pulmonary consumptions, and likewise in what are vulgarly called chalk fones, is what I have experienced; but in what proportion, or whether in quantities sufficient to cause the concretion, is what I cannot say; I ple for I have had but a few grains of each to examine. I have every reason to suspect, that consumptions and feborbitic complaints very frequently arise from a superabundence of this sublimate in the system; and that it is chiefly the cause of the gout and rheumatism, and solely the cause of the stone in the bladder. I make no doubt but these disorders generally proceed from obstructions; and it is probable, that either a precipitation of this sublimate in the system, or else a deficiency of some other secretion, which would hold it in solution until conveyed out of the body, may be the chief cause of those obstructions; and likewise, that different degrees of precipitation may produce different symptoms and disorders."

"That mineral or volatile alkali and bark have been useful in the above disorders, has been affirmed by experienced physicians; and I know an instance of mineral alkali and nitrous ammoniac being serviceable in a pulmonary complaint of some standing."

With respect to the stone, when it acquires a certain magnitude, it is absurd to attempt to dissolve it in the bladder, it wastes so very slowly; and during this time the patient must suffer vast pain, particularly when..."

CONTAINING SUCH DISCOVERIES AS HAVE APPEARED SINCE THE COMPILED SESSIONS OF THE ARTICLE, AND WHICH COULD NOT BE INSERTED IN THEIR PROPER PLACES.

I. VITRIOLIC ETHER.

Mr. Higgin's observations.

On this subject Mr. Higgins has several curious and interesting observations. It is not an easy matter (says he) to ascertain exactly the greatest quantity of dephlogisticated air, which a given quantity of nitrous acid may contain. I always found nitre to vary, not only in its product of phlogisticated and dephlogisticated air, but likewise in their proportion to one another. The purest nitre will yield, about the middle of the process, dephlogisticated air so pure as to contain only about \( \frac{1}{4} \) of phlogisticated air. In the beginning, and nearly about the latter end of the process, air will be produced about twice better than common air. On mixing the different products of a quantity of pure nitre, it was found that, by exposure to the waters of sulphur, \( \frac{1}{4} \) part was left unabsorbed; and this was the utmost purity in which I obtained dephlogisticated air from nitre.

According to M. Lavoisier, 100 grains of nitrous acid contain 79\% of dephlogisticated air, and 20\% of phlogisticated air, which is not quite four to one. But his experiments contradict this; for whatever mode he adopted to decompose nitrous acid, it appeared that the proportion of dephlogisticated air was nearly as five to one of phlogisticated air.

Mr. Cavendish has proved, that nitrous acid may be formed by taking the electric spark in a mixture of three parts of phlogisticated air, and seven of dephlogisticated air, which is but \( \frac{1}{4} \) more of dephlogisticated air than nitrous acid contains; which may apparently contradict Mr. Lavoisier's, as well as my own, estimation of the proportion of the constituent principles of nitrous acid, when in its perfect state. The red nitrous vapour contains three parts of nitrous air and one of dephlogisticated air, or one of phlogisticated and three of dephlogisticated air; but nitrous vapour may be formed with a less proportion of dephlogisticated air; and which, though it may not be so condensible as a more perfect nitrous vapour, yet will, when in contact with pure alkali, unite with it, and form nitre, as was the case in the experiment of Mr. Cavendish.

The common straw-coloured nitrous acid contains more dephlogisticated air than the red nitrous acid or vapour; the proportion appears to be about four to one; but the colour of the vapours may be dispelled by diluting with a few drops of phlogisticated air.

Having once a charge of nitrous and vitriolic acid in a green glass retort, I put it in a sandpot to distil; but the pot being small, the edge came too near the retort, about a quarter of an inch or more above the charge; which, before the process commenced, and when it acquired more than the heat of boiling water, cracked it all round in that direction. Being thus situated, I was obliged to withdraw the fire, and, before the charge got cold, to ladle it into an earthen pan. On introducing it into a fresh retort, I obtained from it nitrous acid nearly as water. The vitriolic acid used in this process not being very perfect, the goodness of the nitrous acid was attributed to the purity of the nitre from whence it was distilled; but in another process, though the same nitre was used with much purer vitriolic acid, the produce was of an high straw colour. On recollecting the abovementioned circumstance, the vitriolic acid and nitre were next mingled in due proportion, and exposed in an earthen pan set in sand, to nearly the heat of boiling water, for half an hour or more, continually exposing fresh surfaces to the air. When the charge was quite cold, I introduced it into a retort, and distilled as colourless nitrous acid as the former. As no nitrous air was emitted during digestion, it must have imbibed dephlogisticated air from the atmosphere.

Mr. Prout found, that strong nitrous acid will set fire to charcoal if it be rendered very dry. He likewise remarked, that nitrous acid, after calcination, was unfit for the experiment. Charcoal, he observes, attracts moisture very forcibly. The first effect of the charcoal on the nitrous acid, he observes, is to withdraw a portion of its water from it; by which it is rendered highly concentrated, at the same time that the condensation of the water heats the charcoal in a small degree, but sufficiently to volatilize a nitrous vapour; which, as soon as it reaches that portion of dry charcoal next the humid part, is condensed.
Effect of nitrous acid on blood.

Mr. Higgins, is very singular. Two parts of blood procured fresh at the butcher's, one of strong nitrous acid, and about one fifth of the whole of water, were digested in the heat nearly of boiling water (fresh portions of water being occasionally added until the whole of the acid was expelled), when it acquired almost the colour, and exactly the taff, of bile. When mixed with a large quantity of water, it acquired a fine yellow colour; and, on standing, deposited a substance of a brighter yellow, though the supernatant liquor still retained a yellow colour and bitter taff, but not so intensely as when the precipitate was suspended in it. The different phases of this process were well worthy of observation. No nitrous acid was produced, and the acid was expelled in the state of a white vapour. The liquor was found to increase in bitterness as the acidity vanished. About the middle of the process, the solution first taffed acid, but was quickly succeeded by a bitter effusion. It appears that the nitrous acid took dephlogisticated air from the blood; for though red nitrous acid was used, it was expelled in a perfect state.

III. NITRE.

Though the artificial generation of the nitrous acid, from a mixture of dephlogisticated and phlogisticated air, is now sufficiently understood, yet we do not well know in what manner nature performs the operation. Some chemists, particularly M. Thouvenal, have found, that purefaction favours the production of nitrous acid. All animal substances, during their decay, give out a vast quantity of phlogisticated air; therefore, if dephlogisticated air be present, it will unite to the phlogisticated air in its nascent state, and form nitrous acid: but Mr. Higgins has observed, that nitrous acid may be generated in plenty where there is no putrid process going on. "The chemical laboratory at Oxford (says he) is near six feet lower than the surface of the earth. The walls are constructed with common limeflour, and arched over with the same; the floor is also paved with stone. It is a large room, and very lofty. There are separate rooms for the chemical preparations, so that nothing is kept in the laboratory but the necessary implements for conducting experiments. There is an area adjoining it on a level with the floor, which, though not very large, is sufficient to admit a free circulation of air. The ashes and sweepings of the laboratory are deposited in it. There is a good link in the centre of this area, so that no stagnated water can lodge there. Notwithstanding all this, the walls of the room afford fresh crops of nitre every three or four months. Dr. Wall, who paid particular attention to this circumstance, and who told me it contained fixed vegetable alkali, requested I would analyze it, and let him know what it contained. I found that two ounces of it contained six drachms of nitrate of nitre, and three of calcareous nitre. The nitre first appears in small whitish filaments as fine as cobweb, which, when they get a little larger, drop off; so that they never acquire sufficient growth to distinguish their figure to a naked eye. On finding that they contained fixed vegetable alkali, I concluded that it proceeded from minute vegetation; but in this I was mistaken; for I found that they were soluble in water, and that they denoted with charcol at every stage of their growth. Having swept this saline efflorescence from the wall, I dug deep into it, but could not obtain nitre from it. When a part had been white-washed, it yielded nitre, but not so abundantly as a neighbouring spot which had not been treated in the same manner. Hence it is evident, that nitrous acid may be formed without the assistance of putrefactive processes in a still damp air, where there is a substance to attract it when half formed, whereby it is in time brought to perfection. The above facts moreover prove, that fixed vegetable alkali is a compound."

IV. MARINE ACID.

Mr. Higgins informs us, that he has, with a view Unsuccessful to decompose fætus, mixed it with manganese in various proportions, and exposed them in a reverberating furnace in a well cloised crucible for three hours, to a fætus heat nearly sufficient to melt cast iron. In the same manner he treated manganese, fætus, charcoal, as well as clay, fætus, and charcoal, and fætus and clay alone, with very little success. He treated calcined bones, fætus, and charcoal, and calcined bones and fætus, as well as lime and fætus, in the same manner, without effecting any apparent change in the fætus. He was informed, however, by Mr. Robertson, apothecary in Binchopgate-Ericeet, that he had partially alkalized it, by expoting it with clay to a fierce heat; but that soon after it got into contact with air, it became neutral again. "If common salt and litharge be fusied (says Mr. Higgins), it is in part decomposed; the acid suffers no decomposition, but unites with the lead; whereby it acquires, when the saline matter is wafted away, a yellow colour. It is evident (adds he) from these facts, that the basis of marine acid is a combustible body, and quite different from light inflammable air, charcoal, or any known inflammable substance; and that it attracts dephlogisticated air with greater force than any substance hitherto discovered. Though charcoal will decompose all other acids, except a few, when united to bodies which will fix them until they acquire a sufficient degree of heat, yet it has no effect upon marine acid."

According to Fourcroy, if alkaline air be confined by mercury, and dephlogisticated marine acid air be added to it (which must be done quickly, as the acid air would disolve the mercury), each bubble produces a slight detonation, and furnishes a very amusing spectacle.

Though in Britain the distillation of the spirit of Method of Method spirit of fætus with clay has long been entirely laid aside for the distilling spirit of fætus with clay, in other countries, and may be effected in the following manner: Having previously deprecitated the fætus, and dried the clay, they are then to be ground, mixed, and sifted together. The mixture is next to be worked with a spatula, and then with the hands, until it is brought into a moderately stiff and uniform mass.
CHEMISTRY.

Marine acid.

This is to be divided into balls about the size of a pigeon's egg, so that they can pass through the neck of the retort; but before they are put into the distilling vessel, it is proper to dry them thoroughly. The retorts must be of stone-ware, and carefully coned, in order to prevent them from breaking with the intense heat to which they are exposed. They are to be filled two-thirds full of embers, and the distillation must be performed in a reverberatory furnace. The receiver at first is not luted on, because that which rises in the beginning of the distillation, being very aqueous, is to be put by itself. When this has come over, another receiver is then to be applied, and cemented with fat lute, and covered with a cloth daubed with a mixture of lime and the whites of eggs. The heat is to be raised until the retort is red-hot, and continued in this degree until the distillation ceases.

Various proportions of clay and salt have been recommended for this process; but it seems probable that not less than ten parts of clay to one of salt, as Pott has directed, will be found necessary. Instead of the clay, some direct the use of bone; but this is inconvenient on account of the iron it contains. Powdered tallow has also been recommended, but this is not always free from iron; and where a very pure spirit is wanted, there is a necessity for having recourse to oil of vitriol, and glass or stone-ware vessels. As the marine acid cannot be separated from the earthy matters, the former theory was abandoned.

1485 Effect of marine acid upon phlogistic matters.

As the marine acid has very little action upon phlogistic matters, it cannot therefore affect oils, either expressed or essential, in a manner similar to the vitriolic matter or nitroils. M. Marges, however, has observed yellow crystals resembling amber formed in bottles, containing a mixture of oils and marine acid of moderate strength, which had stood for several months. The little effect which the marine acid has upon these substances was first suppos'd to be owing to its want of phlogition in itself; but when it was afterwards found, that, by the application of certain substances, which had a great attraction for phlogition, the marine acid was rendered capable of uniting very readily with inflammable matters, the former theory was abandoned. It was now ascertained, that the acid, instead of containing no phlogition, was naturally endowed with a very considerable quantity; and that, in its new state, it was dephlogiticated by the substances applied. On the other hand, the antiphlogitons ascertained, that no change was thus made upon it, farther than adding a quantity of pure air, which they suppose to be the basis of all acids. On this subject, however, M. Corneille maintains, that the marine acid seems to have little action upon inflammable substances, merely because it is weaker than the rest; and likewise that it is often previously combined with some inflammable matter, by which its attraction is prevented. He maintains, that if the marine acid be concentrated in such a manner as to render its specific gravity to that of water as 19 to 16, it will then act upon oils with heat and effervescence, reducing them to a black and thick substance, and even burning them to a kind of coal. Some experiments have been made by Mr Hale, with a view to investigate the action of the marine and vitriolic acids upon balsams and oils; for which purpose he mixed two drachms of smoking spirit of vitriol with one of each of the oily substances to be tried. The results were, that Canada balsam gained one scruple in weight; balsam of caprif 19 grains; flox, and Venice turpentine, each one scruple; apitalum 18 grains; but the essential oils of antifeed, benzoin, bergamot, coriander, and many others, were not altered in any degree. The action of this acid upon inflammable matters, however, is augmented by its being reduced into the form of air.

1486 Gmelin relates, that, by distilling a mixture of five parts of salt, twelve of spirit of wine, and four of vitriolic acid, to which he had previously added one or two parts of water, he obtained a completely dulcified spirit of salt, and an imperfectly dulcified spirit of vitriol, upon rectifying the liquor.

Homburg found, that glass was corroded by the Gläser cor­nigest, and his observation has been confirmed red by Dr Prie­fley, who finds that its corrosive power is augmented by confining the acid in tubes hermetically sealed. Its power is exercised not only on flint­glass, but even on common green gläze; though more powerfully on the former, where it chiefly attacks the red-lead used in its composition. By including marine acid gas for some weeks in a glass tube exposed to heat, an incrustation was formed on the inside, while the air was diminished to 5 of its original bulk, one half of which was absorbed by water; the other was phlogi­gitized air.

1487 The marine acid is generally met with of a yellow or reddish colour, which by Macquer is given as one of the yellow colour of marine acid.

1488 Dephlogiticated spirit of salt.

When the action of this vapour upon any thing is examined, the substance must be put into a bottle in such a manner as to remain in contact with it; or that it may be put into a glass tube, which is suspended and fixed to the stopper, and thus introduced into the bottle.—From its property of destroying all vegetable colours, it promises to be of very considerable use in the arts, provided it could be had in sufficient quantity, and cheap. It bleaches yellow wax, and when properly applied to linen, will whiten it sufficiently, and with out injury in a few hours. This may be effected by steeping the linen for that space of time in water impregnated with the dephlogiticated marine gas. It unites with this fluid rather more easily than fixed air.
Berthollet, in order to impregnate water with it without exposing the operator to the fume, which is extremely disagreeable, put the mixture of marine acid and manganèse into a retort. To this he applied first an empty bottle, and then several others filled with water, and communicating with each other by means of bent tubes; surrounding the whole with ice. When the water in the bottles was saturated, the gas became concrete, and fell to the bottom; but with the smallest heat it arose to the top in bubbles. The specific gravity of the saturated water was that of distilled water, when the thermometer was only five degrees above the freezing point, as 1005 to 1000. This impregnated water is not acid, but has an astringent taste, and has the same action as the gas, though in a weaker degree.

Mr Berthollet has observed, that the addition of alkalis does not prevent, but rather promotes, the discharge of colours; for which reason he directs to add a fixed alkali to the impregnated water in which linen is to be bleached, but which has not hitherto come into use, principally through the high price of the dephlogisticated gas.

The dephlogisticated marine acid does not discharge all colours with equal ease. Those of litmus and syrop of violets are entirely destroyed, and turned white. The colouring matter of Brazil-wood, and some green parts of plants, retain a yellow tint. The leaves of evergreen plants resist its action for a long time, and at last only acquire the yellow colour which they allume by long exposure to the air; and in general the changes of colour which vegetable matters suffer from this gas, are similar to those which take place on long exposure to the air; and by this operation the gas is converted into common marine acid.

Oils and animal fats are thickened by this gas; and by these and other inflammable substances it is reduced to the state of common marine acid. Light is said to produce the same effect. It unites with fixed alkalis and calcareous earths, but without any sensible effervescence; and thus they lose their peculiar taste and colour. M. Berthollet having boiled a retort, to which a pneumatic apparatus was affixed, some of the dephlogisticated marine acid liquor with mineral alkali, thus obtained a considerable quantity of elastic fluid, composed partly of fixed air, partly of the air contained in the vessels, and partly of air considerably rarer than that of the atmosphere. The result of the combination was common salt. On repeating the experiment with lime, no fixed air was obtained; but that which came over became gradually more and more dephlogisticated. Volatile alkali, even when caustic, occasioned an effervescence, and emitted a peculiar kind of air, which was neither fixed nor dephlogisticated, but of a peculiar kind.

Green vitriol is changed to a red by the dephlogisticated gas, but the colour of blue and white vitriol is not affected. By the affittance of light, it acts upon phosphorus, and the result is phosphoric and common marine acids. It does not dissolve ice nor camphor; in which respects it differs from the common marine acid gas.

On mixing marine acid, manganèse, and spirit of wine, and distilling them with a very gentle heat, little air of any kind is produced, but a quantity of ethereal aqua regia very slightly acid. The proportion used by Pelletier were an ounce and a half of manganèse, five ounces of concentrated marine acid, and three ounces of spirit of wine. "In this process (says Mr Kier), the whole of the dephlogisticated acid seems to have united with the spirit of wine, and to have formed ether. The difficulty of combining marine acid with spirit of wine, so as to form an ether, is well known, and though there have been some approximations to it, yet the only instances in which it has been completely effectuated, have succeeded in consequence of the marine acid being dephlogisticated; by which its action on spirit of wine, as well as on all inflammable matters, is greatly increased."

M. Pelleter has observed, that when we put a bit of phosphorous into dephlogisticated marine gas, the former is immediately dissolved, and a light is perceived, the vessel being filled at the same time with white vapours. He has likewise observed, that sea-salt, with excessive quantities of pure air, throws into heated vitriolic acid a product which produces small detonations. To make this fail detonating salt from in quantity, take, for instance, ten pounds of sea-salt, mixing it with three to four pounds of manganèse, and pour on the mixture ten pounds of vitriolic acid, and distil with Woulfe's apparatus. Pass the difengaged acid through a solution of fixed vegetable alkali, either caustic or otherwise. A little more than ten ounces of the new marine salt with excessive of pure air is obtained, and a quantity of salt of Sylvius, or digestible salt. The salt with excessive of pure air crystallizes first, and by means of repeated crystallizations, is entirely disengaged from the other.

V. AQUA REGIA.

This acid, which is named from its property of dissolving gold, is compounded of the nitrous and marine acids. Gold and platinum cannot be dissolved in preparing any other menstruum, nor can regis of antimony and tin be so easily dissolved by any other as aqua regia. It may be made various ways. 1. By adding the two acids to each other directly. 2. By dissolving in the nitrous acid some salt containing marine acid, particularly salt ammoniacal and common salt. 3. By distilling nitrous acid from either of these salts. And, 4. In Dr Prieley's method of impregnating marine acid with nitrous acid vapour.

The only difference between those liquors prepared by the methods above-mentioned is, that when salt ammoniacal or sea-salt are dissolved in the nitrous acid, the aqua regia contains a quantity of cubic nitre, or nitrous ammoniacal, which, tho' it cannot much affect the acid as a solvent, may make a considerable difference in the nature of the precipitate. Thus, gold precipitated from an aqua regia formed by the pure nitrous and marine acids, does not fulminate, though it does so when precipitated from one made with salt ammoniacal. There are no established rules with regard to the proportions of nitrous and marine acids, or of nitrous acid and salt ammoniacal, which ought to be employed for the preparation of aqua regia. The common aqua regia is made by dissolving four ounces of salt ammoniacal in 16 ounces of nitrous acid; but these proportions must be varied, according to the nature of the intended solution.
Methods of preparing borax, and evaporation only; but sometimes the operation is more easily and effectually performed by previous calculation; but then the product is a little less refined, especially if the calcined mass be not well powdered, and then boiled sufficiently in water. Powder of charcoal, he says, may sometimes advantageously be employed in the purification; but in general there is no difference between the crude and purified borax, except in the addition of extraneous matters; at least, as the quantity of acids in the same, the addition of mineral alkalis is useless; these extraneous matters are an animal fat, and a sand composed of clay, lime, and a marl, earth. If the oily matter of tar be separated by passing the lixivium through a stratum of clay, as is done in the preparation of the crystals at Montpelier, it would suggest a method of greatly abbreviating the process of the purification of borax.

VI. BORAX.

In a memoir in Crel's Chemical Annals, by M. Tychon, the author shews, by different experiments, that it may sometimes be purified by solution, filtration, and evaporation only; but that sometimes the operation is more easily and effectually performed by previous calculation; but then the product is a little less refined, especially if the calcined mass be not well powdered, and then boiled sufficiently in water. Powder of charcoal, he says, may be sometimes advantageously employed in the purification; but in general there is no difference between the crude and purified borax, except in the addition of extraneous matters; at least, as the quantity of acids in the same, the addition of mineral alkalis is useless; these extraneous matters are an animal fat, and a sand composed of clay, lime, and a marl, earth. If the oily matter of tar be separated by passing the lixivium through a stratum of clay, as is done in the preparation of the crystals at Montpelier, it would suggest a method of greatly abbreviating the process of the purification of borax.

VII. ACID OF BORAX, OR SEDATIVE SALT.

On the preparation of this salt Mr Beamé observes, that a little more acid ought to be added to the borax than what is just sufficient to saturate its alkaline bases. Unless this be done, the sedative salt remains confounded with the other saline matters in the solution, and of consequence the crystallization must be disturbed. The salt, though formed in an acidulated liquor, is easily deprived of its superfluous acid by draining upon paper. It does not crystallize as soon as the stronger acid separates from its bases, even though the borax had been previously made as strong as possible; but this delay is occasioned by the heat of the liquor; for as soon as it cools, a considerable quantity of crystals is formed.

The acid of borax does not fall into powder when exposed to the air, but rather attracts a little moisture from it. Its taste is at first somewhat astringent, then cooling and bitterish; and lastly, it leaves an agreeable sweetish taste on the tongue. It makes a slopping sound, and feels a little rough between the teeth; and when vitriolic acid is poured upon it, it exhales a transient odour of musk. It is soluble, according to some chemists, in the proportion of one to 20 in cold water, or of one to eight in boiling water. Wenzel informs us, that 960 grains of boiling water dissolve 484 of the salt; while, on the other hand, Morveau affirms, that he could dissolve no more than 183 grains in a pound of distilled water. Roufs informs us, that fixed air of vitriol prevents the solution of the salt in water; and Morveau, borax and its combination.

1. With volatile alkali. The produce of this is a peculiar ammoniacal salt, which does not evaporate when thrown on burning coals, or otherwise intensely heated, but melts into glass of a greyish colour, but transparent, which cracks when exposed to the air; and, on dilution in water, shoots into small crystals, which appear to have lost none of their alkaline bases. It may be decomposed by the acetates as well as the mineral acids, and by fixed alkalis and lime.

2. With magnesia this acid shoots into irregular crystalline grains soluble in vinegar and acid of ants, in which liquids they crystallize like small needles joined together at right angles. They are decomposed by all other acids, and likewise by spirit of wine. In the fire, however, they melt easily without any decomposition; and in the dry way sedative salt decomposes all the earthy parts formed by magnesia and any of the volatile acids.

3. With pure earth of alum, sedative salt forms a salt very difficult of solution, when one part of earth is ground with four times its weight of sedative salt and water. The same kind of earth, mixed with half its weight of sedative salt, forms a hard grey mass, resembling pumice stone; part of which is soluble in water, and yields a mealy sediment, together with some sedative salt unchanged.

4. With flueous earth the sedative salt does not unite in the moist way; but, on melting one part of acid with two of this earth, we obtain a frothy, hard, greyish-white mass, from which, however, the acid may be again procured.

5. Cold is not acted upon in the wet way by acid of borax; nevertheless Roufs observed, that when sedative salt was melted with gold-leaf, it did not vitrify, but became frothy and hard, did not colour the flame of spirit of wine, and only a little of it was soluble in water in which sedative salt had been crystallized.
A solution of borax in which sedative salt was dissolved, did not precipitate gold.

6. *Platinum* is not precipitated from aqua-regia by sedative salt.

7. *Silver* is not affected by melting with an equal quantity of sedative salt; but the latter is vitrified in such a manner as to become insoluble in water.

8. *Mercury* is not dissolved either in the dry or wet ways; but a solution of borax saturated with sedative salt precipitates it in a yellow powder from nitrous acid.

9. *With copper.* On this metal sedative salt acts but weakly, even when the solution is boiling hot; nevertheless, as much of the metal is dissolved, as gives a little white precipitate on the addition of fixed alkali; but volatile alkali does not throw down a blue precipitate, nor turn the solution of that colour. The solution of borax precipitates all solutions of copper in liquids, and then the sedative salt unites with the copper in form of a light green jelly, which, after drying, is of very difficult solution in water. Bergman says, it is of an agreeable green colour, which preserves after being dried; and that, when exposed to the fire, it melts into a dark-red vitreous substance.

Wenzel affords, that by long continued trituration of copper filings with sedative salt he obtained a solution of the metal, which yielded crystals on being evaporated. With twice its weight of copper in a covered crucible, an infusible vitreous mass was obtained.

10. *Tin* is not apparently acted upon by boiling with sedative salt; nevertheless, the solution becomes turbid on the addition of an alkali. By melting the calx with half its weight of sedative salt, we obtain a black mass like the dark coloured tin ore. By rubbing for a long time filings of tin with sedative salt and water, and afterwards digesting the mixture with heat for some days, an hard, sandy, and irregularly shaped mass was obtained, which, by dilution in water, yielded transparent, white, polygonous crystals; and a lot of these crystals obtained was only obtained from the flag produced by melting equal parts of sedative salt and tin filings.

11. *Lead* is not acted upon directly; but, on adding a solution of borax to solutions of the metal in vitriolic, nitrous, marine, or acetous acids, the sedative salt unites with the lead. One part of sedative salt with two of nitric acid gives a fine, greenish-yellow, transparent, and infusible glas.

12. *With iron.* The acid of borax dissolves this metal more easily than any other. The solution is amber-coloured, and yields an ochry sediment, with clusters of yellow crystals containing a little iron. The metal is precipitated by borax from its solutions in vitriolic nitrous, marine, and acetous acids, and the precipitates are soluble in sedative salt. A solution of iron may also be obtained by melting this salt with iron filings, and lixiviating the mafs.

13. *Zinc* communicates a milky colour by digestion with solution of sedative salt. By evaporation it affords a confused saline mass, and a white earthy powder by precipitation with alkali. Flowers of zinc, melted with sedative salt, form a light green infusible flag.

14. *Bismuth,* in its metallic state, is not acted upon by sedative salt, but is precipitated by borax from a mixture of vitriolic and marine acids, in form of a very white powder, which keeps its colour when exposed to air, and melts in the fire to a white, transparent, and permanent glas.

15. *Regulus of antimony* is not acted upon directly, but its calx is dissolved when precipitated by borax from a solution in aqua-regia.

16. *White arsenic* unites with sedative salt either in the dry or moist way, and forms a crystallizable compound, forming elastic ramifications, or white, greyish, and yellowish feline powder.

17. On regulus of cobalt the acid has no direct action; but borax precipitates it from its solution, and the calx melts with the salt into a flag of a bluish-grey colour; and this, by lixiviation and evaporation, affords a feline salt impregnated with cobalt, of a reddish white colour, and of a crumpled form.

18. *Nickel* is precipitated from its solution, and the sedative salt unites with it into a feline substance difficult of solution.

A variety of opinions have been formed concerning the nature of sedative salt. M. Beaneé and M. Cadet particularly have made a great number of experiments on the subject; but as none of these have led to any certain conclusion, we forbear to mention them at present. Thoé of Meffrs. Exchiquet and Struve have indeed established some kind of relation between the acids of borax and phosphorus, and they have made several attempts to analyze the former, but with little determinate success. The most remarkable of these experiments are the following. They distilled, with a fire of the sedative salt, heat, two parts of phosphoric acid evaporated to the confidence of honey, one of sedative salt, and two of water. Towards the end of the distillation a very acid liquor was obtained; and the residuum was a white earth, in quantity above three-fourths of the sedative salt employed, and which, on examination, was found to be the illicious earth; the liquor which passed over into the receiver being found to be the volatile phosphoric acid. If, in this experiment, too much phosphoric acid be added, a greasy matter remains; and, if too little, a part of the sedative salt will remain undecomposed. In their attempts to compose borax, they combined phosphoric acid with mineral alkali, the result of which was a compound resembling borax in many respects. When exposed to the fire it melts into a very fusible glass, which has a mild taste, and seems neutral, but on exposure to the air, becomes moist and acid. On being saturated with alkali a second time and vitrified, it again deliquesces and becomes acid; and the more frequently this operation is repeated, the greater is the resemblance it bears to borax. In this experiment they supposed that the alkali was decomposed, and converted into an earth similar to that of sedative salt.

With earthy substances the results were very remarkable. With earth of alum a crystallizable salt was obtained, which made paper burn with a green flame. Fixed alkali added to a solution of this salt precipitates an earth, and the salt then formed by crystallization resembles borax in several properties. In the dry way the earth of alum, with the phosphoric acid, melts into a glass of the same fusibility as that of borax, and like it is fixed in the fire. The solution of this glass did not crystallize. Common clay
Acid of amber.

It is known to Agricola, that a particular kind of salt could be obtained from amber by distillation; but neither he, nor any succeeding chemist for some time afterwards, ascertained its acid properties. On the contrary, some erred so far as to imagine that it was a volatile salt; but, about the beginning of the present century, its acidity began to be generally acknowledged. This property indeed discloses itself by the taste, which is manifestly acid and empyreumatic, along with the peculiar flavour of amber. According to Scheele, also, the aqueous liquid which passes over in the distillation of amber, is an acid resembling vinegar both in taste and chemical properties; and which of consequence ought not to be confounded with the true acid of amber, which manifests qualities of a very different kind.

The properties of the salt of amber can hardly be investigated until it has been purified; for which, of consequence, various methods have been proposed. Pott recommends crystallization, after having filtered the solution through cotton-wool, in order to retain the oil. Carthey attempts the purification by dissolving the impure salt in spirit of wine, then diluting with six times its quantity of water, and crystallizing the salt. Others recommend sublimation with common salt or sand, and Bergman with pure clay.

The salt of amber digests, by the affinity of heat, in nitrous and marine acids, and in the vitriolic without heat. In none of these combinations, however, does it either alter the dissolving acids, or suffer any alteration itself, except that it becomes whitier; with nitre it detrones and flies off; and if the quantity of salt of amber has been greater than that of nitre, the latter is alkaliized. Stockar informs us, that it expels the marine acid from salt ammoniac, and sublimes before that salt; with which it does not form any union. When sublimed from common salt, it does not alter the latter in any other respect than giving it a darker colour. It precipitates calcareous earth from its solution in vinegar; and it decomposes sugar of lead; but the precipitate differs from plumbo cornue. It does not prevent the solution of lead in the acids of sea-salt and nitre; nor does it produce any phosphorous acid by calcination with charcoal. Hence it appears that it is neither a vitriolic, nitrous, nor marine acid; and M. Bourde-}

---

**CHEMISTRY.**

**Practice.**

1. **With fixed vegetable alkali.** By saturating salt of amber with the fixed vegetable alkali, and then slowly evaporating the solution, we obtain, according to Wenzel, a light deliquecent saline mass; but, according to Stockar, who experimented by the method of Mr Keir, the solution abovementioned affords shining white transparent crystals of a triangular prismatic figure, with the terminating points truncated. These crystals readily dissolve in water, deliquesce in the air, and have a peculiarly bitter saline taste. In the fire they decompose, melt, and remain neutral; though Wenzel has observed, that with an intense heat they are decomposed and become alkaline. These crystals do not change aquafortis into aqua-regia; and though they precipitate both the solutions of lead and silver, the precipitates are neither plumbum cornue nor luna cornua.

2. **With Mineral alkali.** This combination produces long three-sided columnar crystals, intermixed with some that are foliated. These crystals do not deliquesce in the air, and have a saline, bitter, and smoky taste. They are less soluble than common salt, and melt with more difficulty than nitre. They do not become alkaline on burning coals, and, in their other properties, resemble the former.

3. **With volatile alkali.** This salt flows into acicular crystals, having a sharp, saline, bitter, and cooling taste; when heated in a silver spoon, they melt and evaporate entirely; in close vessels they sublime. They do not precipitate solution of silver, nor change spirit of nitre into aqua-regia. A powerful antispasmodic remedy is prepared from rectified spirit of hartshorn and salt of amber.

4. **With lime.** This salt flows into oblong pointed crystals, which do not deliquesce in the air, and are soluble with difficulty even in boiling water; nor, according to Mr Stockar de Neuforn, can they be decomposed by distillation either with acetic or marine acids. They decompose by distillation with nitrous acid, and are decomposed, either in the moist or dry way, by the vitriolic. When mixed with common salt ammoniac in the dry way, they suffer a decomposition; the succinated ammoniacal salt flying off and the combination of marine acid with lime remaining behind.

5. **With magnesia.** This yields a white, gummy, frothy, saline mass, which acquires a yellowish colour when dried by the fire; and, when cool, deliquesces in the air. It is decomposed by alkalies and lime, as well as by the vitriolic acid.

6. **With clay.** By uniting the acid of amber with an edulcorated precipitate of alum with vegetable alkali, Wenzel obtained prismatic crystals, which could not be decomposed by alkalies.

7. **With silver.** The acid of amber has no effect on silver.
Acid of amber and its combinations.

8. With copper. By a long digestion of copper with acid of amber, a green solution is obtained, which by mixture with common salt is rendered turbid, by vitriolic acid white, and lets fall a green precipitate on the addition of fixed alkali. Wenzel, however, could not obtain this precipitation by alkalis. His solution yielded groups of green crystals, gave a crust of copper to zinc, and was precipitated by liver of sulphur.

9. With iron. Wenzel dissolved a precipitate of this metal in acid of amber, and from the solution obtained small, brown, transparent, and slightly coloured solution of metallic iron. Zinc precipitated the precipitate formed by fixed alkali; and the sulphurous acid more; and lead, iron, or zinc, nothing.

10. With tin. Acid of amber dissolves tin when precipitated by a fixed alkali; and the solution yields thin, broad, and foliated transparent crystals. Alkalis throw down but little from this solution; liver of sulphur more; and lead, iron, or zinc, nothing.

11. With lead. Acid of amber whitens the surface of lead in its metallic state, but does not dissolve it; neither can lead be precipitated from its solutions in nitrous and marine acids by salt of amber, though this is denied by Pott. According to Stockar, however, it forms a white precipitate with sugar of lead. This metal precipitated by an alkali, and dissolved in acid of amber, forms long foliated crystals lying upon one another; from the solution of which the lead may be precipitated by alkalis in the form of a grey powder, and by zinc in its metallic state.

12. Zinc, in its metallic state, is readily dissolved by the acid of amber; and by a combination with the precipitate formed by fixed alkali, we obtain long, fleuder, foliated crystals, lying upon one another. The solution lets fall a white precipitate on the addition of fixed alkali only; but this is denied by Stockar, who says that volatile alkali produces a red precipitate.

13. Bismuth. By means of heat, Stockar obtained a solution of this metallic in acid of amber, which was decomposed by alkalis. Wenzel obtained, from a precipitate of bismuth prepared by means of fixed alkali, small, flender, foliated, and yellow crystals; which alkalis cannot decompose, though black precipitates are thrown down by lead and zinc.

14. Regulus of antimony. Little or none of this metallic, in its reguline form, is dissolved in the acid of amber; but it attacks the precipitate made with fixed alkali. This solution is very copiously precipitated by liver of sulphur, but not by alkalis.

The combinations of this acid with gold, platinum, nickel, arsenic, and manganese, have either been found impracticable, or not yet attempted; all those above described are non-deliquescent, and part with their acid when exposed to the fire. The elective attractions of this acid, according to Bergman, areingular, as it adheres more strongly, not only to terra ponderosa and lime, but to magnetia, than to fixed alkali.

On the origin of salt of amber, Mr Keir remarks, that it deserves to be considered as a pure and definite acid. No proofs have been adduced of its being Acid of amber and its combinations.

The former, having distilled spirit of salt with oil of lavender, obtained an acid which smelled like salt of amber, but on evaporation was found not to contain the properties of the muriatic acid. He also relates, that when purifying a considerable quantity of the salt of amber which he had prepared for himself, some sea-fall was separated, which in the distillation had arisen along with it. But this observation cannot be justly applied to show any resemblance between these two, any more than the smell in the former case could show an analogy between it and oil of lavender. This mixture of sea-fall with acid of amber, however, may, readily explain the mistake of M. Bourdelin already mentioned. M. Weilram and M. Hermilliat have both laboured in vain to convert the acid of amber into acids of sugar and tartar by frequent distillations with spirit of nitre; and their want of success confirms the account already given, that the acids of nitre and amber have no action upon each other, farther than that the former is phlogi- or changed into red fumes, and the latter becomes whiter. Nevertheless, if Mr Scheele's observation of the identity of the acid liquor, which comes over in the distillation of amber with acetic acid, holds good, we shall have the best reason yet given to ascribe the origin of this acid to the vegetable kingdom; and when we consider the very different properties that are ascribed by the vegetable acids, which, however, are convertible into one another, no reason can be drawn from the diversity of its properties with those of other vegetable acids, against its having a common origin with them. Indeed the natural history of amber, its similarity to gums and resins, and its involved infefts, afford other arguments in favour of the opinion.

IX. Acid of Arsenic.

M. Berthollet remarks upon Mr Scheele's process. M. Pellecier, that during the operation a great quantity of the muriatic acid is expelled from the acid. M. Pelleier has found another method of procuring the arfenical acid. He mixes common white arsenic with nitrous ammoniac, and distills the mixture. At first phlogi- or changed into red fumes, and the latter becomes whiter. Nevertheless, if Mr Scheele's observation of the identity of the acid liquor, which comes over in the distillation of amber with acetic acid, holds good, we shall have the best reason yet given to ascribe the origin of this acid to the vegetable kingdom; and when we consider the very different properties that are ascribed by the vegetable acids, which, however, are convertible into one another, no reason can be drawn from the diversity of its properties with those of other vegetable acids, against its having a common origin with them. Indeed the natural history of amber, its similarity to gums and resins, and its involved infefts, afford other arguments in favour of the opinion.

IX. Acid of Arsenic.

1495

M. Berthollet remarks upon Mr Scheele's process. M. Pellecier, that during the operation a great quantity of the muriatic acid is expelled from the acid. M. Pelleier has found another method of procuring the arsenical acid. He mixes common white arsenic with nitrous ammoniac, and distills the mixture. At first phlogi- or changed into red fumes, and the latter becomes whiter. Nevertheless, if Mr Scheele's observation of the identity of the acid liquor, which comes over in the distillation of amber with acetic acid, holds good, we shall have the best reason yet given to ascribe the origin of this acid to the vegetable kingdom; and when we consider the very different properties that are ascribed by the vegetable acids, which, however, are convertible into one another, no reason can be drawn from the diversity of its properties with those of other vegetable acids, against its having a common origin with them. Indeed the natural history of amber, its similarity to gums and resins, and its involved infefts, afford other arguments in favour of the opinion.
the arsenic, as it had that necessary to convert it into calx before the operation of converting it into an acid was begun. On the other hand, M. Bergman affirms, that one-fifth of white arsenic is phlogiston, and that this calx is converted into acid merely by being deprived of its phlogiston. Thus the facts related by these two celebrated chemists differ enormously from one another; M. Berthollet affirming that the arsenic gains a ninth of its original weight in the process of acidification; and M. Bergman, that it loses a fifth part of the same. M. Berthollet endeavours to reconcile this, by supposing that Bergman had employed marine acid for the preparation of his arsénical acid, which is well known to carry off with it some part of most of those substances with which it is capable of combining; and to this he attributes the loss of weight in Bergman’s process.

IX. Acid of Molybdæna.

The opinion of M. Bergman concerning the metallic nature of the acid of molybdæna has obtained some confirmation from the experiments of M. Pelletier. He was not able indeed to obtain any regular; but by means of oil alone he procured, by two hours' vehement heat, a substance slightly agglutinated with a metallic lustre, containing small round grains of a grey metallic colour, very visible by the help of a magnifier. These he supposes to have been a true regium of molybdæna; which he found to possess the following properties. 1. It is calcinable by fire into white calx. 2. It detaches with nitre, and the residuum is a calx of molybdæna united with the alkali of the nitre. 3. It is converted into a white calx by means of nitrous acid. 4. It yields inflammable air when treated with alkalies in the dry way, and forms peculiar compounds with them. 4. It forms regenerated molybdæna with sulphur. 6. It unites, and forms peculiar substances with metals. By uniting it with silver, iron, and copper, we have friable reguline masses; and refractory powders with lead and tin.

Our author, in consequence of his experiments, considers molybdæna as a metallic substance mineralized by sulphur; and the earth called the acid of molybdæna as a calx much dephtophosphated, which has retained part of the air contained in the nitrous acid. He observes likewise an analogy between molybdæna and antimony in their chemical refuls. Both of them yield vitrifiable argentine flowers by similar operations, and both are changed into white earths by nitrous acid; but they differ in the two following respects.

1. The latter easily gives a flible regulus; but the molybdæna seems to be the most refractory of all the semimetals. 2. The calx of regium of antimony is soluble by alkalies in the moist way; but that of molybdæna is not.

X. Acid of Tungsten or Wolfram.

Mr Luyant, who has examined this mineral, gives the following account of it. 1. It is infusible by the blow-pipe, though the angles of the pieces into which it is broken are thereby rounded. 2. It effervescs with microcosmic salt, and melts before the blow-pipe into a reddish glass. 3. With borax it effervescs; and by the outward flame of the blow-pipe is changed into a reddish glass; by the internal flame into a green-tined one. 4. Heated by itself in a crucible, it swelled, became spongy, semi-inflamed, and was attracted by the magnet. 5. With an equal part of nitre it denatured, or boiled up with a blue flame round the edges, and nitrous vapours arose. The mass was soluble in water, and let fall a white precipitate with acid. 6. It melted readily with fixed alkali, leaving a kind of black matter in the crucible, and a smaller quantity of lighter coloured sublimate on the filter. Thefe refuls showed a mixture of iron and manganese. 6. With nitrous acid the filtered solution let fall a white precipitate, at first sweet, but afterwtrds bitterish and harsh, and which caused a disagreeable fenation in the throat; and the acidity of the solution of it was manifested, by its turning the tincture of turnip or red.

Having examined the substance by means of liquids in Mr Scheele's way, they obtained the same yellow powder which he had characterized as the acid of wolfram, along with a very small residuum, which appeared to contain a mixture of tin. Proceeding further in the analysis, they found that wolfram is composed of manganese, calx of iron, the yellow matter called the acid of tungsten by Bergman and Scheele, with a very little mixture of quartz and tin, and which they considered as accidental.

They now proceeded to examine the yellow matter, of the yellow matter produced by the two celebrated chemists just mentioned, called the acid by Mr Scheele.
not allow to be a simple acid, though they admit that it contains one; and affirm, that its properties are various according to the circumstances of its precipitation. The properties of it, as described by them, are the following. 1. It is fusible before the blow-pipe, exhibiting the same phenomena as the yellow matter. 2. By calcination in a little pot or telt, it emits the smell of nitrous acid, and turns yellow; but, on cooling, remains white, infipid, and infusible; and this residuum melts by itself before the blow-pipe. 3. A yellow colour is produced either by vitriolic or marine acids; and the filtrated liquor affords a neutral salt with balls of fixed alkali, according to the nature of the acid employed. If the vitriolic acid is employed, and the operation performed in a retort, a quantity of nitrous acid passes over. If, instead of pouring the acid on the salt, it be poured upon its solution, no precipitation will be formed, not even by making the liquor alkali, but without any loss of its property, a fluid is produced, which did not emit the smell of that sort. Having poured nitrous acid upon a portion of the falt, which did not dissolve entirely, in volatile alkali, but without any perfect saturation taking place; and the alkali always prevails. 2. The solution being set in a sand-bath, produced needle-like crystals, which had a sharp bitter taste, exciting a disagreeable sensation in the throat. Their solution turned the tincture of turpentine red, and the liquor from which they were crystallized had the same properties. 3. Having repeated these experiments with different quantities of the same crystals, leaving some longer on the fire than others, solutions were obtained, whose acidity was in proportion to the time they had remained on the fire; but during the operation they all emitted the smell of volatile alkali. By calcination this salt was entirely disintegrated, and the residuum was a yellow powder, perfectly similar to that with which the operation was begun. On making use of a retort for the operation, the remaining powder was blue. 4. This salt precipitates the vitriolic salts of iron, copper, zinc, and alun, calcareous nitre, marine mercurial salt; the acetic salts of lead and copper; and with lime-water regenerates tungsten. The vitriolic acid decomposes it, and forms a blue precipitate; the nitrous and marine acids produce a yellow; but no precipitate is occasioned by the Prussian alkali. 

Having poured nitrous acid upon a portion of the solution with excess of alkali, a white powder was precipitated, which, after edulcoration, had a taste at first sweet, but afterwards sharp and bitter, and its solution turned the tincture of turpentine red. This, on examination, appeared to be a triple salt formed of the yellow powder, volatile alkali, and the precipitating acid.

The following experiments realize the conjecture of Bergman, that the acid of tungsten is the basis of a preparation of the metal.

1. "Having kept 100 grains of the yellow powder (says M. Luys) in a Zamora crucible well covered, and set the whole in a strong fire for half an hour, it became a spongy mass of a bluish black colour, the surface of which was crystallized into fine points, like plumo antimony, and the inside compact, and of the same colour. It was too hard to be broken in pieces by the fingers; and, when ground, was reduced to a dark-blue colour.

2. "Having mixed 100 grains of the same powder with 100 of sulphur, and put the mixture in a Zamora crucible on a strong fire for a quarter of an hour, it came out a dark-blue mass, which was easily broken by the
Acid of tungsten.

CHEMISTRY.

§ 86

Having placed this portion again to calcine over a strong fire in a muffle; it suffered no sensible alteration in weight or colour; for it neither grew yellow, nor took the brown colour of the platinum, but kept the same blackness as before it was calcined. It must be attended to, that in the washings there was not so much care taken to collect all the platinum as to deprive it of the yellow colour, and for this reason the water carried off part of the fine black powder: and consequentially the increase which the platinum preferred, after being washed and calcined the second time, ought to be computed more than the 18 grains which it showed by its weight.

Having mixed the yellow powder with other metals in the preceding proportions, and treated them in the same manner, the result was as follows:

1. With silver it formed a button of a whitish-brown colour, something spongy, which with a few strokes of a hammer extended itself easily, but on continuing them split in pieces. This button weighed 142 grains, and in the most perfect mixture we have obtained, except that with iron.

2. With copper it gave a button of a copperish red, which approached to a dark brown, was spongy, and pretty ductile, and weighed 133 grains.

3. With crude or cast-iron, of a white quality, it gives a perfect button, the fracture of which was compact, and of a whitish brown colour: it was hard, harsh, and weighed 137 grains.

4. “With lead it formed a button of a dull dark-brown, with very little lustre; spongy, very ductile, and splitting into leaves when hammered: it weighed 127 grains.

5. “The button formed with tin was of a lighter brown than the last, very spongy, somewhat ductile, and weighed 136 grains.

6. “That with antimony was of a dark-brown colour, shining, something spongy, harsh, and broke in pieces easily: it weighed 108 grains.

7. “That of bismuth presented a fracture, which, when seen in one light, was of a dark-brown colour, with the lustre of a metal; and in another appeared like earth, without any lustre: but in both cases one could distinguish an infinity of little holes over the whole mass. This button was pretty hard, harsh, and weighed 68 grains.

8. “With manganese it gave a button of a dark bluish-brown colour and earthy aspect; and on examining the internal part of it with a lens, it resembled impure drops of iron: it weighed 107 grains.

ETMULLER is among the first authors who mentions the existence of this acid, and speaks of obtaining it by distillation. Nothing of its properties, however, was known, until Margraafa undertook to examine it; of whose experiments we have an account in the Memoirs of the Berlin Academy for 1749. Since his time a number of chemists have profected the subject.

(a) “The first time we made this experiment, we broke the crucible without letting it cool entirely; and as soon as the matter was in contact with the air, it took fire, and its dark brown colour turned instantly yellow.”
Acid of ants.

The acid in question is a natural juice which the insects discharge when irritated, and which is very pungent to the smell as well as taste. Thus it may instantly be perceived on turning up an ant-hill in spring or summer. The *formica rufa* of Linnæus are those insects which have hitherto supplied this acid. Mr Arvidfon advises to collect them in the months of June and July, by laying some smooth sticks upon an ant-hill; which being then disturbed, the ants will run upon the sticks in great numbers, and may then be swept off into a vessel containing water until it be full. Hermbfadt collects them in the same manner, but into a dry bottle, to avoid the evaporation of the superfuous liquid. Bucholtz having moistened the inside of a narrow necked glass bottle with honey and water, sunk it in a disturbed ant-hill until the mouth was level with the ground; on which the insects, allured by the smell of the honey, went into the bottle, and could not get out.

For obtaining the acid, Margraaf employed distillation, with the addition of fresh water. Thus he obtained, from 24 ounces of fresh ants, 11 ounces and two drachms of acid, some volatile alkali, empyreumatic oil, and a residuum containing earth and fixed salt. Arvidfon made use of two methods: One consisted in distilling the ants when dry; from a pound of which, in this state, he obtained eight ounces of acid besides the empyreumatic oil. His other method was to collect, in a piece of linen, the ants previously cleaned by washing in water, then to pour boiling water upon them, and to repeat the operation until it could extract no more acid; which is then obtained by squeezing the linen, mixing all the liquors, and filtering them. Thus from a pound of ants he obtained a quart of acid liquor, which tasted like vinegar, but was specifically heavier. By distillation Hermbfadt obtained from a pound of dry ants ten ounces and a half of yellow empyreumatic liquor, which did not taste more strongly acid than the spirit obtained by distilling wood, on which floated three drachms of a brown fettid oil, in all respects like that of hartthorn. In the retort was left a black residuum weighing one ounce six drachms, which exhibited signs of containing volatile alkali. By distilling a pound of ants with three of water, according to Mr Margraaf’s method, he obtained an acid liquor and some oil in the receiver; and from the surface of that which remained undistilled, he collected a drachm and an half of fat oil.

The specific gravity of the acid liquor obtained by Mr Arvidfon’s maceration was 1.0011; that of the same liquor, when distilled, 1.0075; and of the acid concentrated by freezing, 1.0453. According to Bucholtz, the acid liquor thus obtained by maceration did not grow in the leaft mufdy in the space of four weeks; during which it was allowed to rest in order to free itself perfectly from the impurities it contained. Mr Hermbfadt, however, prefers Margraaf’s method of distillation to that of Arvidfon’s macerations, not only as being more rapid, but also as less laborious; though he finds fault also with Margraaf’s method, as diluting the acid too much, and altering it so that it has not the smell of living ants. He totally disapproves of the method of distilling dried acid of ants, as the acid is thus in a great measure decomposed, and the remainder united with much oil. To avoid all these inconveniences, he contrived another method, namely, to express the juice of the insects; by which means he obtained at once a concentrated liquor fit for distillation. In this way he obtained from two pounds of dried ants 21 ounces and two drachms of juice, which had a pungent and highly acid smell, resembling the vapours of fluoro acid; in taste resembling concentrated vinegar and acid of tartar; to which last it might be compared for strength of acidity. By distilling eight-ounces of this expressed liquor, he obtained six ounces and a half of clear acid, equal in strength to a very concentrated vinegar.

The acid, when thus procured in purity, has a pungent, not unpleasant smell, a sharp, caustic taste, and of the pure an agreeable acidity. It reddens blue paper, syrups of violets, and litmus; blackens the vitriolic acid, and converts part of it into a sulphurous vapour. It is also decomposed by distillation with nitrous acid. Spirit of falt likewife, when dephlogisticated, decomposes it, but not in its ordinary state. It does not form sulphur by an union with phlogiston, but produces inflammable vapours by dissolving iron or zinc. By the affinities of a gentle heat it dissolves foot, but oils with much more difficulty, and powder of charcoal not at all. It does not unite with vitriolic ether; but in distilling a mixture of this acid with spirit of wine, Mr Arvidfon saw some traces of an ether, and M. Bucholtz perfectly succeeded in making an ether by means of it. It unites with fixed alkali, forming, according to M. Margraaf, a neutral falt, consisting of oblong deliquecent crystals, from which very little acid could be procured by distillation per fe, but on adding concentrated oil of vitriol, a very strong and pure acid was obtained, from a mixture of which with spirit of wine, M. Bucholtz readily obtained a true ether. With mineral alkali it forms deliquecent foliated crystals of a fatty bitter taste, and soluble in twice their weight of water. With volatile alkali it forms an ammoniacal liquor; which, according to Arvidfon, cannot be brought into a dry state; but Mr Arvidfon says he has obtained crystals from it, though very thin and deliquecent. Margraaf obtained dry crystals by uniting this acid, with chalk or coral; and Arvidfon observes that this salt is transparent, cubical, or rhomboidal, nondeliquecent, soluble in eight parts of water, of a bitter taste, and insoluble in spirit of wine. No acid can be obtained from it by distillation per fe. From a solution of magnesia in this acid, Mr Arvidfon obtained some saline particles by deposition, and afterwards an efflorescence of transparent salt rising round a saline mass. This salt had scarcely any taste, was soluble in 12 parts of water, and insoluble in spirit of wine. With ponderous earth the acid formed a cluster of bitter needle-like crystals, which did not deliquece, were soluble in four times their quantity of water, insoluble in spirit of wine, and when burnt gave out a smell like that of burnt sugar, leaving a coal which effervesed with acid. It unites with difficulty to the earth of alum, and can scarcely be saturated with it. It does not precipitate silver, lead, or mercury, from their solution in nitrous acid; whence it seems to have no affinity to the ma-

that the

ripe acid; and as it does not precipitate lime from the marine acid, it seems to have as little with the vitriolic.

From his experiments, however, Margraaff concluded, that the acid of ants, in many respects, though not in all, has a great affinity with the acetous acid. From this it is distinguished by forming different compounds, and likewise by having different affinities. It dissolves the acetous acid also in all instances, and the arseneal acid from cobalt and nickel. It has a greater attraction for fixed alkalis than for lime.

As a solvent it acts but weakly upon copper; not at all, or very little, on silver, lead, tin, regulus of antimony, or bimuth, but strongly on iron or zinc. It dissolves, however, the calces of copper, silver, zinc, and lead, without affecting those of tin, regulus of antimony, or bimuth. The calx of quicksilver, according to Margraaff, is revived by it. According to Avdion, it crystalizes with iron, zinc, or lead; does not act upon the regulus of antimony, of arsenic, cobalt, or nickel; though it dissolves their calces as well as the precipitate of manganife. Gold, mercury, and the calx of platina, are not affected by it; but it crystalizes with those of copper, silver, lead, bimuth, and mercury.

In its strength of attraction, the acid of ants exceeds those of vinegar, borax, and the volatile sulphurous and nitrous acids. Infests armed with stings, as bees, wasps, and hornets, are likewise said to difcharge a very acid juice when irritated; and Mr Bonnet has observed a very strong acid ejected by a caterpillar which he distinguishes by the name of grande cheville du faul a quest fourche. None of these, however, have been as yet particularly examined.

XII. Acid of Apples.

That the juices of unripe fruits contain some kind of an acid has been universally known, and attempts to investigate the nature of it have been made some time ago; but it is to Mr Scheele that we owe the discovery of the particular acid now treated of. He had observed that the juice of citrons contained a peculiar acid; which, by being united with lime, formed a salt very insoluble in water; and which therefore by means of lime could be readily separated from the mucilaginous part of the juice. By adding vitriolic acid to this compound of lime with the acid juice, almost in the same manner in which he used to procure the acid of tartar, the lime was again separated, and the pure acid of citrons obtained. Proceeding in the same manner with other fruit, he found that an acid, agreeing in every respect with that of citrons, could be procured from the juice of the ribes grossularia.

Examining the juice which remained after the separation of the former acid from the citrons, he found that it still contained another acid; which being saturated with more calcareous earth, formed a salt easily soluble in water, and therefore remained suspended in the juice. To separate this new salt, he added some spirit of wine, by which the salt was precipitated; but finding that it still contained much gummy matter, he judged that it would be proper to attempt a separation of this gum before he precipitated the salt. For this purpose he evaporated some of the juice of the ribes grossularia to the consistency of honey, dissolving the mass afterwards in spirit of wine. Thus the acids, which are soluble in the spirit, were easily separated by filtration from the insoluble gum. He then evaporated the spirit, adding to the remainder twice its quantity of water, with as much chalk as was necessary for the saturation. The liquor was next boiled for two minutes; during which the insoluble salt was precipitated, and the liquor separated from it by filtration contained the solution of chalk in the new acid. To this solution he added spirit of wine, which again precipitated the salt, while some faphonaceous and fuccharine matters remained dissolved in the spirit.

Having thus at last obtained the salt in a state of purity, he proceeded to examine its nature; and found, 1. That some of it, spread on his nail, soon dried, and assumed the appearance of varnish. 2. It was very soluble in water, and turned litmus red. 3. When the solution had stood some days exposed to air, it was found to have deposited a number of small crystals, which could only be dissolved by a quantity of boiling water; and this salt was also found to be completely neutralized, so that, it yielded its calcareous earth to a fixed alkali.

The salt was decomposed by heating per fac in a crucible, and left a mild calcareous earth. The acid was separated from the earth by adding oil of vitriol diluted with water until gypsum was no longer precipitated, and the new acid was left disengaged, so that it could be separated by filtration. By this operation, however, all the lime was not precipitated; so that the separation of the acid was not complete. He observed that the acid had a greater attraction for lead than for lime; and therefore made use of the method he had formerly discovered for separating the acid of forrel. To the acid he added a solution of fugar of lead; by which the acid was precipitated along with the lead, and the vinegar was left in the liquor. To this precipitate, cleaned from the acceous acid by filtration, he added vitriolic acid, which expelled the weaker vegetable one, and thus left it quite pure and free from any heterogeneous mixture.

The juice of apples, either ripe or unripe, was found to contain no acid of citrons, but a large quantity of the new acid; which, being thus alone, he could more easily procure by a single operation. The best method of procuring this he found to be by saturating the juice of the apples with a solution of fixed vegetable alkali, and pouring a solution of fugar of lead to that of the salt just mentioned. The effect of this was a double decomposition, and a precipitate of lead combined with the new acid. To the carbonated precipitate he then added a dilute vitriolic acid till he could no longer perceive any sweet taste in the liquor; for the first portions of the vitriolic acid dissolve a part of the calx of lead, and impart a sweetish taste to the liquor, which is fusible, notwithstanding its acridity; but when the quantity of vitriolic acid is sufficient to saturate the whole of the calx, all the metal falls to the bottom, and the sweetness ceases; so that the acid is at once obtained pure.

The acid of apples is possessed of the following properties. 1. It cannot be crystallized, but always remains in a liquid state; or, if much evaporated, extracts the moisture of the air. 2. With fixed alcalies.
Acid. of apples. of all kinds forms deliquescent salts. 3. With calcareous earth it forms small irregularly shaped crystals, which cannot be dissolved in a large quantity of boiling water; but if the acid is superabundant, the salt readily dissolves in lime-water. 4. It is effectual by pungent, earth in the same manner as by lime. 5. Earth of alum, with the acid of apples, a salt not very soluble in water. 6. With magnesia the acid forms a deliquescent salt. 7. Iron is dissolved into a brown liquor, which does not crystallize. 8. The solution of zinc affords fine crystals. 9. On other metals it has no remarkable effects. From the acid of citrons it differs. 1. The acid of citrons yields into fine crystals. 2. The acid of apples can be easily converted into that of sugar, which Mr. Scheele could not accomplish with that of citrons; though Mr. Wetzlumberg has since done it. 3. The salt formed with the citron acid and lime is almost insoluble in water; but that with acid of apples and lime is easily soluble. 4. Acid of apples precipitates mercury, lead, and silver from their solution in nitrous acid, but likewise the solution of gold, when diluted with water; but the acid of citrons does not alter any of these solutions. 5. The acid of citrons seems to have a greater attraction for lime than that of apples.

It is remarkable that this acid is the first produced in the process for making sugar. If a dilute acid of nitro-sulfur be drawn off from a quantity of sugar until the mixture becomes a little brown, which is a sign that all the nitrous acid is evaporated, the syrup will be found to have acquired a fourth taint; and if, by means of lime, we next separate all the acid of sugar, another will still remain, which dissolves the calcareous earth. When this acid is saturated with chalk, and the solution filtered and mixed with spirit of wine, a coagulation takes place. On separating the coagulated part by means of a sieve, dissolving it in water, and then adding some vinegar of lead, the clax of lead will be precipitated; and if the new acid is then separated from the metal by means of diluted oil of vitriol, it will be found to possess all the properties of the acid of apples, and is indeed the same. The spirit of wine, which has been employed to precipitate the calcareous salt, leaves on evaporation a residuum of a bitter taste, very deliquescent, similar to the sapodaceous extract of the citron.

The following are the results of Mr. Scheele's experiments with the nitrous acid upon different substances.

1. From gum arabic he obtained both the acid of apples and of sugar. 2. The same products were obtained from manna. 3. From sugar of milk he obtained not only its own peculiar acid, but those of apples and sugar. 4. Gum tragacanth, during its solution in nitrous acids, lets fall a white powder, which was found to be the acid of the sugar of milk. This gum contained also the acid of apples and of sugar, and a salt formed from lime and the acid of apples. 5. Starch left an undissolved matter; which being separated by filtration, and washed, resembled a thick oil like tallow, which, however, was found to be soluble in spirit of wine. By distillation he obtained from this oil a man sugar acid similar to that of vinegar, and an oil which has the smell of tallow, and congeals by cold; and, besides these substances, he found that starch yielded the acids of apples and sugar.

Acid of apples, with a large quantity of calcareous faccharine salt. 7. Extract of aloes indicated the existence of the acids of sugar and apples, and left the greatest part of its bitter taste. During the digestion a resinous matter was separated, which smelled like flowers of benzoin, and took fire on being heated in a retort. 8. Extract of coloquinti was converted by nitrous acid into a resinous substance, and showed some signs of containing acid of sugar. 9. The extracts of Peruvian bark and of the other plants examined by Mr. Scheele, gave both the acids of apples and sugar.

10. These two acids were likewise obtained from an infusion of roasted coffee, evaporated to the condensation of a syrup. 11. The same products were obtained from an extract of rhubarb, which yielded also a resinous matter. 12. Juice of poppies afforded the same results. 13. Extract of galls did the same. 14. The essential oils afforded little, if none of the acids; but the oil of parley and seeds seemed to be entirely convertible into them. 15. With a very concentrated acid he was able also to decompose animal substances. From glue he thus obtained fine crystals of acid of sugar, and afterwards acid of apples. Fingolfs, whites and yolks of eggs, afforded the same products. From all these substances, especially the last, a fat matter was separated: but it was remarkable that the gas, expelled during the process, was composed of a little fixed air, a great quantity of phlogisticated air, and very little nitrous air, whereas no phlogisticated air is obtained in the usual process for preparing acid of sugar. He observed also that in the process for this acid, a small quantity of vinegar is found in the receiver. He could not obtain the acid of sugar from the sapodaceous extract of urine; but got instead of it a salt, which, when completely purified, resembled exactly the flowers of benzoin. The same salt is precipitated in abundance by adding to the extract of urine a little vitriolic or marine acid; and Mr. Scheele had already remarked that the same salt is obtained in the distillation of sugar of milk.

From the various experiments which have been made on this acid, it seems, according to Mr. Keir, to be in truth of this an intermediate state between acid of tartar and acid of sugar. This, however, ought not to prevent it from being accounted a separate and distinct acid.
and he further informs us, that this acid of apples may be changed entirely into those of sugar and vinegar, by means of strong nitrous acid.

XIII. Acetous Acid.

It is generally believed, that the combination of this acid with volatile alkali is altogether incapable of crystallization; but Scheffer and Morveau inform us, that it may be reduced into small needle-shaped crystals, when the spiritus Mindereri is evaporated to the confine of a syrup, and left exposed to the cold. The salt has a very sharp and burning taste, but a considerable quantity is lost during the evaporation. Weftendorf, by adding his concentrated vinegar to volatile alkali, obtained a transparent liquor which did not crystallize. By distillation it went over entirely into the receiver, leaving a white spot on the retort. A saline transparent mass, however, appeared in the receiver under the clear fluid. On separating it from the liquid, and exposing it to a gentle heat, it melted, threw out white vapours, and in a few minutes shot into sharp crystals ressembling nitre. These remained unchanged in the cold; but when melted with a gentle warmth, smoked and evaporated. Their taste was first sharp, and then sweet.

The salt formed by uniting acetous acid with calcareous earth has a sharp bitter taste, and flowers into crystals somewhat resembling ears of corn. These do not delugate in the air, unless the acid has been superabundant. They are decomposed by distillation per fe, the acid coming over in white inflammable vapours smelling like acetous ether, somewhat empyreumatic, and condensing into a reddish brown liquor. By rectification this liquor becomes very volatile and inflammable; on adding water, it acquires a milky appearance, and drops of oil seem to flow upon the surface; a reddish brown liquor, with a thick black oil, remain after rectification in the retort. On mixing this calcareous salt with that of Glauber, a double decomposition takes place; we have a gypsum and the mineral alkali combined with acetous acid. By calcination, the mineral alkali may be obtained from this salt in a state of purity. This acetous calcareous salt is not soluble in spirit of wine.

On saturating this acid with magnesia, and evaporating the liquor, we obtain a viscid salinie mass like mucilage of gum arabic, which does not flow into crystals, but dilates in the air. It has a sweetish taste at first, but is afterwards bitter. It is soluble in spirit of wine, and parts with its acid by distillation without addition.

Acetous acid dissolves zinc both in its metallic and calciform state, and even when mixed with other metals. By concentrated vinegar the zinc is dissolved with great heat, sulphureous smell, and exhalation of inflammable matter. By this union we obtain a congealed mass, which on dilution with warm water flows into oblong sharp crystals, or the first crystallization, and afterwards into crystals of a flattened form. From this liquor indeed crystals of various forms have been obtained by different chemists. Mounet obtained from it a pearl-coloured salt in friable talcy crystals; which when thrown on the coals, crystallized a little at first, and gave a bluish flame, and then melted, letting its acetous acid escape, while a yellow calx remained. Hellest acid informs us, that this salt by distillation per se in water, affords an inflammable liquor, and an oil at first yellow and then green, with white flowers burning with a blue flame. Weftendorf obtained no oil in this distillation, but some acetous acid; a sweet-tasted empyreumatic liquor impregnated with zinc; sweet flowers, or sublimate, soluble in water, and burning with a green flame. On applying a stronger heat, the zinc was sublimed in its metallic form, leaving a spongy coal at the bottom of the retort. The solution gives a green colour to syrup of violets, lets fall a white precipitate on the addition of alkalis or an infusion of gall. It is not precipitated by common salt, vitriolated tartar, vitriolic or marine acids, blue vitriol, or corrosive sublimate; but forms a red precipitate when added to a solution of gold; a white precipitate with solution of silver; a crystalline pearly precipitate with solution of mercury; and crystalline precipitates with solutions of bismuth and tin. According to Bergman, it is decomposed by acid of arsenic.

Though regulus of arsenic is not soluble in this hydrochloric acid, its calx may be dissolved either in common or distilled vinegar. M. Cadet obtained a smoking liquor by distillation from a mixture of white arsenic and terra foliata tartari. This experiment has been repeated by the chemists of Dijon, and attended with the following curious circumstances. “We digested (say they), in a sand-bath, five ounces of distilled vinegar on white pulverized arsenic; the filtrated liquor was covered, during evaporation, with a white faine crust. Of this substance were formed 150 grains; on which fixed alkali appeared to have no effect, and which was at first considered as pure arsenic. However, a cat, which had swallowed 72 grains of it, was only affected with vomitings that day and the next, and afterwards perfectly recovered. A similar dose of vinegar was given to a little dog; but as he ran away, the supposed to effect it had upon him could not be discovered; but he was afterwards returned after good health, and never showed any uneasiness—whence it may be concluded that vinegar is in some measure an antidote against the pernicious qualities of arsenic. “On redissolving this faine crust in pure water, filtering and mixing it with liquid alkali, an irregularly crystallized salt was formed in it afer a few days standing. By this salt a yellow precipitate was thrown down from the nitrous solution of silver; whereas the solution of arsenic and terra foliata tartari threw down a white one.

Equal parts of terra foliata tartari and arsenic, distilled in a retort, gave first a small quantity of limpid liquor with a penetrating smell of garlic, and which had the property of reddening syrup of violets; while solution of arsenic in water turns that syrup green. The vinegar which now arose was not faturated when arsenic, but effervesced strongly with fixed alkali, with which it became turbid, but did not let fall any precipitate. On changing the receiver, there came over a reddish brown liquor, accompanied with thick vapours, diffusing an intolerable smell, in which that of arsenic could scarcely be distinguished. On continuing the operation, a black powder sublimed into the neck of the
Acetous acid.

The red liquor still preserved its property of smoking though cold; diffusing at the same time its peculiar and abominable fetor, from which the apartment could scarce be freed in several days. This liquor does not alter the colour of syrup of violers, but effervesces slightly with fixed alkali, letting fall at the same time a yellow precipitate, which, however, disappeared on an attempt to separate it by filtration.

M. Cadet had observed, that the smoking liquor of arsenic did not kindle at the approach of a lighted candle; but that, on pouring it from the receiver into another vessel, it had kindled the fat lure with which the juncutures had been cloathed, and which had been dried during the operation: but we, being devious of examining more fully the nature of the red liquor which collects at the bottom, and has the appearance of oil, having decanted that which swims on the top, and poured the remainder on several days paper, before many drops had passed, there arose a thick smoke forming a column from the vessel to the ceiling; a flight ebullition was perceived at the sides of the vessel, and a beautiful rose-coloured flame appeared for a few moments. The paper filter was burnt at one side, but most of it was only blackened. After the flame was extinguished, a fat reddish matter remained: which being melted on burning coals, swelled considerably, emitting a white flame. It then sunk, and left on the coal a black spot, which could not be effaced but by the most vehement fire.

At the time these observations were made, the liquor had been distilled for three weeks, and the bottle frequently opened. The inflammability could not proceed from the concentration of the vinegar: for the rofe-colour of the flame, the precipitation of the sublimate, and the fixity of the spot remaining on the coal, evidently showed that the two substances were in a state of combination; which is also further evinced by the los of the inflammable property when the liquor was decomposed by fixed alkali. The smell of the liquor, however, though so intolerably fetid, was attended with no other inconvenience than a disagreeable sensation in the throat, which further strengthened the suspicion that vinegar is an antidote against arsenic.

The saline brown mass remaining in the retort was partly dissolved by hot water; and the filtrated lixivium was very limpid, but emitted the peculiar smell of the phosphoric liquor. By evaporation it yielded a salt which did not deliquece in the air, of an irregular shape; and which being put on burning coals, did not smear febibly of arsenic; lost its water of crystallization; and became mealy and white without being disipated by heat. On exposing the residuum to the air, it was found next day resolved into a liquor; whence it is probable that most of it was composed of crystallized alkali, having received from the decomposition of the vinegar as much fixed air as was necessary for its crystallization.

This acid does not act upon mercury in its metallic state, but dissolves the mercurial calces, as red precipitate, turbid mineral, and the precipitate formed by adding fixed alkali to a solution of mercury in nitrous acid; with all which it forms white, shining, feally crystals, like those of sedative salt.

Vinegar does not act upon silver in its metallic state, but readily dissolves the yellow calces precipitated from its solution in nitrous acid by microcosmic salt and volatile alkali. By the help of a boiling heat also it very copiously dissolves the precipitate obtained by means of a fixed alkali. The least mentioned solution yields shining, oblong, needle-shaped, crystals, which are changed to a calx by means of several acids, especially the muriatic. The silver is thrown down in its metallic form by zinc, iron, tin, copper, and quicksilver.

Though the acetic acid has no effect upon gold in its metallic state, yet a solution of this metal is decomposed by crude vinegar, which produces both a metallic precipitate and dark violet-coloured powder. Diftilled vinegar throws down the gold in its metallic form. The precipitate by fixed alkali digested with and volatile acid is of a purple colour. This, as well as fulminating gold, is dissolved by Westendorff's concentrated vinegar; the fulminating gold very easily.

The solution is of a yellow colour; and with volatile alkali affords a yellow precipitate; with lixivium fanguinis, a blue one, both of which fulminate. The dry salt of gold dissolves in the acetic acid, and produces oblong yellow crystals.

This acid has no effect on far oils, farther than that on inflammable when distilled together, some mixture takes place, as malleable subliment the Abbe Rozier has observed. Neither does distilled vinegar act upon essential oils, though M. Westendorff's distilled vinegar dissolved above a fixth part of oil of rosemary, and about half its weight of camphor. The latter solution was inflammable, and let fall the camphor on the addition of water. The acid dissolves all the true gums, and some of those called gum-refins, after being long digested with them. By long boiling, Boerhave observes, that it dissolves the bones, cartilages, flesh, and ligamaments of animals.

The concentration of this acid may be effected by concentrating it with alkalies, earths, and metals. By tincture of the combining it with copper, and then crystallizing and acetic acid distilling the compound, we obtain the acid in the highest state of concentration in which it is usually produced. To produce this, we have only to distill verdigris, or rather its crystallized form in a retort. The operation must be begun by a very gentle fire, which brings over an aqueous liquor. This is to be set aside, in order to procure the more concentrated acid, which comes over with a stronger fire.

On changing the receiver, and augmenting the heat, we obtain a very strong acid which comes over partly in drops, and partly in white vapours. It is called radical vinegar, or sometimes spirit of Venus, and has a very pungent smell, almost as suffocating as that of volatile sulphurous acid. As the last portions of it adhere pretty strongly to the metal, we are obliged to raise the heat to such a degree as to make the retort quite red in order perfectly to separate them. Hence some part of the metal is raised along with the acid, which, dissolving in the receiver, gives the liquor a greenish colour; but from this it may be easily freed by a second distillation, when it rises with a very gentle heat, and the retort, together with a little arsenic in its metallic form, and a matter which took fire by a lighted candle like sulphur.

"The red liquor still preserved its property of smoking though cold; diffusing at the same time its peculiar and abominable fetor, from which the apartment could scarce be freed in several days. This liquor does not alter the colour of syrup of violers, but effervesces slightly with fixed alkali, letting fall at the same time a yellow precipitate, which, however, disappeared on an attempt to separate it by filtration."
Acetic acid.

And becomes extremely white. Crystals of verdigris afford about one half their weight of radical vinegar; but verdigris itself much less, and of a more oily quality.

If this acid be heated in a wide-mouthed pan, and fire applied to it, it will burn entirely away like spirit of wine. This observation we owe to the count de Lauragais, who has likewise observed, that it is capable of crystallization. This, however, takes place only with the last portions which came over, and the crystals appear in the form of plates or needles. The marquis de Courtrivon, who has repeated and confirmed the experiment of the count de Lauragais, supposes this phenomenon to be owing to a sulphur-like mixture of acetic acid and phlogiston. Leonhardi supposes an analogy between these crystals and the white crystals of acetic acid and phlogiston. Leonhardi supposes an analogy between these crystals and the white salt of copper expelled at the end of the operation by the count de Laflone. This salt was at first very white, and fixed on the neck of the retort pretty thick; but unless quickly collected, was soon destroyed by the succeeding vapours. When exposed to the air, it attracts moisture, and runs into a greenish liquid. It is uncommonly light, and in such small quantity, that scarce five or six grains can be collected from a pound of verdigris. Its taste is acid, astringent, very unpleasant and permanent. It readily and totally dissolves in water, and partially in spirit of wine, leaving a yellow powder totally soluble in volatile alkali, and imparting a leathery, not oily, but roughened appearance to its air.

Experience has shown that radical vinegar differs considerably in its properties from the common acid. It has a greater attraction for alkalis, forms with them more perfect combinations, and is less volatile. M. Berthollet observes, that when vinegar concentrated by frost and radical vinegar, are reduced to equal densities, by adding water to the heavier of the two, they differ very much both in smell and taste. Laflone found, that radical vinegar formed a crystallizable compound with volatile alkali; and Berthollet has observed the same with regard to fixed vegetable alkali. The crystals of the latter with radical vinegar were flat, transparent, and flexible, slowly deliquescent in the air. On comparing the salts formed by the two acids, he found, that the accesor salt rendered the syrup of violets green; but its colour remained unaltered with that made with radical vinegar. The latter also required a stronger fire to expel part of its acid; it was also whiter, and had a less acid taste. On pouring radical vinegar on the acetic salt, the solution afforded, by evaporation and crystallization, a salt perfectly similar to that procured directly from radical vinegar and fixed alkali. On distilling the mixture, the radical vinegar appeared to have expelled the common acetic acid, as the liquor which came over effervesced with vegetable alkali, and formed with it a terra fossilataria.

"It seems probable (says Mr Keir), that the radical vinegar contains a larger portion of the aerial principle than the common acetic acid; by which it undergoes a change similar to that of marine acid, when brought into that state in which it is said to be dephlogisticated. This air it may acquire from the metallic salt, which being deprived of its air is reduced acid.
small feathery crystals are formed, of a sharp saline taste, and easily soluble in water. 11. An arfrigent salt is formed with earth of alum.

All these earthy salts are easily decomposed by the mineral acids as well as by alkalies. The acid of benzoin itself reddens litmus, but has little effect upon fyrup of violets.

effects of nitrous acid upon it.

From it spirit of nitre, as in the preparation of acid benzoin cured from nitre, either by precipitation, from the nitrous acid, and ur unarmed from that on treatment tallow in the usual manner for obtaining acid of fugar; for thus, not the sebaeous, but the facharine acid is found to be produced. It has a very great force of attraction, and by means of heat decompounds even the vitriolic salts themselves; but in the moist way is expelled by the three mineral acids, though it expels all the vegetable ones, as well as those of flour and arsentic. Its most remarkable property is its effect on tin. The filings of this metal, especially with the assistance of heat, are corroded by it into a yellow powder, and at the same time give out a very fetid smell. The solution, though filtered, still continues turbid, and deposits more yellow powder, acquiring at the same time a fine rofe-re colour. By adding water to this yellow powder, a white deliquecent salt may be obtained, and a similar one obtained by dissolving a yellow powder precipitated by this acid from solution of tin in aqua-regia.

It corrodes lead rather than dissolves it; but dissolves a considerable quantity of minium, and changes the reft to a white powder. This solution is sweetish, and is not precipitated by common salt. The metal is precipitated by sebaeous acid from the nitrous, in white needle-like crystals, easily soluble in water. A like precipitation takes place in solution of fugar of lead; but the precipitate is fill soluble in strong vinegar, provided it be not adulterated with oil of vitriol.

In its elective attractions it agrees with the acids of apples and of flour, preferring magnesia to fixed alkali.

XVI. Acid of galls.

Though it has for a long time been known that the infusion of galls has the property of reddening vegetable juices, dissolving iron, and decomposing liver of sulphur, these effects were generally ascribed to its astringency. Of late, however, it has been found that besides this astringent principle a true acid exists in galls; and to this, rather than to the astringent principle, are we to ascribe the properties of galls in inflating a black with solution of vitriol, &c.

To separate the acid from the other matters contained in the galls, we must add fixed alkali to a decoction of them; by which means the astringent matter will be thrown down, and the acid remain in the liquor joined to the alkali, the precipitate, washed with clean water, dried, and redissolved, blackened a solution of vitriol but faintly, and no more than what may be supposed to proceed from some remaining acid, which could not be abstrafed. This is proved by dissolving

(a) By this is meant urine evaporated to a thick consistence, and deprived of most of its salts by solution in spirit of wine.
CHEMISTRY.

Acid of galls.

An acid obtained from galls by distillation.

Filling the astringent matter in question, when an acid liquor comes over, has the property of blackening solution of vitriol. Scheele observed, that when acid liquor of an agreeable smell, without oil, and afterwards a kind of volatile salt, which is the true acid of the galls. Hence he infers, that this salt is contained ready formed in the galls themselves; but so much involved in some gummy or other matter, that it cannot be easily obtained separately.

The acid of galls is capable of being separated by crystallization. In an infusion made with cold water, Scheele observed a sediment which appeared to have a crystalline form, and which was acid to the taffe, and had the property of blackening solution of vitriol. By expelling the infusion for a long time to the air, and removing from time to time the muddy skin which grew upon it, a large quantity of sediment was formed.

On redissolving this in warm water, filtering and evaporating it very slowly, an acid salt was obtained in small crystals like sand, which had the following properties: 1. It tasted acid, effervesced with chalk, and reddened litmus. 2. Three parts of boiling water dissolved two of the salt; but 24 parts of cold water were required to dissolve one. 3. It is likewise soluble in spirit of wine; four parts of which are required to dissolve one of the salt when cold, but only an equal quantity when afflited by a boiling heat.

The salt is deliquescent by an open fire, melts and burns with a pleasant smell, leaving behind a hard insoluble coal, which does not easily burn to ashes.

By distillation an acid water is first obtained without any oil; then a sublimate, which remains fluid while the neck of the retort is hot, and then crystallizes. This sublimate has the taste and smell of flowers of benzoin; is soluble in water and in spirit of wine; reddens litmus; and precipitates metallic solutions of the following colours, viz. gold of a dark brown; silver of a grey colour; copper of a black; lead of a white colour; mercury of an orange; bismuth, lemon-coloured. The acid of molybdana became yellow coloured, but no precipitate ensued. Solutions of various kinds of earths were not altered; but lime-water afforded a copious grey-coloured precipitate. 6. By treating this acid with that of nitre, in the manner directed for producing acetic acid of fugar, it was changed into the latter.

XVII. Identity of the Vegetable Acids.

On the proofs of the identity of the vegetable acids with one another, Mr Keir makes the following remarks: "The experiments and observations which have been made, prove evidently a strong analogy between the acetic acid, spirit of wine, tartar, and acid of fugar; and they seem to show the existence of a common principle or basis in all of them, modified either by the addition of another principle not common to all of them, or by different proportions of the same principle. None of the opinions on this subject, however, are quite satisfactory. The production of the acetic acid by treating spirit of wine with other acids, does not prove that the acetic acid was contained in the spirit of wine, but only in concurrence with them, that they contain some common prin-

There is no fact adduced to support Morveau's identity, that fixed air is absorbed during the acetic fermentation; or that the presence of this fixed air is necessary. The decomposition of all vegetable acids by heat, and the production therefrom of fixed and inflammable gases, show that these acids contain none of the same principles as these elastic fluids, but do not prove that the gases existed in the fluids. We have good reason to believe that acetic acid does not contain any fixed air already formed; for it yields none when vitriolic acid is added to it, or to foliated earth; nevertheless, my opinion that vegetable and animal acids are, by heat, in a great measure convertible into fixed air, seems to be sufficiently proved by experiments.

Thus Hales has shown the great quantities of this gas which tartar yields on distillation. Berthollet has obtained the fixed and inflammable gases from foliated earth; and Dr Higgins has verified this experiment, and deduced the quantities. From 7680 grains of foliated earth, the Doctor obtained:

Cautic alkali - 3862.994 grains.
Fixed air - 1475.594.
Inflammable air - 1047.6018.
Oily matter retained in the re- 

Iiduum - 78.
Oil - 182.
Water condensed - 340.
Deficiency attributed chiefly to water - 726.0402.

As fixed and inflammable gases may be obtained from every vegetable substance by fire, nothing can be inferred from these experiments to explain particularly the nature of the acetic acid, excepting that it contains some of the inflammable matter common to the vegetable kingdom, and especially of the matter common to vegetable acids; all which also, when analysed, furnish large quantities of these two gases.

"Although we are far (adds our author) from the knowledge requisite to give a complete theory of the acetic fermentation, yet it may be useful to explain the ideas that appear most probable. In all the instances that we know of the formation of acids, whether effected by combustion, as the acids of sulphur and phosphorus, or by repeated abstractions of nitrous acid, as in the process for making acetic acid of sugar, a very sensible quantity of pure air is absorbed. In the case of combustion we know, from the weight acquired, that there is a great absorption of air; and in the latter case, of acids being produced by application of nitrous acid, as this acid consists of nitrous and pure air, and as in these operations a quantity of the nitrous gas is expelled, there seems but little doubt that there also the pure air of the nitrous acid is united with the substance employed in the formation of the new acid. Hence, from all that we know, the absorption of air takes place in all acidifying processes. But it also actually takes place in the acetic fermentation, as has been observed, particularly by the Abbé Rozier; and it is generally known, that air is necessary to the formation of vinegar. The next question is, What is the basis? And from the experiments already related, of forming the acetic acid by means of spirit of wine, it seems probable, either that this spirit is the basis of the acetic acid, or that it contains this basis; and from the convertibility of the acids of tartar and of fugar.
Identity of sugar into the acetic acid by the processes above described, it seems probable that these also contain the same common bases; which, being united with a determined quantity of pure air, forms acid of tarter; with a larger quantity, acid of sugar; and with a still larger, the acetic acid.

"An inflammable spirit is said to appear at the end of the distillation of radical vinegar from verdigris. Now, if the ardent spirit were contained in the verdigris, as it is more volatile than the acid, it ought to come over first; but as it appears only towards the end of the distillation, it seems to be formed during the operation; and I imagine, that the metal, when almost deprived of its acid, attracts some of the air of the remaining acid; and the part or basis of the acid thus deprived of its air becomes then an inflammable spirit, and in some cases an oil appears. But as the quantity of acid thus decomposed is very small, and little air of consequence remains united with the metallic part of the verdigris, the copper appears rather in a metallic than calciform state after the operation. But zinc, during its solution in concentrated vinegar, decomposes the acid as it does the vitriolic and other strong acids, and accordingly inflammable vapours are produced; and what is remarkable, these vapours have a sulphureous smell. Iron always, during its solution to like inflammable gas.

We must not imagine that we are yet able to explain completely what passes in the acetic fermentation, or that the acetic acid is a compound of mere spirit and pure air. Besides this combination of spirit and air, it is observed, that a precipitation always takes place before the fermentation is completed, of some mucilaginous matter, which dipoles the vinegar to putrefy, and from which it therefore ought to be carefully separated. Stahl affirms, that without a deposition of such sediment, vinegar cannot be made from sugar, wine, or other juice. Besides the matter that is deposited, probably as mucilaginous as the liquor as ever been observed therein; for, by distillation, much of a similar extractive matter is left in the retort. What the nature of this matter is, and how it is formed, has not yet been examined. Though distillation frees the acid from much of this extractive substance, yet we have no reason to believe that we have ever obtained it entirely free from inflammable matter; as it retains even when combined with alcalies and with metals. When sugar of lead and other acetic salts are distilled with a strong heat, the substances remaining in the retort have been observed to possess the properties of a pyrophorus; and this will happen whatever pains have been taken to purify the vinegar employed. See the article Pyrophorus. This shows the existence of an inflammable matter in this acid; and which may perhaps be essential in its composition, and necessary to its properties. Although fermentation is the usual mode of obtaining acetic acid, yet it appears from the instances observed by latter chemists, that it is not essential to its formation, but that it is also formed in various chemical processes; and the acid obtained by distillation from woods, wax, &c. are very analogous to vinegar. It appears also on treating the acid of sugar with nitric acid, as has been observed both by Weframb and Scheele. The latter further acquaints us, that he obtained it in analysing a tallow like oil, which remained undisolved upon digesting starch in nitrous acid. As acid of sugar also may be obtained from a variety of animal substances, and as this acid is convertible into the acetic we have one reason more added to many others, to prove that the matters of vegetable and animal substances are not capable of any chemical distinction."

XVIII. ADDITION TO SECT. I. § 20. concerning the volatility of a Mixture of Marine and Nitrous Acids.

This is much less sensible when the acids are weaker than when they are concentrated. On mixing the two when moderately smoking, and which had remained for a long time separate without occasioning any disturbance, a vividly smoking aqua-regia has been produced, which would either drive out the flopple, or burst the bottle in warm weather. On distilling a pretty strong nitrous acid from sal ammoniac, Mr. Bèrthé observed, that the vapours which came over were so exceedingly elastic, that notwithstanding every precaution which could be taken in such a case, the distillation could not be continued. By letting this escape, however, Mr. Cornette observed, that the distillation of these two substances may be carried on to the end, without any inconvenience, and the aqua-regia will then be no longer troublesome.

XIX. TEST for ACIDS and ALKALIES.

The general method recommended for discovering a small quantity of acid or alkali in any liquid, is by trying it with any vegetable blue, such as syrup of violets; when, if the acid prevails in the liquor, the syrup will acquire a red colour, more or less deep according to the quantity of acid; or if the alkali prevails, it will change the syrup green in like proportion. Since the late improvements in chemistry, however, the syrup has been found deficient in accuracy, and the infusion of turpentine, or of an artificial preparation called litmus, have been substituted instead of it. The infusion of limus is blue, and, like syrup of violets, becomes red with acids. It is so sensible that it will discover one grain of oil of vitriol though mixed with 100,000 of water. Unfortunately, however, this infusion does not change its colour on mixture with alcalies; it is therefore necessary to mix it with just such much vinegar as will turn the infusion red, which will then be restored to its blue colour by being mixed with any alkaline liquor. The blue infusion of limus is also a test of the presence of fixed air in water, with which it turns red, as it does with other acids.

The great sensibility of this test would leave very little reason to search for any other, were it always an exact test of the point of saturation of acids and alcalies; but, from the following fact, this appears to Mr Watt to be dubious. A mixture of phlogisticated nitrous acid with an alkali will appear to be acid by the test of limus, when other tests, such as the infusion of the petals of the scarlet rose, of the blue iris, of violets, and of other flowers, will show the same liquor to be alkaline, by turning green so evidently as to leave no room to doubt.

When Mr. Watt made this discovery, the scarlet rose...
Red cabbage answers the purpose of both more sensibility with regard to acids than litmus, but much less than paper, and dry them in a dry, put them up in glass bottles well corked; and, with vitriolic acid, and digest or infuse the dry leaves in it, ... filter it immediately; otherwise it ... green nor purple; when it has received this colour, filter it immediately; otherwise it ... paper, and dry them in a gentle heat; when perfectly dry, put them up in glass bottles well corked; and, when you want to use them, acidulate some water with vitriolic acid, and digest or infuse the dry leaves in it, until they give out their colour; then strain the liquor through a cloth, and add to it a quantity of fine whiting or chalk, stirring it frequently, until it becomes of a true blue colour, neither inclining to green nor purple; when you perceive that it has acquired this colour, filter it immediately; otherwise it will become greenish by standing longer on the whitening. This liquor will deposit a small quantity of gypsum, and, by the addition of a little spirit of wine, will keep good for some days; but will then become somewhat putrid and reddish. If too much spirit is added, it destroys the colour. If the liquor is wanted to keep longer, it may be neutralized by a fixed alkali instead of chalk.

2. As thus the liquor cannot be long preferred without requiring to be neutralized aforest jove before it is used; and as the putrid fermentation which it undergoes, and perhaps the alkalies or spirit of wine mixed with it, seem to lessen its sensibility; in order to preserve its virtues while kept in a liquid state, some fresh leaves of the cabbage, minced as above directed, may be infused in a mixture of vitriolic acid and water, of about the degree of acidity of vinegar; and it may be neutralized, as it is wanted, either by means of chalk, or of the fixed or volatile alkali. It must be observed, however, that if the liquor has an excess of alkali, it will soon lose its colour, and become yellow; from which state it cannot be restored; care should therefore be taken to bring it very cautiously to a blue, and not to let it verge towards a green.

3. In this manner, Mr. Watt prepared a red infusion of violets; which, on being neutralized, formed a very sensitive test, though he did not know how long these properties would be preserved; but he is of opinion that the coloured infusions of other vegetables may be preserved in the same manner by the antifeptic power of the vitriolic acid, in such a manner as to lose little of their original sensibility. Paper fresh stained with these tests, in their neutral state, has sufficient sensibility for many experiments; but the alum and glue which enter into the preparation of writing paper, seem, in some degree, to fix the colour; and paper which is not fixed becomes somewhat transparent when wetted; which renders small changes of colour imperceptible. Where accuracy is required, therefore, the test should be used in a liquid state.

Mr. Higgin's claims the first discovery of the constituent parts of volatile alkali, or at least of an experiment leading to it. "About the latter end of March 1785 (says he), I found that nitrous acid poured on tin filings, and immediately mixed with fixed vegetable alkali, generated volatile alkali in great abundance: so singular a fact did not fail of deeply impressing my mind, though at the time I could not account for it. About a fortnight after, I mentioned the circumstance to Dr. Brockleby. He told me he was going to meet some philosophical gentlemen at Sir Joseph Banks's, and desired I would generate some alkali to exhibit before them; accordingly I did; and had the pleasure of accompanying him thither. The December following I mentioned the fact to Dr. Cauet, and likewise the copious generation of volatile alkali from Prussian blue, vegetable alkali, and water; on which we agreed to make a set of experiments upon the subject. At present I shall only give an account of the following, which drew our particular attention. Into a glass cylinder, made for the purpose, we charged three parts of alkaline air, and to this added one part of dephlogisticated air; we passed the electrical spark repeatedly in it, without apparently effecting the smallest change. When it had received about 100 strong shocks, a small quantity of moisture appeared on the sides of the glass, and the brastr conductors seemed to be corroded; when we had passed 60 more shocks in it, the quantity of moisture seemed to increase, and acquire a greenish colour, though at this time the column of air suffered no diminution. On examining the air, it burned with a languid greenish flame, from which we inferred that the dephlogisticated air was totally condensed: it still retained an alkaline smell; and the alkaline part was not readily absorbed by water.

XX. VOLATILE ALKALI.
Prussian blue.

XXI. **Prussian Blue.**

The acid of this substance, as far as it contains an acid, is supposed to be that of phorphorus. Mr. Woulfe proposed a test of this kind for discovering iron in mineral waters, which, he observed, would not be affected by acids; but the lixivium described by him had the bad property of letting fall the Prussian blue it contains in a few weeks. The precipitate of copper, however, treated again with alkali, retained this property upwards of nine months. The volatile alkali, he observes, is dissolved by the Prussian acid; and the crystals deposited are rendered blue by the colouring matter, though the colour at first is lost by the union of the alkali with the substance already made. The metals were precipitated by this test of the following colours: Gold of a brownish yellow, the precipitate afterwards becoming of a full yellow; platina of a deep blue, but when quite pure, of a yellow colour, turning slightly green. Silver in the nitrous acid was precipitated of a whitish colour; copper from all the different acids was precipitated of a deep brown colour, the liquid remaining greenish; green vitriol left a deep blue powder, leaving a colourless lixivium; sugar of lead and mercurised tin gave a white powder; nitrated mercury a white or yellowish precipitate; the Hillfeld manganese a brownish blue, but that from Devonshire a blue, which first became ash-coloured and then reddish. Nitrated bismuth afforded a white precipitate, and the lixivium was slightly green; mercurised antimony yielded a white precipitate, with a yellowish lixivium: vitriolated zinc a whitish cobalt in aqua-regia a reddish white powder: the precipitate of arsenic and the different earths was commonly white.

XXIII. **New Chemical Nomenclature.**

When this nomenclature was first published, M. Lavoisier informs us, that some blame was thrown upon the authors for changing the language, which had received the function of their matters, and been adopted by them. In answer to this, however, he urges, that Meffrs. Bergman and Maquer had expressed a wish for some reformations in the chemical language. Mr. Bergman had even written to M. Morveau on the subject in the following terms. "Show no favour to any improper denomination: those who are already possessed of knowledge, cannot be deprived of it by new terms; those who have their knowledge to acquire, will be enabled by your improvement on the language of the science to acquire it sooner."

The following is M. Lavoisier's explanation of the principles on which his new language is composed, and new nomenclature.

"Acids confit of two substances, belonging to that order which comprehends such as appear to us to be simple substances. The one of these is the principle of acidity, and common to all acids; from it therefore should the name of the class and genus be borrowed: the other, which is peculiar to each acid, and distinguishes them from one another, should apply the specific name. But in most of the acids, the two constituent principles, the acidifying and the acidified, may exist in different proportion, forming different degrees of equilibrium or saturation; this is observed of the sulphur and sulphurous acid. These two states of the same acid we have expressed by varying the termination of the specific name.

"Metallic substances, after being exposed to the compound action of air and fire, lose their metallic luster, gain an increase of weight, and assume an earthy appearance. In this state they are, like acids, compound bodies, consisting of one principle common to all, and another peculiar to each of them. We have therefore in like manner classed them under a generic name, derived from the principle which is common to them all, the name which we have adopted is Oxide: The peculiar names of the metals from which they are formed, serve to distinguish these compounds from one another.

"Combustible substances, which, in acids and metallic oxides, exist as specific and peculiar principles, are capable of becoming, in their turn, the common principle of a great number of substances. Combinations of sulphur, were long the only compounds of this sort known; but of late the experiments of Meffrs. Vandremonde, Monge, and Berthollet, have shown that coal combines with iron and perhaps with various other metals; and that the result of its combination with iron are, according to the proportions, steel, plum-bago, etc. It is also known from the experiments of M. Pelletier, that phorphorus combines with many metallic substances. We have therefore arranged these different combinations together under generic names, formed from the name of the common substance, with a termination indicating this analogy; and have distinguished them from each other by specific names derived from the names of the peculiar substances."
CHEMISTRY.

It was found some time more difficult to form a nomenclature for the compounds of those three simple substances; because they are so very numerous, and

still more, because it is impossible to express the na-
ture of their constituent principles, without using more
compound names. In bodies belonging to this class,
such as neutral salts for instance, we had to consider,
1. the acidifying principle common to them all; 2. the
acidifiable principle which peculiarizes the acid; 3.
the saline, earthy, or metallic base, which determines
the particular species of the salt. We have derived the
name of each class of salts from that of the acidifiable
principle, common to all the individuals of the class;
and have then distinguished each species by the name of
the saline, earthy, or metallic base peculiar to it.

As salt, consisting of any three principles, may,
without losing any of these principles, pass through
different states by the variation of their proportions;
our nomenclature would have been defective without
expressions for these different states. We have expres-
sed them chiefly by a change of termination, making
all names of salts in the same state to end with the
same termination.

In Wiegleb's General System of Chemistry translita-
ted by Hopln, we have another nomenclature formed
on different principles. In this he gives to fixed ve-
getable alkali the name of Spodium, from the Greek
word ςποδίων (spodion). The mineral alkali he calls natrum,
the name by which it was anciently distinguished; and
the volatile alkali ammonium, from sal ammoniac which
contains it in great quantity. The compound salts
may be distinguished into double, triple, and quadru-
ple; though, in the scheme given in the work, the first
division is omitted, as tending only to create confusion.
The irregular salts, consisting of those which are triple
and quadruple, are admitted. Such as are imperfect
by reason of an excess of acid, he says, are best deno-
minated by converting the adjective, expressive of the
base, into a participle; a practice which, on many oc-
casions, though countenanced by the authority of a late
eminent writer, seems awkward and stiff. The excess
of acid is denominated by the word hyperoxys, and a
defect of it by hypoxys. Hence his denominations are
formed in the following manner.

Salts with excess of acid. Cream of tartar, or tarta-
rus spodatus, or tartaroxys spodicus. Acid vitriolated
tartar, or vitriolatum spodatum, vitrioloxys spodicus.
The salts which are imperfect from a defect of acid
have their denominations by mentioning the base before
the acid, and expressing the former substantively, the
latter adjectively. Thus,

Salt of tartar, aerated vegetable Oxyfpeodium, aero-
alkali, spodium aerocraticum, { arocraticum.
Acid vitriolated alkali, ammoni-
Oxysmonium, o
um aerocraticum.

Oxycalcitis aero-

Oxynatrum bora-
cisticus.

With respect to other terms, Mr Wiegleb expresses
the acid with which any base is combined, by the ter-
mination erotic, from the Greek σποδις (spodion), added
to it; excepting only those with the nitrous and mu-
riatic acids: and these (for what reason does not ap-
pear) he calls Aponitra and Epimurit. His genera of
salts are as follow,

6. Arsenicates. 7. Barylithicrates, (those with acid
of tungsten). 8. Molybdanocrates. 9. Photocrates,
(with acid of phosphiur). 10. Elecrocates. 11. Oxy-
crates, (with the acetic acid); or epoxycrates, with
the aerated acid). 12. Tartars; or, with the acid changed
(with the acid of gall). 15. Citriocrates. 16. Meli-
crates (with the acid of apples). 17. Benzocrates. 18.
Acrocates. 22. Galacocrates. 23. Galac-meliiocrates
Cyanoocrates (with the colouring matter of Prussian
blue). 26. Serocrates. 27. Bombycicrates. 28. Zo-
halithocrates, (with adjadic of calculus).

On the subject of nomenclatures it is obvious to
remark, that whatever may be the defects of the old
one, we are ready to be involved in much greater
difficulties by the introduction of a new one. Or sup-
pousing a new language to be adopted, where would
be the security for its permanence? That which ap-
pears most specious at one period, may still be su-
perfected by the refinements of another; and colourable
pretensions would never be wanting to succesive inno-
vators. Hence a continual fluctuation, and an endless
vocabulary. As the nomenclature first abovemention-
ed, however, has attracted so small degree of attention,
we shall here subjoin a scheme of it, as well for the
satisfaction of our readers in general, as for the gratifi-
cation of those in particular who may have imbibed the
doctrines of its authors.

[Follows The Whole-sheet Table.]
TABLE, showing the Manner in which Natural Bodies, considered in a Chemical View, may be divided into Clases; with their several Subdivisions; their Properties defined; and the Manner in which they are obtained, pointed out.

NATURAL BODIES, considered as the Objects of Chemistry, may be divided into the following Clases, viz.

1. SALTS. 2. EARTHS. 3. METALS. 4. INFLAMMABLES. 5. WATERS. 6. AIRS.

I. SALTS.

These are soluable in water, rapid, and not inflammable. They are either Acids or Alkalis.

1. Acids are distinguished by turning syrup of violets red, or forming with alkalis neutral salts; and are supposed to consist of dephlogisticated air condenved, as their acidifying principle. The different acids yet known are, 1. Vitriolic, fixed. The most ponderous of all fluids next to mercury, the most fixed in the fire, and the most powerful of all the acids. Obtained chiefly from sulphur by inflammation.

2. Vitriolic, volatile. Obtained also from sulphur by inflammation; air being admitted during the process. It acts less powerfully as a solvent than when in its fixed state.

3. Nitrous or Aquafortis: a volatile fluid, generally met with of a reddish colour, and emitting noxious fumes, when in its concentrated state; though this is found not to be essential to it, but owing to a mixture of phlogiston. In its pure state it is almost as colourless as water, and stinks very little. It is next in strength to the vitriolic acid, and obtained chiefly from nitre. It consists of dephlogisticated and phlogisticated air condenved, and may be obtained by taking the electre spark for a long time in a mixture of these. By uniting with some metals it appears to be converted into volatile alkali.

4. Muriiure, or spirit of sea-salt. A volatile fluid, generally of a fine yellow colour; though this also is owing to the admixture of foreign substances, generally of iron. Inferior in power to the former, and obtained from sea-salt. Naturally this acid seems to be in an aerial state, but easily contracts an union with water. On mixture with manganese, it is wholly converted into a yellow, and almost indecomposible vapour, called dephlogisticated spirit of salt; but which, on mixture with inflammable air, recombines the marine acid.

5. Florid acid. Obtained from a species of spar, has little acid power, but is remarkable for its property of corroding glasses.

6. Acid of borax, or volatile salt. Obtained from borax in the form of fclay crystals; found also naturally in some waters in Italy, and in certain minerals in other countries.

7. Acetic acid. Obtained by allowing any fermentable liquor to proceed in the fermentation till past the vinous state. It is much less corrosive, and less powerful as a solvent, than the vitriolic, nitrous, or marine acids.

8. Acid of tartar. Procured from the hard substance called tartar, deposited on the fides of wine vessels.

9. Acid of sugar. Found naturally in the juice of ferrel, and procured artificially by means of nitrous acid from sugar and a great variety of other substances. Assumes a dry form.

10. Acid of phosphorus. Obtained artificially from urine, and in large quantity from calcined bones; found naturally in some kinds of lead-ore; and in vast quantities in Spain united with calcareous earth. Assumes a solid form, and melts into gla6s.

11. Acid of ants. Procured from the animal from which it takes its name, by expression or distillation, in a fluid form.

12. Acid of amber. Obtained in a solid form from amber.

13. Acid of arsene. Obtained from that substance by means of nitrous acid. It is extremely fixed in the fire.

15. Acid of lapis pondersius, tungsten, or wolfram. Obtained as an acid, per fo, from this substance by Mr. Scheele; but its real acidity is denied by other chemists. Is in the form of a yellow powder.

16. Acid of milk. Obtained in a fluid form from that liquor.

17. Acid of sugar or milk. Obtained in a form of a white powder, by means of nitrous acid, from sugar of milk.

19. Acid of benzoin. Obtained in a solid form from that gum by sublimation or lixiviation with quicklime.

20. Acid of lemon. Obtained from the juice of that fruit by crystallization.

21. Sebaceous acid, or acid of fat. Obtained in a fluid state from fruit by distillation.

22. Acid of citrus. Obtained in a fluid state from the juice of that and other fruits.

23. Acid of apples. Obtained in a fluid state from the juice of apples and other fruits.

24. Acid of forrel. Obtained in a solid form from the juice of that plant, the same with acid of sugar.

II. ALKALIS. These turn syrup of violets green, and with acids form neutral salts. They are,

1. Fixed vegetable, or Potassa. Always obtained from the ashes of burnt vegetables. A deliquescent salt.

2. Fixed jada. A solid crystalline salt, sometimes found native, as the natrum of Egypt; and sometimes by burning sea-weed as kelp.

3. Volatile. Obtained from sal ammoniac, from the foot of burning bodies, and from the putrefactive fermentation. It is naturally in the state of an invisible and elastic vapour, constituting a species of aerial fluid, and consists of phlogisticated and inflammable air.

NEUTRAL SALTS.

These are always compofed of an acid and an alkali, and are of many different kinds, as may be seen in the following table.

EARTH SALTS.

Composed of an acid joined to an earthy basis, as alum and gypsum. See the following table.

METALLIC SALTS.

Formed of an acid and metal. The principal of these are vitriols, the others may be seen in the following table.

ESSENTIAL SALTS.

Obtained from vegetables, and contain an acid joined with the juices of the plant in a particular manner not to be imitated by art. To these belong sugar, mansa, honey, and others of that sort.

II. EARTHS.
CHEMISTRY.

II. EARTHS.

These are solid bodies, not soluble in water, nor inflammable; and if fused in the fire, never resume their earthy form again, but take that of glass. They are divided into absorbent, crystalline, and argillaceous.

I. Absorbent Earths are capable of being united with acids, and are either calcareous, or not calcareous.

1. **Lime-stone, or marble.** This is of infinite variety as to colour and texture. Marble is the hardest and finest. Those kinds of lime-stone which feel unctuous to the touch, are generally impregnated with clay; those that feel gritty, or where the lime is hard and weighty, contain sand; this is the best for building; the other for manure.

2. **Clay.** A white, friable, soft substance. This is much more free of heterogeneous matters than any lime-stone, and is easily calcined into quicklime. It is probably nothing else than lime-stone suddenly concreted without being crystallized.

3. **Sea shells.** Such as found plentifully everywhere. With alkaline substances they are easily changed into glass; and hence are used in medicine.

4. **Terra pondersa.** A fine white earth sometimes found combined with fixed air, but more commonly with the vitriolic acid; and forming with it a very heavy compound, named lapathum pondersa. It is found in mines and veins of rocks.

b. The absorbent earths which cannot be reduced into quicklime are,

1. **Magnesia alba.** A white earth, usually found combined with the vitriolic acid, and forming bitter purging salt. It is likewise obtained from the mother-levy of nitre, the ashes of burnt vegetables, &c.

2. **Earth of alum.** A particular kind of absorbent earth, found in many places mixed with sulphureous pyrites, as in Yorkshire, &c. Clay of any kind may by a particular process be converted into this earth.

3. **Earth of animals.** This is obtained by the calcination of animal substances, and by precipitation in the process for making acid of milk. It can hardly be converted into glass; and is therefore used as a basis for white enamels, &c. It is said to consist of the phosphoric acid united to calcareous earth.

II. Crystalline or Vitreous Earths, are hard, and strike fire with flint; may be calcined in the fire; but are not soluble in acids.

a. Of this kind are,

1. **Sand and Flint;** found plentifully everywhere. With alkaline substances they are easily changed into glass; and hence are termed vitreous.

2. Precious stones of all kinds are likewise referable to this class; but they are of a much greater degree of hardness and transparency than the others.

III. Argillaceous Earths are distinguished by acquiring a very hard consistence when formed into a paste with water, and exposed to a considerable degree of heat; not soluble in acids. They are,

1. **Common clay.** It is of many different colours; but chiefly red, yellow, or white. The purest is that which burns white in the fire.

2. **Medical bauxite.** These are of different sorts; but are only a purer kind of clay, sometimes mixed with a little iron or other matters.

3. **Lapis nephriticus, or fleasite.** These are indurated clays, found in various parts. They are at first soft and readily cut; but turn extremely hard in the air. Many other varieties of these earths might be mentioned; but as they do not differ in their chemical properties so much as in their external appearance, and being all mixed with one another, they more properly belong to the natural historian than the chemist.

III. Metallic Substances.

These are bodies of a hard and solid texture; fusible in the fire, and resuming their proper form afterwards; not miscible with water, nor inflammable. They are divided into Metals and Semimetals.

I. Metals are malleable; and the species are,

1. **Gold.** The most ponderous and fixed in the fire of all bodies except platinum, and the most ductile of any. It has a yellow colour, and is more commonly found in its metallic state than any other metal. It has no proper ore; but is found in ores of silver, and almost all sands contain some of it.

2. **Silver** is next to gold in malleability and ductility; but less fixed in the fire than either it or platinum. It is sometimes found in its native state; but most commonly in that of an ore with sulphur, sometimes with arsenic, and assuming different appearances.

3. **Platina.** A white metal of a greater specific gravity than gold, and altogether as fixed in the fire; the most difficult to be melted of all known substances; refuting the tales which usually have been applied for discovering the purity of gold, supposed from hence to be the fairest of the ancients. Found in South America.

4. **Copper.** Of a reddish colour, hard and sonorous; admits of being extended greatly under the hammer, either hot or cold. It is difficult of fusion. It is generally found in the flake of an ore with sulphur. There are a great variety of ores of it, extremely beautiful, blue, red, green, and yellow.

5. **Iron.** A grey-coloured metal, extremely ductile when hot; the lightest of them all except tin. It is the only metal certainly known to admit of being welded; though platina is likewise said to posses some share of this property. It is likewise the only one capable of being tempered by cooling. It is found almost everywhere; and its ores are infinitely various.

6. **Tin.** A white soft metal, the lightest of the whole, and very ductile. The ores of it are generally arseneal, and assume a crystalline appearance; their colour being most usually of a dark brown, and sometimes very beautiful.

7. **Lead.**
Table.

CHEMISTRY.

7. Lead. A metal of a dull bluish colour, exceedingly soft and malleable, and very weighty. Seldom found in its metallic state, but usually in an ore with sulphur or arsenic; but seldom with sulphur alone. The principal ores of it are the cubic, called galena and the glaysy, called spar.

8. Mercury or quicksilver; formerly accounted a semimetal, on account of its fluidity, but now reckoned among the most perfect metals. It is a white, opaque, metallic body; fluid, except in a very intense degree of cold; very heavy, and easily volatilized by heat. Sometimes found in its fluid form, but usually in a beautiful red ore with sulphur, called cinnabar.

II. SEMIMETALS are brittle, and do not stretch under the hammer. They are,

1. Zinc. A bluish white substance of a fibrous texture, considerably hard and sonorous, with a small degree of ductility; easily fused and volatilized. Its principal ore is lapis calaminaris.

2. Bismuth or tin-glaf. A white ponderous, hard, brittle and sonorous body, of a plated texture; easily fused and vitrified. It is only reduced to an ore by arsenic. Its appearance much the same with regulus of antimony.

3. Antimony. A blackish substance, of a fibrous needle-like texture; hard, brittle, and of a considerable weight; not difficult of fusion, and easily convertible into glafs. Its only ore is with sulphur, which is the crude antimony.

4. Arsenic. A bright, sparkling, whitish-coloured semimetal; of a plated texture; very brittle, and extremely volatile. It is generally found in the ores of other metals.

5. Cobalt. A brittle semimetal fusible in a moderate heat, and easily convertible into a beautiful blue glafs, called finalt. It is always obtained from an arfenchale ore, likewise called cobalt.

6. Nickel. A reddish white substance, of a close texture, and very bright; easily melted, but very difficult to vitrify.

IV. INFLAMMABLE SUBSTANCES,

Are those which continue to burn of themselves when once set on fire. They are divided into oils, sulphur or brimstone, alcohol or ardent spirits and charcoal.

I. OILS are thickish, viscous fluids, not miscible with water. Divided into animal, vegetable, and fossil.

a, b. The animal and vegetable oils are,

1. Expressed. These are of a mild and bland taste, inodorous, and not soluble in alcohol. They are obtained by expression, as oil of olives, rape-seed, almonds, &c. Animal fats are of the same nature, as is also wax.

2. Essential. These are always obtained by distillation, posses the taste and flavour of the subject from whence they are drawn, and are soluble in alcohol. Of this kind are oil of cloves, spike, &c. The oil of ants is an example in the animal kingdom.

3. Empyreumatic. These are obtained by a considerable degree of heat, and posses an acidic taste and burnt-like flavour, as oil of hartshorn. They are soluble in spirit of wine.

4. Fossil oils. These are found in the earth in their native state; and are called, when pure, naphtha; which is of an acidic taste, and extremely volatile, not miscible with alcohol. A great many inflammable fossils contain this, as bitumens, pit-coal, &c.

II. SULPHUR or BRIMSTONE. This is a dry friable substance, not miscible with water. It is found in many mineral substances, metallic ores, &c. but is for the most part met with in pyrites. Great quantities of it are found in the neighbourhood of volcanoes.

III. ALCOHOL or ARDENT SPIRITS. This is a fluid of an acidic and volatile nature, miscible with water; obtained from fermented vegetable juices by distillation; as from the juice of the grape, malt-liquors, rice, &c.

IV. CHARCOAL. The residuum of most inflammable matters after undergoing distillation with a strong fire. A black substance, acted upon with difficulty by acids; soluble in bary-sulphur, and entirely dissoluble into inflammable air by a very violent heat. Of great use as fuel, and essentially necessary in metallurgy and other arts.

V. WATER.

A colourless inelastic fluid well known. It is either simple or mineral.

I. Simple, or pure-rain-water, as it called, though the most homogeneous fluid of this kind with which we are acquainted, is not perfectly pure, but always contains a portion of mucilaginous matter, which can never be perfectly separated. It is supposed to consist of dephlogisticated and inflammable air condensed.

II. MINERAL waters are these spring-waters impregnated with saline substances; the diversity of which is exceeding great; but they all agree in having an acid joined with them. The most common sorts are impregnated with iron and sulphur.

VI. AIR.

An invisible and permanently elastic fluid, is of the following kinds: Dephlogisticated, phlogisticated, fixed or fixable, inflammable, nitrous, vitriolic acid air, marine acid air, dephlogisticated marine acid, alkaline air, hepatic air, atmospheric air.

1. Dephlogisticated. An elastic fluid naturally extricated in the processes of vegetation; artificially procured from nitre, sulphuretum, manganese, water, &c. eminently capable of supporting flame and animal life. One of the component parts of our atmosphere.

TABLE, showing the several Combinations that the SIMPLE CHEMICAL ELEMENTARY BODIES admit of with one another; the Compound resulting from that Mixture; and the Manner in which the Union is effected: With some Account of the principal Uses to which these are applied in Arts or Manufactures.

N. B. This mark*, put above any word, denotes that there is some difficulty in the process, or that the union is not very complete.

**VITRIOLIC ACID may be combined with the following substances, viz.**

<table>
<thead>
<tr>
<th>ACIDS.</th>
<th>ALKALIES.</th>
<th>EARTHS.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nitrous Acid. A mixture which readily inflames oils. By solution, generating heat.</td>
<td>Muriatic, Vegetable, and all other Acids yet known. By solution, generating heat. But these mixtures are applied to no particular use in medicine or arts.</td>
<td>Calcareous. Secret ammonia. By solution. Formerly suppos'd a most powerful menstruum for metals, &amp;c. but without any just foundation.</td>
</tr>
<tr>
<td>Muriatic, Vegetable, and all other Acids yet known. By solution, generating heat.</td>
<td>Vegetable. Nitrum vitriatum. A vitriolated tartar, obtained by distilling from nitre with the vitriolic acid.</td>
<td>Terra ponderosa. With this it unites in preference to alkalis, forming a very heavy and insoluble substance called <em>spathum ponderosum</em>.</td>
</tr>
<tr>
<td>Vitriolated tartar. By solution and crystallization, or double elective attraction from a great variety of bodies.</td>
<td>Sal polychrestum. By deflagrating nitre with sulphur. There are many other kinds of vitriolated tartar, known formerly by different names, and suppos'd to be pollosed of particular properties, but they are now neglected.</td>
<td>Cyphium or Paris-plaster. Often found in a native state. May be artificially formed by precipitating from a solution of chalk in a very concentrated nitrous acid. Used as a cement: for taking impressions from medals, &amp;c.</td>
</tr>
<tr>
<td>By precipitation from a very dilute solution of chalk in the nitrous acid, by means of the vitriolic acid.</td>
<td>A corroded calx. By simple corrosion. This when perfectly edulcorated with water is found to be a true gypsfum.</td>
<td>Tale aæffet, &amp;c. A native production which cannot be perfectly imitated by art. Used for holding objects in microscopes, making incombustible cloth, &amp;c.</td>

</table>

**CALCAREOUS EARTHS.**

- Magnesia. Effon, or magnesia Glauber's salt. By solution and crystallization. Much used in medicine for the same purposes as real Glauber's salt.
### CHEMISTRY

**Earth of Alum.** *Alum.* By solution, crystallization, &c. Used by dyers as a preparatory for taking on the colours, papermakers, goldsmiths, &c.

**Earth of Animals, Osteocella, &c.** By solution. The mixtures of these are not applied to any particular use.

**Clay*.** *Aluna.* By digelling pure clay for some time in this acid, and exposing it for some time to the air, an alum is produced; and if the clay is precipitated from this aluminous concrete, it is found to be a pure earth of alum, soluble in all acids.

**Flint.** A thickish coagulum. By digelling the liquor filices in the vitriolic acid.

**Gold*.** Imperfectly. By a particular process after being separated from aqua regia.

**Silver*.** By solution, after it has been precipitated from the nitrous acid by alcalies. The fumes which arise in this solution are inflammable.

**Copper.** *Blue vitriol.* This is sometimes a native production, but in this way it is never pure. It is artificially prepared by solution in a very concentrated acid, and crystallizing it.

**Iron.**

- *Salt of iron.* By calcining the crystals of green vitriol till they are converted into a white powder.
- *Caleochar of vitriol.* By continuing the calculation till it assumes a brown colour.

**Lead.** An indiffoluble concretor. By precipitation from the nitrous acid.

**Tin.** *Jupiter corrosivus,* or *infertilis* of Paracelsus. By boiling heat, and repeated coctions with fresh acid when it is evaporated.

**Mercury.**

- *Ignis Oechnus,* or *infernalis* of Paracelsus. By a boiling heat, and repeated coctions with fresh acid when it is evaporated, and then washing with water.

**Antimony*.** A metallic salt. By elective attraction from butter of antimony.

**Zinc.** *White vitriol.* Often found in its native state. Artificially made by solution and crystallization in a diluted acid. Used by painters for drying.

**Bismuth.** A corroded calx. By solution in a concentrated acid.

**Arsenic.** By ditto.

**Cobalt.** A rose-coloured mixture. By solution. If this is precipitated by a fixed alkali, and again dissolved, the liquor appears of a beautiful red.

**Expressed.** A blackish gummy-like mass. By solution, generating a considerable heat. Native gums are supposed to owe their origin to a mixture of this kind.

**Essential.** A dark-coloured resinous mass. A great heat and violent efferecence being produced by this mixture. Native refrains supposed the same.

**Oils.**

- **Empyreumatic.** Little known. By solution.
- **Fossil.** A substance resembling amber. By solution.

**Sulphur*.** Here there is no proper union of substances; but if sulphur is boiled in this acid, it becomes less inflammable and more fixed than any ordinary sulphur.

- *Vitrineal ether.* By careful solution and distillation, the ether being separated by the addition of water.
- *Spirit of vitriol dulext.* By solution and distillation.
- *Oleum dulext.* By continuing the heat after the ether has arisen.
- *Oleum aurcrentum mineral.* By redistilling the residuum of the last with alcohol. A medicine much celebrated by Hoffman.
- *Sulphur.* By putting the heat after the oil comes over. It is to be observed that this is produced in every combination of this acid with metals or alum.

**WATER.** An acidulated water. Sometimes, though seldom, found issuing along with native springs. Applied to no particular use.

**Nitrous Acid** may be combined with the following substances, viz.

**Vitriolic,** as above.

**Acids.**

- *Muratic.* *Aqua regia.* By solution. This is the only proper menstruum for gold; and it is a solution of tin in this menstruum which is the basis of the scarlet dye.
- *Vegetable,* and all others. By ditto. These compounds have no particular names, nor are applied to any particular uses in medicine or arts.

**ALKALIES.**

- *Fossil.* *Cubic nitre.* By solution.
- *Volatile.* *Nitrous ammoniac.* By solution. This differs from all the other ammonical salts, by being soluble in alcohol.

**EARTHS.**

- *Calcaneous.* Deliquescence crystals. By ditto and crystallization.
- *Earth of Alum,* and all other absorbent earths. By solution. The compounds have no names nor any remarkable properties hitherto discovered.

**Crystaline Earths*.** By solution after precipitation from the liquor filices.
## CHEMISTRY

Table.

### GOLD
- Slightly impregnated. By a boiling heat in close vessels, after the ordinary method of separating silver from gold by the nitrous acid. It spontaneously subdues in the air.
  - A fluid solution. By solution. This when diluted with water stains hair and bones black; as also marble, agate, jasper, &c. of different colours.

### SILVER
- Sal metalleum. By solution and crystallization.
  - Catarrhium lunaire, lunar caustik, or lapic infernalis. By inculpating the solution to dryness.

### COPPER
- A green-coloured solution. By solution.

### IRON
- A greenish solution, if a diluted acid is employed; if otherwise, it is of a yellowish colour: evaporated to dryness, it depletes in the air.
  - A yellow solution. By dissolving in a diluted acid. If much water is added, the metal is precipitated.

### LEAD
- Saturati fulminans. By inculpating the solution. This explodes when put upon the fire with greater force than nitre, and has been proposed to be used as an ingredient in gun-powder to augment its force.

### TIN
- A solution or corroded calx. By a careful solution without heat it remains suspended; if otherwise, it falls down in form of a calx. This is commonly shipped to be the composition used in dyeing scarlet; but by mistake: for it is a solution of tin in aqua-regia that communicates that fine colour to cochineal. The same solution is the basis of the powder which tinges glass of a ruby colour. It is the precipitate of gold from aqua-regia by means of tin.
  - A limpid solution, intently corrosive. By solution.

### MERCURY
- Red precipitate. By evaporating the solution to dryness, and then calcining till it is reduced red.
- Mercurius corrosivus fistus. By precipitating from the nitrous acid by fixed alkali.
  - White precipitate. By ditto with the volatile alkali.

### BISMUTH
- A greenish solution. By using a concentrated acid. This might be applied in some cases in the art of dyeing; but is not yet come into general use.
  - Magistery of bismuth. By precipitating from the solution by means of water. This has been employed as a cosmetic, but is inefficacious and unsafe. If mixed with pomegran, this stains hair of a dark colour without injuring it.

### ZINC
- A corroded solution. By the ordinary means.
  - A colourless calx. By simple corrosion.

### ANTIMONY
- Bzoaric mineral. By distilling from butter of antimony, after having added the nitrous acid.
- Antimonium diaphoreticum. By adding nitre to crude antimony, and desaglating.
- Cerusa antimonii. By desaglating regulus of antimony with nitre.

### COBALT
- Rose-coloured crystals. By adding muriatic acid, and allowing it to crystallize.
- Green sympathetic ink. By dissolving these crystals in water. The solution is red when cold, and green when warm; when wrote with, it disappears when dry; but when held to the fire it becomes green; and again disappears when cold.

### NICKEL
- An expressed. A thick bituminous-like substance. Upon the mixture a considerable degree of heat is generated, and sometimes, though very seldom, actual flame is produced.
  - Expressed. A thick bituminous-like substance. Upon the mixture a considerable degree of heat is generated, and sometimes, though very seldom, actual flame is produced.

### ESSENTIAL
- Ditto. A more violent heat is generated upon the mixture with these oils than any other, and with many of them an actual flame is produced.

### OILS
- Empyreumatic. This mixture has no name, nor is it applied to any remarkable use in arts.

### FOSSILE
- Ditto.

### ALCOHOL
- Nitrous ether. By distilling; the ether arising to the surface.
- Spiritus nitri dulcis. By distilling a little, and then distilling.

### WATER
- Acidulated water. By solution.

The MURIATIC ACID may be combined with the following Substances. viz.

### ACIDS
- Vitriolic and Nitrous. As in the former part of this Table.
- Vegetable, and all others yet known. By solution: but as none of these mixtures are applied to any particular purpose, we take no notice of them.

### VEGETABLE
- Digilose. By solution and crystallization.

### FOSSILE
- Sal grem. A native foible salt, found in mines in Poland, Spain, etc. of the same nature as common salt, but more pure.

### VOLATILE
- Common ammoniac. Obtained at large by a particular process from foot. Artificially made by mixing the acid and alkali, and crystallizing.

### EARTHS
- Liquid shell. By solution. A substance whose effects in medicine have been greatly extolled.
- Calcareous. By evaporating liquid shell to dryness. It naturally deliquesces.

### OSTROCHELLA, MAGNESIA, and other absorbents. By solution: but the properties or uses of these are not known.
### Table.

</tbody>
</table>

**V I N E G A R** may be combined with the following Substances, viz.

**ACIDS.**

**VITRIOLIC** | Nitrous, and Muriatic, as in the above table. It likewise unites with all other acids, generating heat; but the properties or uses of these are not known.

**Vegetable.** Regenerated tartar. By solution and crystallization.

**Alkalies.**

**Fossil.** Polybrest of Rochelle. By ditto.

**Volatile.** Spiritus Mindereri. By solution.

**EARTHS.**

**Magnesia.** Dr. Black's purging salt. By solution. It unites with all the other absorbent earths; but the properties of these mixtures are unknown.

**Copper.** Verdegri. By solution and crystallization; or at large, by stratifying copper-plates with the hulks of the grape.

**Iron.** Sal martis aperiens. By solution and crystallization.

**Lead.** Saccharum Saturni. By solution and crystallization.

**Tin** | This is not properly dissolved; but the acid is evidently impregnated. By the ordinary means of solution.

**Mercury** *A fluid solution.* | By employing a precipitate of mercury from the nitrous acid by alkalies.

**Zinc** | A colourless solution of a sweetish taste. By digesting for some time.

**SEMIMETALS.**

**Antimony**, *Vinum benedictum.* This is not a proper solution of the metal, but the acid is impregnated with an emetic quality.

**Arsenic** | Vinum arsenicicum. By ditto. A curious phosphoric liquor.

**Bismuth** | An auffere flippic liquor. By strong coction.

**Oils** | The union here is imperfect, nor have any of them obtained particular names.

**Alcohol.** A mixture much used for anointing sprains, &c.

**Water.** Acidulated water.

**ACID** or **TARTAR** may be combined with the following Substances, viz.

**ALKALIES.**

**Vegetable.**

Cream of tartar with excess of acid.

Soluble tartar, when completely saturated.

**Fossil.** Rochelle salt.

**ALKALIES.**

A salt very difficult of solution with excess of acid.

**Volatile.** A beautiful and soluble salt when perfectly saturated.

**EARTH.**
CHEMISTRY.

Table.

EARTH.  
Calcaceous. An indissoluble felenite.
METALS.  
Copper. A fine green colour for painting.
SEMIMETAL.  
Cobalt. Emetic tartar.

ACID or URINE may be combined with the following substances, viz.

ACIDS of all kinds. The nature of these not known.

Fixed Vegetable. A salt not easily crystallized, the nature of which is not known.

Fossil. A fine crystallized salt used in medicine.

Volatile. A glass-like saline substance called microcrystalline salt. The acid is always found in this state by evaporating urine.

VITRESCENT EARTHS. A glass of different sorts. By fusion.

Lead. An inflammable malleable mass. By calcining the dry salt with lead.

Tin. A mass resembling zinc; and inflammable. By ditto.

Copper. A corroded powder, or green solution. By a boiling heat in a watery solution of the acid.

Mercury. A semi-opaque mass. By fusion with the acid, in its solid form.

Zinc. A true phosphorus. By fusion with the dry acid.

Antimony. A brilliant striated mass. By fusion with the dry acid.

Arsenic. A mixture but little changed in appearance from ordinary bismuth. By fusion.

OILS. BALDWIN'S PHOSPHORUS. By distilling with substances that contain oils or inflammable matter.

FLUOR ACID, may be combined with the following substances, viz.

ALKALIES.

Fixed Vegetable. A gelatinous saline mass which cannot be crystallized. Great part of it is also diffused by evaporation to dryness.

Fossil. A substance similar to the foregoing.

Volatile. Lets fall a quantity of siliceous earth, and forms a crystallizable ammoniacal salt.

Lime.

Magnesia. A gelatinous matter.

Earth of Alum.

Siliceous Earth. After long standing, crystals of quartz.

Silver. The calxes of these metals partially dissolved; but the properties of the solution unknown.

Quick Silver.

Copper. The calx easily soluble, and affording blue crystals; the metal only partially so.

Iron. Disolved with violence with the emission of inflammable vapours into an uncrystallizable liquor.

ACID or SUGAR may be combined with the following substances, viz.

ALKALIES.

Fixed Vegetable. A salt scarce capable of crystallization when perfectly neutral.

Fossil. A salt difficultly soluble in water.

Volatile. An ammoniacal salt flowing into quadrangular prisms.

Lime. A kind of felenite from which the acid cannot be separated by a burning heat.

Terra Ponderosa. A salt formed into angular crystals, scarce soluble in water.

Magnesia. A white powder insoluble without an excess of acid.

Earth of Alum. A yellow pellucid mass incapable of crystallization, and liquefying in the air.

Gold.

Silver.

Platina.

Quick Silver.

The calxes of all these metals dissolved, but the nitre of the solutions unknown.

SEMIMETAL. Cobalt. A yellow-coloured salt forming a sympathetic ink with sea-fall.

INFLAMMABLES. Alcohol. An ether which cannot easily be set on fire unless previously heated, and burning with a blue flame.

ACID or BORAX or SEDATIVE SALT may be combined with the following substances, viz.

ALKALIES.

Fixed Vegetable. A native substance, which may be imitated by art. It is of great use in promoting the fusing of metals and earths.

Volatile. An ammoniacal salt flowing into small crystals, and melting by an intense heat into a greyish-coloured glass.

EARTHS.

Magnesia. A salt crystallizable in vinegar and acid of ants. Decomposed by other acids and spirit of wine.

Earth of Alum. In certain proportions a salt difficult of solution; in others a hard mass resembling pumice-stone, yet partially soluble in water.

METALS.
**Table.**

<table>
<thead>
<tr>
<th>METAL.</th>
<th>SEMIMETAL. (BISMUTH)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>IRON.</strong></td>
<td>An amber-coloured solution yielding crystals of a yellow colour.</td>
</tr>
<tr>
<td><strong>ARSENIC.</strong></td>
<td>A crystallizable compound shooting into pointed ramifications, or forming a greyish, white, or yellow powder.</td>
</tr>
<tr>
<td><strong>ALKOHOL.</strong></td>
<td>A solution with a considerable heat, which burns with a green flame.</td>
</tr>
<tr>
<td><strong>WATER.</strong></td>
<td>A solution in a considerable heat. The other mixtures with this acid not known.</td>
</tr>
</tbody>
</table>

**ALKALIES.**

- **FUSED VEGETABLE.** A transparent and crystallizable salt, but deliquescent.
- **FOSSIL.** A crystallizable salt not deliquescent.
- **VOLATILE.** An ammoniacal salt shooting into acicular crystals.
- **LINE.** A crystallizable salt, difficult of solution and not deliquescent. Decomposed by common salt ammoniac.
- **MAGNESIA.** A gummy deliquescent saline mass, not crystallizable.
- **EARTH OF ALUM.** A prismatic salt incapable of decomposition by alcalies.
- **SILVER.** A salt shooting into thin oblong crystals obtained from the precipitate; but no solution of the perfect metal.
- **COPPER.** A crystallizable salt of a green colour.
- **IRON.** A crystallizable salt of a brown colour.
- **TIN.** A crystallizable salt from the precipitate, scarcely to be decomposed by alcalies.
- **LEAD.** A crystallizable salt from the precipitate.
- **ZINC.** A crystallizable salt.

**SEMIMETALS.**

- **BISMUTH.** A crystallizable salt from the precipitate, not to be decomposed by alcalies.
- **REGULUS OF ANTIMONY.** A solution of the precipitate.

**ALKALIES.**

- **FUSED VEGETABLE.** A crystallizable salt, deliquescent in the air.
- **FOSSIL.** A salt of a similar nature.
- **VOLATILE.** An ammoniacal liquor, crystallizable with difficulty.
- **CHALK OR CORAL.** A crystallizable salt which does not deliquesce.
- **MAGNESIA.** A saline liquor scarcely crystallizable.
- **TERRA PONDEROSA.** An ammoniacal liquor, crystallizable with difficulty.
- **EARTH OF ALUM.** Unites with difficulty, and scarcely to the point of saturation. The nature of the compound not known.
- **SILVER.** By solution. The calx of silver precipitated from aquafortis by alcalies; but does not act upon it in its metallic state.
- **COPPER.** Beautiful green crystals. By dissolving and crystallizing calcined copper. It acts slowly upon it in its metallic state.
- **LEAD.** A salt resembling faccharum saturni. By dissolving the red calx of lead. But it does not act upon it in its metallic state.

**SEMIMETALS.**

- **ZINC.** Elegant crystals. By the ordinary means.

The effects of this acid upon other bodies, or the use to which these combinations might be applied, are not yet sufficiently known.

**ALKALIES.**

- **FUSED VEGETABLE.** A ponderous salt shooting into fine crystals by supersaturation with acid.
- **FOSSIL.** A salt crystallizable when perfectly neutral.
- **VOLATILE.** A peculiar kind of ammoniacal salt parting with the alkali, and decomposing some of it in a strong fire.
- **CHALK.** A crystallizable salt scarcely soluble.
- **MAGNESIA.** A gelatinous mass which cannot be crystallized.
- **TERRA PONDEROSA.** An in soluble white powder.
- **COPPER.** A green-coloured solution.
- **IRON.** A very thick gelatinous solution.
- **LEAD.** A solution which cannot be crystallized.
- **TIN.** A gelatinous solution in the moist way. A mixture taking fire in close vessels in the dry way.
- **SILVER.** A solution in the moist way, and in the dry, a mixture taking fire in close vessels.
- **BISMUTH.** A partial solution.
- **ZINC.** A partial solution.
- **REGULUS OF ANTIMONY.** A partial solution.
- **COBALT.** A partial solution of a red colour.
- **MANGANESE.** A partial solution in its natural state. When the manganese is phlogisticated, a crystallizable salt may be obtained.

**INFLAMMABLES.**

- **CHARCOAL.** A mixture taking fire and subliming when heated in close vessels.
- **OIL OF TURPENTINE, &c.** A thick black substance after some days digestion.
- **SULPHUR.** A red sublimate.
ALKALI. Fixed Vegetable. A cryflallizable salt.
Volatilc. A neutral salt, the nature of which is unknown.

ACID or MILK may be combined with the following Substances, viz.

ALKALIES. Fixed Vegetable. A deliquecent salt soluble in alcohol.

ACID or MILK may be combined with the following Substances, viz.

ALKALIES. Fixed Vegetable. A deliquecent salt, parting with much of the alkali by heat.

EARTHS. Calcareous and Argillaceous. Deliqucenl salts.
Maganesia. A salt more easily crystallized, but deliquecent.
Copper. A blue solution, which cannot be crystallized.

METALS. Iron. A brown solution, with the emission of inflammable air, yielding no crystals.
Lead. An astringent fuscithion solution, which does not crystallize.

SEMIMETAL. Zinc. A cryflallizable salt, with the emission of inflammable air during the solution.

ACID of SUGAR or MILK may be combined with the following Substances, viz.

ALKALIES. Fixed Vegetable. A salt very difficult of solution.

EARTHS. Absorbsent and Argillaceous. Insoluble salts.

ACID of APPLES may be combined with the following Substances, viz.

ALKALIES. Fixed Vegetable, Fossil, and Volatile. Deliquecent salts.

EARTHS. Magnesia. A deliquecent salt.
Earth of Alum. A salt very difficult of solution.

METALS. Iron. A brown solution, which does not crystallize.

SEMIMETAL. Zinc. A fine cryfiallizable salt.

ACID of FAT may be combined with the following Substances, viz.

ALKALIES. Fixed Vegetable, and Fossil. Neutral salts of a particular nature.

EARTHS. Magnesia. A cryfiallizable salt of a brown colour.
Earth of Alum. A gummy mass, which refuses to cryfiallize.

METALS. Silver. A solution of the calx.
Platinum. The calx copiously dissolved, and even the perfect metal attacked by distillation to dryness.
Copper. A green solution, which cannot be cryfiallized.

SEMIMETALS. Zinc. Disolved in its metallic state.

ACID of BENZOIN may be combined with the following Substances, viz.

ALKALIES. Fixed Vegetable. A salt shooting into pointed feathery crystals.

EARTHS. Magnesia. A cryfiallizable salt easily soluble.

METALS. Gold*. After having precipitated it from aqua-regia, it dissolves it if the alkali has been calcined with animal substances.
Silver*. After having precipitated it from the nitrous acid, it dissolves it if the alkali has been calcined in contact with the flame.
OILS. EMPYREUMATIC.

SEMMETALS. ANTIMONY. • COBALT.

SULPHUR.

WATER.

ALKALI, as above.

SEMIMETALS.

ACIDS.

AIR.

METALS.

TIN. A corroded powder. By the ordinary means of solution.

COPPER. By ditto.

LEAD. A fluid solution. By ditto. This stains hair black.

IRON*. A blood-coloured solution. By dropping a solution of iron in the nitrous acid, into an alkaline lixivium.

MERCURY*. A fluid solution. After precipitating it from acids, if the alkalai is in too large proportions, it then dissolves it, especially if the alkalai has been calcined in contact with the flame.

ZINC*. By solution, after having precipitated it from the nitrous acid.

BISMUTH*. By solution, after having precipitated it from the nitrous acid.

Kerne1 mineral. By dissolving antimony in an alkaline lixivium, filtering, and allowing it to stand in a cool place till it precipitates.

Golden sulphur of antimony. By dissolving a crude antimony in an alkaline lixivium, and precipitating by an acid.

Hepar antimonii. By deflagrating crude antimony with nitre.

Gross metal1orum. Is hepar antimonii pulverized and edulecorated with water.

Diaphoretic antimony. By deflagrating regulus of antimony with nitre.

Antimoniated nitre. By dissolving diaphoretic antimony in water, and allowing it to crystallize.

Magdebury of antimony. By precipitating a solution of diaphoretic antimony by adding vinegar.

Regulus antimonii medocinalis. By fusing crude antimony with alkali. This is not properly a compound of alkali and antimony, but of another kind. But as it is a term much used, it was proper to explain it.

ARSENIC*. A metallic arsicalc fall. By a particular elective attraction from regulus of antimony and nitre.

EXRESSED. Soap. The best hard soap is made of olive-oil and foilial alkali. The ordinary white soap of this country is made of tallow and potash; black soap with whale-oil and potash.

ESSENTIAL. Saponaceous mafs. Best made by pouring spirit of wine upon caustic alkali and then oil, digesting and skaking.

OILS.

EMPYREUMATIC. This mixture dissolves gold when precipitated from aqua regia; and is the basis of the fine colour called Prussian blue; and has various other properties, as yet but little known.

FOSSILE. This has no name, nor are the properties well known; but from some observations that have been made on native soapy waters, it is probable that it would keep linen much longer white than any other kind of soap.

SULPHUR. Hepar sulphuri. By injecting alkalis upon melted sulphur.

WATER.

Alkalies lixivium, when caustic, or even the ordinary solution of mild alkali, is a fluid of great power in washing, bleaching, &c.

AIR. Fixed. Mild alkali. This is the general state in which alkalis are found; but if they are rendered caustic by means of quick-lime or otherwise, they again absorb it from the air, or from many other bodies, by elective attraction. When perfectly mild, this alkali may be made to assume a crystalline form.

The volatile alkali, or spirit of sal ammoniac, can be united with these bodies, viz.

ACIDS: Vitriolic, Nitrous, Muriatic, Vegetable; of Urine, of Amber, of Ants, &c.

ALKALI, as above.

GOLD*. Aurea fulminans. A powder obtained by precipitating it from aqua regia by volatile alkalis.

A liquid solution. By adding a large proportion of alkali after it has been precipitated from aqua regia. This deposits the gold when long exposed to the air. The curious vegetation called arbor Dianae is formed by adding mercury to this solution. A violently fulminating powder obtained by digestion.

SILVER*. A solution. After it has been precipitated from the nitrous acid. A fulminating powder by digestion.

PLATINA*. By solution, after having precipitated it from aqua regia.

A blue-coloured solution. By the ordinary means. This when evaporated to dryness, and mixed with tallow, tinges the flame green.

COPPER. Sapphire-coloured crystals. By crystallizing the solution.

Venus fulminans. By evaporating the solution to dryness.

Aqua cerulea sapphirina. By mixing sal ammoniac, quick-lime, and thin plates of copper, with water, and allowing them to remain a night.

IRON. By ordinary solution.

LEAD. By ditto.

TIN. The mixts that are produced by these metals are little known.

BISMUTH*. By solution, after having precipitated it from the nitrous acid.

ANTIMONY.

COBALT. A reddish liquor. By solution.

NICKEL. A blue liquor. By ditto.

EXPRESSED. Has no name. By solution.

ESSENTIAL. Sal volatile oleiforun. By ditto with some difficulty, unless the alkali is in a caustic flame.

OILS. EMPYREUMATIC. A pungent oily substance, of great power in medicine. The principal one of this kind in use is spirit of hartbhorn.

FOSSE. A particular kind of soapy substance.
CHEMISTRY.

SULPHUR. Smoking spirit of sulphur. By distilling sal ammoniac, quick-lime, and sulphur.
ALCOHOL*. By distilling alcohol from volatile alkalies, it acquires a caustic fiery taste; but the union is not complete.
WATER. This solution might be of use in washing or bleaching; but, unless in particular cases, would be too expensive.

It coagulates with alcohol.
AIR. Fixed. Mild volatile alkali. The usual state in which it is found; nor has any method yet been discovered of rendering it solid but in this state.

EXPRESSED OILS may be combined with the following Substances, viz.

ALCALIES: Fixed and Volatile, as above.
METALS. Lead*. Ditto. By folution when the tin is in the state of a calx.
SEMIMETALS. Zinc*. Ditto. By ditto.
OILS: Of all kinds. By mixture or mixture.

SULPHUR. Balsam of Sulphur. By solution in a boiling heat.

ALCOHOL. After expressed oils are freed from soap or plasters, they are soluble in alcohol; but not in their ordinary state.

ESSENTIAL OILS may be combined with the following Substances, viz.

ACIDS: Vitriolic, Nitrous, Murieatic, Vegetable, of Urine, of Amber, as in the foregoing part of this Table.
ALCALIES: Fixed and Volatile, as above.
CALCAREOUS EARTHS. A kind of plaster. By mixture when in a caustic state.
METALS. Lead*. Ditto. By folution when the calx of lead is in the state of a calx.

OILS: Essential, Empyreumatic, and Fossil. By mixture but their uses are not much known.

SULPHUR. Balsam of Sulphur. By solution in a boiling heat.

ALCOHOL. After expressed oils are freed from soap or plasters, they are soluble in alcohol; but not in their ordinary state.

EMPYREUMATIC OILS may be combined with the following Substances, viz.

ACIDS: Vitriolic and Nitrous, &c. as above.
ALCALIES: Fixed and Volatile, as above.

OILS: Of all kinds. By mixture.

SULPHUR. A balsam of sulphur. By solution, imperfectly; better by adding essential oils to the solution made by expressed oils or balsam of sulphur.

ALCOHOL. Imperfect mixture. By distillation.

WATER. Distilled water of the shops. By distilling recent vegetable substances with water.

FOSSILE OILS may be combined with the following Substances, viz.

ACIDS: Vitriolic and Nitrous, as above.

OILS: Of all kinds. By mixture.

SULPHUR. With some difficulty, by folution.

ALCOHOL. By folution. By repeated distillations the oils are rendered much more subtile.

SULPHUR may be combined with the following, Substances, viz.

ACIDS: Vitriolic, with the phenomena above described.

ALCALIES: Fixed and Volatile, as above.

SILVER. A mass of red-like colour. By adding sulphur to red-hot silver, and fusing; found also with it in the state of an ore.

LEAD. A sparkling friable mass, hardly fusible. By deflagrating sulphur with lead. This in a native state forms the ore of lead called galena.

COPPER. A black brittle mass, easily fusible. By adding sulphur to red-hot copper, or fusing with sulphur and fusible. Naturally in some yellow pyrites.

A spongy-like droops, easily fusible. By putting sulphur to red-hot iron. This is also found naturally in the common yellow or brown pyrites.

A fulminating compound. By mixing filings of iron with sulphur, moistening them with water, and pressure them hard, they in a few hours burst out into flame. This composition has been employed for imitating earthquakes.

Crocus martis. By deflagrating with iron.

Crocus martis apericnt. By calcining the crocus martis in the fire till it attains a red appearance.

Crocus martis afinitys. By heating the heat still further.

TIN. A dark-coloured mass, resembling antimony. By fusion.

Ethiops natual. By heating flowers of sulphur, and pouring the mercury upon it, and stirring it well. Its natural ore is called cinnabar.

MERCURY. Fallicitus cinnabar. By applying the mercury and sulphur to each other in their pure state, and subliming.

Cinnabar of antimony. By subliming corrosive sublimate and crude antimony; or the residuum, after distilling butter of antimony.
Table.

**CHEMISTRY.**

**SEMIMETALS.**

**ALCOHOL** may be combined with the following Substances, viz.

**ACIDS:** Vitriolic, Nitrous, Muriatic, Vegetable, and of Borax, as above.

**ALKALI:** Volatile, as above.

**METALLIC** eales, in some particular cases.

**OILS:** Exprefsed, Effential, and Fossil, as above.

**WATER.** Gas of fire. By receiving the fumes of burning sulphur in water. This ought rather to be called a union of the volatile vitriolic acid with water.

**ACIDS:** Vitriolic, Nitrous, Muriatic, Vegetable, and of Borax, as above.

**SEMIMETALS.**

**GOLD may be combined with the following Substances, viz.:**

**ACIDS:** Vitriolic*, Nitrous*, and Muriatic*. In the circumstances and with the phenomena above described.

**ALKALIES:** Fixed*, and Volatile*, as above.

**METALS.**

**SILVER may be combined with the following Substances, viz.**

**ACIDS:** Vitriolic*, Nitrous*, Muriatic*, Vegetable*, and Acid of Anis*, as above.

**ALKALIES:** Fixed* and Volatile*, as above.

**CRYSTALLINE** earts and other vitreous matters. A fine yellow opaque glafs. The finest yellow paint for porcelain is procured from glafs mixed with silver.

**SEMIMETALS.**

**SULPHUR, as above.**

**LEAD may be combined with the following Substances, viz.:**

**ACIDS:** Vitriolic, Nitrous, Muriatic, Vegetable, of Urine, of Anis, as above.

**ALKALIES:** Fixed and Volatile, as above.

---

TIN may be combined with the following Substances, viz.|
| ACIDS: Vitriolic*, Nitrous*, Muriatic, Vegetable*, of Urine, as above. |
| ALKALIES: Fixed and Volatile, as above. |
| CRYSTALLINE EARTHS or other vitreous matters. An opaque white vitreous mass, which forms the basis of white enamels. |
| | Gold, Silver, and Lead, as above. |
| | Platinum. A coarse hard metal which tarnishes in the air. |
| | Copper. A brittle mass. When the copper is in small proportions, it is firmer and harder than pure tin. |
| METALS. | This, in right proportions with a little zinc, forms bell-metal. |
| | Iron. A white brittle compound. By heating filings of iron red-hot, and pouring melted tin upon them, a metal resembling the finest silver is made of iron, tin, and a certain proportion of arsenic. |
| | Mercury. This amalgam forms foils for mirrors; and forms the yellow pigment called aurum molacum. |
| | Zinc. Hard and brittle. When the zinc is in small proportions, it forms a very fine kind of pewter. |
| SEMIMETALS. | Antimony*. Regulus veneris. By elective attraction from copper and crude antimony. |
| | Bismuth. Bright, hard, and sonorous, when a small proportion of bismuth is used. This is very easily fused, and employed as a folder. |
| | Arsenic. A substance in external appearance resembling zinc. |
| | Cobalt. By fusion. |
| | Nickel. A brittle metallic mass. |
| OILS: Essential, as above. |
| SULPHUR, as above. |

COPPER may be combined with the following Substances, viz.|
| ACIDS: Vitriolic, Nitrous, Muriatic, Vegetable, of Urine, of Amber, of Ants, as above. |
| ALKALIES: Fixed, and Volatile, as above. |
| METALS. | Gold, Silver, Lead*, and Tin, as above. |
| | Platinum. A white and hard compound, which does not tarnish so soon as pure copper, and admits of a fine polish. |
| | Iron. Harder and paler than copper. Easily fused. |
| | Mercury*. A curious amalgam. Soft at first, but afterwards brittle. By triturating mercury with verdigris, common salt, vinegar, and water. |
| | Brass. Commonly made by cementation with calamine. The larger the proportion of zinc, the paler, harder, and more brittle is the brass. |
| | Spelter. A native substance, found in Cornwall, consisting of zinc and copper, and used as a folder. |
| SE IMETALS. | Antimony. By fusion. |
| | Bismuth. A pailish brittle mass. Somewhat resembling silver. |
| | Arsenic. White copper. By pouring arsenic, fused with nitre, upon copper in fusion. If too large a proportion of arsenic is used, it makes the compound black and apt to tarnish. |
| | Cobalt. White and brittle. |
| | Nickel. White and brittle, and apt to tarnish. |
| OILS: Essential, as above. |
| SULPHUR, as above. |

IRON
### Table. CHEMISTRY.

IRON may be combined with the following Substances, viz.

| ACIDS: Vitriolic, Nitrous, Muratic, Vegetable, of Urine, of Amber, of Ants, as above. |
| ALKALIES: Fixed*, and Volatile, as above. |
| VITREOUS EARTHS. A transparent glass. In general blackish; but sometimes yellow, green, or blue. The colour is influenced by the degree of heat as well as nature of the ingredients. |

#### METALS.

- **Gold**, Silver*, Lead*, Tin, and Copper, as above.
- **Platina.** A white substance resembling silver.
- **Zinc.** A compound resembling silver.
- **Arsonic.** A white, hard, and brittle compound. By fusing with soap or tartar. A metal resembling fine steel is made by fusing cast iron with a little arsenic and glass.
- **Bismuth.** A silvery for iron. By putting this amalgam upon iron, and evaporating the mercury. It has much the appearance of silver.
- **Cobalt.** By mixing first with nickel, and then adding mercury.

#### SULPHUR, as above.

**MERCURY may be combined with the following Substances, viz.**

| ACIDS: Vitriolic, Nitrous, Muratic, Vegetable*, of Urine, as above. |
| ALKALIES. Fixed*, as above. |
| METALS. |
- **Gold**, Silver*, Lead*, Tin, and Copper, as above.
- **Platina.** The compound resulting from this mixture is not known.
- **Zinc.** An amalgam. Soft or hard, according to the proportions employed.
- **Antimony.** By melting the regulus, and pouring it upon boiling mercury. By frequently distilling from this amalgam, the mercury is rendered much more pure, and then is called animated mercury.
- **Bismuth.** A metal resembling fine steel is made by fusing cast iron with a little arsenic and glass.
- **Cobalt.** By mixing first with nickel, and then adding mercury.

#### SULPHUR, as above.

**ZINC may be combined with the following Substances, viz.**

| ACIDS: Vitriolic, Nitrous, Muratic, Vegetable, of Urine, of Amber, of Ants, as above. |
| METALS. |
- **Gold**, Silver, Lead, Tin, Copper, and Iron, as above.
- **Platina.** A hard substance.
- **Mercury, as above.**
- **Antimony.** This mixture is applied to no particular use.
- **Arsenic.** A black and friable mass.
- **Cobalt.** The particular nature and properties of this mixt is not known.

#### OIL: Expressed*, as above.

**ANTIMONY may be combined with the following Substances, viz.**

| ACIDS: Vitriolic*, Nitrous, Vegetable*, and Urinous. With the phenomena, and by the means above described. |
| ALKALIES: Fixed and Volatile, as above. |
| VITREOUS EARTHS. A thin penetrating glass; which is a powerful flux of metals. |

#### METALS.

- **Gold**, Silver, Lead, Tin*, Copper, and Iron, as above.
- **Platina.** A hard mass.
- **Mercury, and Zinc, as above.**
- **Bismuth.** A mass resembling regulus of Antimony.
- **Arsenic.** The nature and qualities of this mixt are not known.
- **Cobalt.** Nature unknown.
- **Nickel.** Ditto.

#### SULPHUR, as above.

**BISMUTH may be combined with the following Substances, viz.**

| ACIDS: Vitriolic, Nitrous, Muratic, Vegetable, and Urinous; with the phenomena, &c. above described. |
| ALKALIES: Fixed*, and Volatile*, as above. |
| VITREOUS MATTERS. A yellow glass. The ore of Bismuth affords with these a blue glass; but this is probably owing to some mixture of Cobalt with it. |

#### METALS.

- **Gold**, Silver, Lead, Tin, Copper, and Iron, as above.
- **Platina.** This mixture changes its colour much on being exposed to the air.
- **Mercury, as above.**
- **Antimony, as above.**
- **Arsenic.** Nature not known.
- **Cobalt*.** By mixing first with with nickel or regulus of antimony, and then adding cobalt; but it cannot be united by itself.
- **Nickel.** This mixt is not known.

#### SULPHUR, as above.

**ARSENIC may be combined with the following Substances, viz.**

| ACIDS: Vitriolic, Muratic*, Vegetable*, and Urinous; with the phenomena, &c. abovementioned. |
| ALKALIES. |
ALKALIES: Fixed, and Volatile; with the phenomena, and by the means mentioned above.

VITREOUS MATTERS. A glass which greatly promotes the fusion of other substances. The arsenic must first be prepared by diffusing and precipitating from alkali.

METALS: 
{GOLD, Silver, Lead, Tin, Copper, and Iron, as above.
{PLATINA.

SEMIMETALS. 
{ZINC, Antimony, and Bismuth, as above.

NICKEL. The phenomena attending these mixtures have not been as yet particularly observed.

SULPHUR, as above.

**PLATINA may be combined with the following Substances, viz.**

ACIDS: Muriatic; with the phenomena, &c. mentioned above.

ALKALI: Volatile, as above.

METALS: 
{GOLD, Silver, Mercury, Tin, Copper, and Iron, as above.

SEMIMETALS. 
{ZINC, Bismuth, and Arsenic, as above.

NICKEL. The phenomena attending these mixtures not yet observed.

**COBALT may be combined with the following Substances, viz.**

ACIDS: Vitriolic, Nitrous, Muriatic, and Urinous; with the phenomena, &c. as above described.

ALKALI: Volatile, as above.

METALS: 
{GOLD, Platinum, Mercury, Lead, Tin, Copper, and Iron, as above.

SEMIMETALS. 
{ZINC, Antimony, Bismuth*, and Arsenic, as above.

NICKEL. The properties of this compound not known.

**NICKEL may be combined with the following Substances, viz.**

ACIDS: Nitrous, and Muriatic; with the phenomena, &c. as mentioned above.

ALKALI: Volatile, as above.

METALS: Gold, Platinum, Lead, Tin, Copper, and Iron, as above.

SEMIMETALS: Antimony, Bismuth, Arsenic, and Cobalt, as above.

SULPHUR, as above.

**ABSORBENT EARTHS may be combined with the following Substances, viz.**

ACIDS: Vitriolic, Nitrous, Muriatic, and Vegetable; with the phenomena, and by the affinities abovementioned.

ALKALIES: Fixed as above.

EARTHS. 
{CRYSTALLINE. By this mixture they are both much easier melted into a glass than by themselves, but not without the addition of some alkali.

ARGILLACEOUS. This mixture easily runs into a glass without any addition.

WATER. 
{LIME-WATER. By solution. It is sometimes found flowing out of the earth in springs; and as it always quits the water when exposed to the air, it is there deposited on the banks of the streams, forming the fomy incrustations called perrifications; and filtering through the pores of the earth, and dropping through the roofs of subterraneous caves, it forms the curious incrustations found hanging from the roof of such places; sometimes affuming forms stupendously magnificent.

AIR. 
{FLINT. Lime-flint. It is from the quality that quick-lime has of absorbing its air, again with it resuming its fomy confluence, that it is fitted for a cement in building; and the great hardness of the cements in old buildings is owing to the air being more perfectly united with these than in newer works.

**CRYSTALLINE or VITREOUS EARTHS may be combined with the following Substances, viz.**

ACIDS: Vitriolic*, and Nitrous*; with the phenomena, &c. as abovementioned.

ALKALI: Fixed, as above.

ABSORBENT EARTHS: as above.

ARGILLACEOUS EARTHS. A mass running into a glass in a moderate heat.

METALS: Lead, Tin, Copper, and Iron, as above.

WATER. Although this is not soluble in water by any operation that we are acquainted with; yet, from its crystalline form, it is probable that it has once suspended; and certainly it is so at this day in those petrifying springs whose incrustations are of the crystalline sort.

SEMIMETALS: Antimony, Bismuth, Arsenic, and Cobalt, as above.

**ARGILLACEOUS EARTH may be combined with Absorbent and Crystalline Earths, as above.** With water it only unites into a paste of a mechanical nature.
Acid; its specific gravity, 400. This acid and its combinations particularly treated of, 863. Procured by a particular kind of fermentation, ib. May be reduced into an aerial form, 883. Its combination with inflammable bodies, 884. Produces a greater quantity of ether than the vitriolic acid and milk seems to be of the acetoic kind, 978. When may be converted into an acetoic acid, 979. May be almost entirely destroyed by fire, by bringing it nearer to the flame of tartar, 1002. Wettum's unsuccessful attempt to do so, 1003. Dr. Croll's opinion of the possibility of this transmutation, 1004. Method recommended by him for trying the experiment, 1005. His experiments proving that all the vegetable acids, 1006, &c. Manganese soluble with difficulty in it, 1369. Procurable from the residue of vitriolic ether, 2722. Beha is prepared by mixing the oxidizing acid of milk with that of ants, 1504. How to bring it nearer to the liquor, 1513. Why it cannot be dissolved in water, 1585. Effects of the marine acid on metallic substances, 1813. Of its miscibility with nitrous acid, 2765. The Decomposition of vitriolated tartar furthered by the marine acid, 339. Of the specific gravity of pure vitriolic acid, 346. To determine its specific gravity, 388. Of the quantity of real acid contained in it, 389. Quantity of the acid, water, and tartar, 392. Experiments on the specific gravity and composition of the marine acid, 366. Dilution of the concentrated acid necessary for these experiments, 392. How to find the specific gravity of pure vitriolic acid, 397. Quantity of acid, water, and tartar, 398. Specific gravity of the acetous acid, 399. Of the precipitates of alum and mercury contained in it, 400. How to determine the quantity of pure acid in it, 400. Of the precipitates of pure acid taken up by milk vegetable tartar, 418. Of the quantities of acid and water in spirit of nitre, 446. Quantity of pure acid contained in marine action spirit, 448. Quantity of vitriolic acid necessary to saturate material alum in the marine acid, 450. Of the fumes of the acid saturated by dephlogisticated nitrous acid, 452. How by marine acid, 453. Quantity of marine acid contained in marine action spirit, 458. Of the quantities of acid and water in spirit of nitre, 459. Why the marine acid acts in a weak spirit, 460. How to prepare the marine acid, 461. Of the precipitates of the acid, 462. Cutting proper for them, 473. Of the vitriolic acid and its combinations, 501, &c. See Vitriolic acid.

Mahlke of Mr Morveau concerning the excess of acid contained in alum detected by Mr. Kirwan, 642. This excess necessary to render alum soluble in water, 643. Too great an excess prevents this, 648. The nitrous acid, 681. This excess is remedied by the addition of pure clay to the liquor, 681. &c. See $d$ Ion. The superfluous acid might be advantageously dissolved, 689. Nitrous acid and its combinations, 724, &c. See Nitrous acid. Experiments on the transmutation of vitriolic into nitrous acid, 721. Incomplete, 722. Marine acid and its combinations, 728, &c. See Nitrous acid. This acid may be dephlogisticated by spirit of nitre or manganece, 780. Mr. Scheele's method of doing it by means of magnesium, 791. Properties of dephlogisticated.

Argonnts, origin of the fable of them, 9.

Arsenic: its diffusion and precipitation, 245, 368; Calculation of the quantity of phlogiston contained in regulus of arsenic, 328; Precipitated by bitumen from the nitrous acid, 369. And by copper from the vitriolic acid, 357. The quantity of vitriolic acid taken up by regulus of arsenic, 503. Of nitrous acid, 503. Of marine acid, 504. Compound of a particular kind of acid and phlogiston 240. Unites with sulphur, ib. is soluble in water, ib. Experiments on this decomposition, ib. Phenomena on diffusion with the vitriolic acid, 717; Diphlogiulated with the nitrous acid, 770. Of the alteration of corrosive sublimate by arsenic, 918. Oil and butter of arsenic, 823. Formed by subliming arsenic with corrosive sublimate, ib. Of the arseneal acid, 916. See Arsenious acid of. A single grain of regulus decreases the maleability of an ounce of gold, 1092. Has a great affinity with tin, 1279. Methods of separating arsenic from tin, 1280. The crackling noise of tin in vessels, 1281. The arseneal acid 1831. Precipitated with mercury, 457. No effect of gold on arsenic, 949. Diphlogiulated arsenic, 949. Diphlogiulated with it by other acids, 1156. Liver of arsenic formed by combining it with fixed alkali, 1276. Arsenic unites with some metals, and crystallizes with iron and zinc, 1277. Unites readily with sulphur, 1278. Compounds thence refracting, ib. 1279. Phenomena exhibited by mineralization of regulus of arsenic 1286. How to prepare pure regulus of arsenic, 1285. A native regulus called melaphosphorus, 1286. This contains a large quantity of iron, which will not obey the magnetic coil the regulus is diphlogiulated, ib. Great volatility of the regulus arsenic, 1287. It destroys the maleability of the metals with which it unites, 1288. May be expelled by heat from all of them except platinum, 1590. Volatilized in the dust except platinum, ib. Effects of arsenic upon alkaline salts and water, 1290. Decomposes corrosive sublimate 1291. The regulus converted into a white insoluble salt very rapidly, 1292. Effects of it on metallic fusions, 1293. Platinum may be melted by means of arsenic, 1294. Effects of it on manganesse in conjunction with nitric acid, 1301. Phenomena on diffusion with manganesse, 1305.

Arseneus acid of, first discovered by Mr. Scheele, 1946. Two methods of procuring it, 917. By means of nitrous acid, 918. By diphlogiulated spirit of nitre, 919. This acid equally poisons with the regulus arsenic, 920. Decomposes its phlogiston, 921. Takes fire and sublimes fractionally into regulus with charcoal, 923. Becomes black and thick with oil of turpentine, 934. Forms a very thick gelatinous fluid, 935. Forms a crysalline salt with vitriolic acid and from other metals which will unite with it, 936. Diffuses terra ponderosa, 938. Of the nlinecas, 1282. Of the arsenical acid, 1395. Of the nlinecas, 1437. Of the arsenical acid, 1496. Differences of it between the different acids and alkalics, 174. Attraction of phlogiston supposed to be the cause of causticity, 719. Kirwan's definition of chemical attraction, 260. Difference between it and cohesion, 261. Geoffroy's rule for determining the degrees of chemical attraction, 262. True method of determining the quantity of attraction each of the acids has for the different bases, 265. This quantity expressed by that of the bases taken up by the different acids. Attraction of metallic calxes to phlogiston determined, 326. Attractions powers of different substan­ cees both expressed by numbers, 264. Differences of the attracive powers of the different acids to metallic substances, 296. Arsenum fulminans, its nature and properties, 1103. It is known in the 17th century, 1104. The first directions for its preparation given by Basili Valentine, 1105. The use of volatile alkali for this purpose but lately known, 1106. Difference of treatment of the increase of weight in the metal by being converted into arsenum fulminans, 1107. Explodes with incredible force, 1108. Twenty grains of it more than equivalent to half a pound of gun-powder, ib. Does not explode in close vessels, 1109. The utmost caution necessary in managing it in the open air, ib. Dr. Lewis's account of the heat necessary to make it explode, 1110. Explodes by friction, fierce sufficient to occasion any heat, 1111. Terrible accidents occasioned by it. The force of the explosion directed equally every way, 1112. Particulars relating to the explosion, ib. Will not explode when moist, 1113. Thirteen grains of it more than sufficient to produce the explosion, ib. Cause of the explosion attributed to a saline principle, 1113. This opinion thought to be erroneous by Mr. Bergman, 1176. Why the fulminating property is destroyed by trituration with fixed alkali, ib. The explosion rendered more violent by boiling with fixed alkali, ib. Why the fulminating property is destroyed too strong a solution of alkali, or with concentrated vitriolic acid, ib. Neither the presence of nitrous or marine acids necessary for the production of fulminating gold, 1117. The explosion is not occasioned by fixed air, 1118. How the fulminating calxes may be prepared, 1119. The calx most readily thrown down by volatile alkali, ib. A fulminating calx produced from solution of gold in diphlogiulated spirit of salt, ib. Mr. Bergman's theory of the cause of the explosion, 1120. Volatile alkali the true cause of it 1121. Great quantity of chloride liquid generated by the explosion of aurum fulminans, 1123. Why a flight calculated by Lord, 1124. His opinion of heat 28, 29. See Volatile, fulminating, phlogiston. Belpre, a name for the marmor metallicum, or combination of terra ponderosa with vitriolic acid, 1050.

Belpre, a name for the marmor metallicum, or combination of terra ponderosa with vitriolic acid, 1050.

Belpre, a name for the marmor metallicum, or combination of terra ponderosa with vitriolic acid, 1050.

Belpre, a name for the marmor metallicum, or combination of terra ponderosa with vitriolic acid, 1050.

Belpre, a name for the marmor metallicum, or combination of terra ponderosa with vitriolic acid, 1050.
CHEMISTRY.

Effects of acid of arsenic upon it, 912. It is convertible into litharge and glaeb. 1750 Occupies less space when in fusion than when in a solid state, ib. Mekkelin's difference between the metal and vitriolic acid, 1751 Precipitates the fusion of all the metals with which it is mixed, ib. It may be assayed but without any advantage, 1748.

Bitten, a kind of salt prepared from it, frequently furnisht the use of the true Glaucon's salt, 952. How to prepare the marine acid from it, 936.

Bismuth particularly treated of, 1447. Whether they are of a vegetable or mineral origin, ib. Mitchell's opinion that they are only vegetable refined altered, ib. Dr Lewis's reasons for being of a contrary opinion, ib.

Birk, Dr. Dredge's history of heat, 32. Experiments by which he was led to the discovery of latent heat, 42. His method of calculating the quantity of heat produced by the combination of various substances. Difference between his calculations and that of Dr Crawford, 51. Expansive force of water in freezing explained by Dr Black's theory of latent heat, 108. His experiments on the conversion of water into vapour, 121. His observations on chemical vessels, 557. His directions for performing the operation of solution, 175. Description of his portable furnace, 26 602. How it is adapted to the various operations of chemistry, 603. Of the heating proper for the conversion of that metal, 604. Method of applying the lustre, 605. His account of the preparation of nitre, 774. His conclusions concerning the nature of that fusible metal, 732. His method of making nitrous ether, 775. Shows a method of making it without any spirit of wine, 777.

Black lead, a valuable material for some chemical vessels, 562.

Bleaching, how performed by means of desphogliticated spirit of salt, 1754.

Blood, strangely altered in its properties by mixture with nitrous acid, 1477.

Bismuth: Of its precipitation from acids, 241. Copper and bismuth precipitate one another alternately from the nitrous acid, 257. Is fusible in vitriolic acid, 491. Increases the fusibility of tin and lead, 543. A compound of this kind fusible in boiling water, 544. Dissolved in great quantities by nitric acid, 547. After precipitating the metal, take it up again, ib. The same thing happens with fixed alkalies calcined with inflammable matter, ib. Mekkelin of bismuth prepared by adding water to the nitrous solution, 766. Neuman's observations concerning this preparation, ib.

Borax, composed of a peculiar kind of acid and mineral alkali, 85. How prepared in the East Indies, ib. Of its state when first impure, ib. Of its crystallization with alkalines, ib. Said to be adulterated during this operation, ib. This denied by Dr Black, ib. Simple dissolution and filtration all that is necessary, ib. On the mode of purifying it, ib. Its purification according to others, 1490. Has a glinious quality, by which it gives a gleam to silk, ib. Its properties with various salts, 856.

Borax, acid of, found in a kind of mineral in Germany, 858. Procured from the salt, 859. How prepared by sublimation, 858. How converted into a kind of vitriolic acid, 860. Dissolves in spirit of wine, ib. Makes no change on the colour of vegetable juices, ib. With various salts, ib. How to prepare the fusitive salt from it, 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Its effects on coal, 1503. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib. 1491. Properties of the salt, 1492. Its combinations with volatile alkalis, 863. Beauan's opinion concerning the conversion of preparing the fusive salt from it, ib.
Calcium - a name given to mercurius by the Egyptians, 524. Bergman's experiments, 525. How to produce it, 526. Its poisonous property, 647. Mrs Higgin's experiments, 1456. His conclusions concerning its composition, 1436. Is found universally in urine, 1436. Bergman's experiments on its fructification in various earth contained in it separated by means of the vitriolic acid, 1462. Red colour of the solution in nitric acid accounted for, 1462. Mr Higgin's experiments, 1436. His account of its component parts, 1465. Experiments on the sublimation arising from it on distillation, 1465. Experiments with nitric acid, 1465. Crystalized by the nitric solution by exposure to the sun, 1467. Remarks on the remedies proper for distilling the stone, 1469. Sublimation of calcium nitrate, with the combustible and geyser properties, 1470. Diffusion ought not to be attempted when the stone is large, ib. Calcium of the acid obtained from it, 982. All these operations produced in the human body of the same nature, ib. Diffused by concentrated vitriolic, and by the nitric acid, but not by the marine acid, ib. The acid of calcium produces deep red spots on the skin, 983. Affumes a blood-red colour by evaporation, ib. Colcan, a name given to mercury's ducal since several times sublimed, 814. Repeated sublimation no improvement on the medicine, ib. Coals of the distilled metal, with various degrees of phlogiston, contained in metallic solutions, 214. Reasons for believing that metals are reduced to a calx by solution, 215. Increase of attraction between the calx of iron and phlogiston demonstpered, 543. Calx of iron foible in lissivum fanguis, 1175. But not when highly dephlogistated, 1176. Camphor, a volatile substance belonging to the class of essential oils, Vol. IV.

CHIMISTRY.

INDEX.

Calcination, 549. Quantity of phlogiston lost by metals during that operation, 359. Of the affinity of their calcines for the calx, 360. The art of calcination of metals by fire described, 532. Of their calcination and increase of weight by acids, 533. Reson of this increase, 534. Solubility of metals increased by calcination, 545. How to perform the operation of calcination, 548. Why a light calcination destroys the exploisive property of sunfum fulmine, 1154. Effects of violent calcination on nickel, 1507.

Calcined metals. See Calcination, Calcine, Calx, and Metal.

Calx, a name given to mercurius by the Egyptians, 524. Bergman's experiments, 525. His conclusions concerning its composition, 1436. Is found universally in urine, 1436. Bergman's experiments on its fructification in various earth contained in it separated by means of the vitriolic acid, 1462. Red colour of the solution in nitric acid accounted for, 1462. Mr Higgin's experiments, 1436. His account of its component parts, 1465. Experiments on the sublimation arising from it on distillation, 1465. Experiments with nitric acid, 1465. Crystalized by the nitric solution by exposure to the sun, 1467. Remarks on the remedies proper for distilling the stone, 1469. Sublimation of calcium nitrate, with the combustible and geyser properties, 1470. Diffusion ought not to be attempted when the stone is large, ib. Calcium of the acid obtained from it, 982. All these operations produced in the human body of the same nature, ib. Diffused by concentrated vitriolic, and by the nitric acid, but not by the marine acid, ib. The acid of calcium produces deep red spots on the skin, 983. Affumes a blood-red colour by evaporation, ib. Colcan, a name given to mercury's ducal since several times sublimed, 814. Repeated sublimation no improvement on the medicine, ib. Coals of the distilled metal, with various degrees of phlogiston, contained in metallic solutions, 214. Reasons for believing that metals are reduced to a calx by solution, 215. Increase of attraction between the calx of iron and phlogiston demonstrated, 543. Calx of iron foible in lissivum fanguis, 1175. But not when highly dephlogistated, 1176. Camphor, a volatile substance belonging to the class of essential oils, Vol. IV.

CHEMISTRY.

Chlorpyrites, a substance belonging to the class of essential oils, Vol. IV.

Calcination - quantity of phlogiston lost by metals during that operation, 359. Of the affinity of their calcines for the calx, 360. The art of calcination of metals by fire described, 532. Of their calcination and increase of weight by acids, 533. Reson of this increase, 534. Solubility of metals increased by calcination, 545. How to perform the operation of calcination, 548. Why a light calcination destroys the exploisive property of sunfum fulmine, 1154. Effects of violent calcination on nickel, 1507.

Calcined metals. See Calcination, Calcine, Calx, and Metal.

Calx, a name given to mercurius by the Egyptians, 524. Bergman's experiments, 525. His conclusions concerning its composition, 1436. Is found universally in urine, 1436. Bergman's experiments on its fructification in various earth contained in it separated by means of the vitriolic acid, 1462. Red colour of the solution in nitric acid accounted for, 1462. Mr Higgin's experiments, 1436. His account of its component parts, 1465. Experiments on the sublimation arising from it on distillation, 1465. Experiments with nitric acid, 1465. Crystalized by the nitric solution by exposure to the sun, 1467. Remarks on the remedies proper for distilling the stone, 1469. Sublimation of calcium nitrate, with the combustible and geyser properties, 1470. Diffusion ought not to be attempted when the stone is large, ib. Calcium of the acid obtained from it, 982. All these operations produced in the human body of the same nature, ib. Diffused by concentrated vitriolic, and by the nitric acid, but not by the marine acid, ib. The acid of calcium produces deep red spots on the skin, 983. Affumes a blood-red colour by evaporation, ib. Colcan, a name given to mercury's ducal since several times sublimed, 814. Repeated sublimation no improvement on the medicine, ib. Coals of the distilled metal, with various degrees of phlogiston, contained in metallic solutions, 214. Reasons for believing that metals are reduced to a calx by solution, 215. Increase of attraction between the calx of iron and phlogiston demonstrated, 543. Calx of iron foible in lissivum fanguis, 1175. But not when highly dephlogistated, 1176. Camphor, a volatile substance belonging to the class of essential oils, Vol. IV.

CHEMISTRY.

Chlorpyrites, a substance belonging to the class of essential oils, Vol. IV.
Forms a red solution with the nitric acid, 769. Discoverable in ores by means of this acid, 770. Forms a beautiful symptomatic ink with marine acid, 832. Diffluented by the acid of arsenic, 954. The femimental particularly described, and its properties considered, 1393. Its caixa, called aequor, described, 1394. But this, the effect of the caixa extremely difficult, 1396. Its properties when exposed to heat, 1297. Calcines spontaneously in the air, 1398. A beautiful blue glass formed from its calc, 1399. Phenomenon of its with vitriolic acid, 1300. With nitric acid, 1301. With marine acid, 1302. With the acid of tartar, ib. With fulphur, 1305. May be separated from nickel by nitre, 1311. Method of preparing a red salt from means of the vitriolic acid, 1312.

Colours: difference bewtixt it and chemical attraction, 261.

Colour of metallic solutions caused by phlogiston, 218. A beautiful white one from lead, 703. A green one from copper and cream of tartar, 1290. How to reduce the colour of gold, 1310. Of silver, 1317.

Colouring matter of Prussian blue investigated by Mr. Scheele, 1317. This matter flies off from the liquid when exposed to the air, 1317. This effect supposed to be owing to fixed air in the atmosphere, 1173. The colouring matter fixed by the addition of some green vitriol to the lixivium, 1174. Cruc of iron soluble in the lixivium, 1175. But not when highly dephlogiophticated, 1176. The colouring matter taken up by the air after it has been expelled by acids, 1177. Effects of diffusing the lixivium with vitriolic acid, 1178. Attempts to procure it, 1179. Neutral salt formed by it for discovering iron in mineral waters, 1180. Effects of dissolving the salt with oil of vitriol, 1181. The colouring matter unites with volatile alkali, 1182. How to free it perfectly from any vitriolic taint, 1183. To prevent its escape through the lute during digestion, 1184. The colouring matter neither acid nor alkaline, 1185. Forms a kind of ammoniacal salt with volatile alkali, 1186. Dissolves magnesia alba, 1187. Very little terra ponderosa, 1188. Dissolves lime, but not clay, 1189. This solution moist proper for making experiments on metals. Precipitates the solutions of silver and quicksilver in nitric acid, and of iron in fixed air, 1190. Its effects on the metallic calces, 1192. On metallic solutions, 1193. Its constituent parts investigated by experiment, 1194. Is of an inflammable nature, 1195. Supposed to contain aerial acid and phlogiston, 1196. Ingredients in its composition, 1200. Unsuccessful attempts to produce it by volatile alkalies in a liquid state, 1200. Successful method with marine alkali, 1201. With charcoal, 1201. Its volatility decreased by manganeze, 1204. Can separate only mercury and silver from their solution in nitric acid, 1190. Its poisonous properties established by the addition of lead, 1194. Its acidity, 1196. Forms a triple salt with regulus of antimonious and marine acid, 357. Precipitates regulus of antimony from the marine acid, 370. Production of copper from it diffused by the vitriolic acid, 454. Inflammable and vitriolic air produced from its solution in nitric acid, 1190. From this air, 349. The colouring matter used by Dr. Cramer for making nitre, 728. Confront, Dr., his explanation of Irving's theory of heat, 36. Diffusion greatly in his calculations from Dr. Cramer, 48. His accounts of feasible heat, 49. Differs from Dr. Black, 51. His opinion concerning heat in the abstract, 54. His method of determining the proportional quantities of heat in bodies, 77. Insufficiency of his method, 78. His solution of the difficulty concerning the diminution of heat, 86. Insignificant, 91.

Colours of metals sometimes heavier than either of the ingredients, 1156. More fusible than either of them finely, 542. Great fusibility of those of tin and bismuth, 545. Fusibility of those produced by the addition of lead, ib. One fusible in the heat of boiling water, 544. Platina unites readily with compound metals, 1143. Carbonated acids phlogiophticated by alkalies, 409. Concentrated nitric acid diffusible leas metal than when diluted, 469. How to obtain a very concentrated acetic acid, 881. Violent action of the concentrated nitric acid upon molybdaena, 660. Marmer metallic soluble in concentrated vitriolic acid, 1063. Precipitated from it unchanged by vegetable acids, 1064. Why the concentrated vitriolic acid diffusible manganese without addition, 1178. Condensation of vapour produces a great quantity of heat, 43, 125. Dr. Black's method of calculating it, 44. Condensed water, the difficulty with which it melts, a mean of preventing inundations in countries where snow and ice abound, 88.

Coprecipitate: is precipitated with out any decomposition by all of vitriol 315. May be decomposed by silver in the dry, but not in the moist, 332. Of its preparation from quicksilver, 57. Differences of its quality according to the different methods by which it is prepared, 816. Reason of its not being precipitated, 923. Method of making it at Amsterdam, ib. Observations on the different methods, 987. Of its adulteration with arsenic, 818. Yields no butter of arsenic with sublimation with that substance, 945, 946. Its use in the preparation of butter of antimony, 851. Of its sublimation with manganese, 1597.

Cream of tartar, how prepared, 886. Analyzed by Mr. Scheele, 887. Regarded as, ib. Croll, Dr., a mistake of his concerning the production of Glauber's salt of alum and common salt corrected, 272. His method of crystallizing the acid of lemon, 997. His attempts to bring vinegar nearer to the state of taxed, 1004. His proofs that all vegetable acids can be derived from one origin, 1006.

Cross metallicum, how prepared, 1265. Grenet, Dr., discovers the new metallic called nickel, 1306.

Crucibles: of the most proper material for them, 585. Achard's method of making them from eals of platin, 587. Mr. Port's directions for making them, 588. Dr. Lewis's observations on their construction, 589. Porcelain probably the finest material for vessels of this kind, 591. Of Reaumur's porcelain as a material for crucibles, 592.

Cruor: produced by the fluor acid on the surface of water, 838. Found to be of the nature of a fluidic compound, 839. Confronted with this in his attempts to determine the nature of this earth, 830. The same cruor produced from artificial fluor, 831. Formed on the supposition that the earth is formed by the union of the acid and water, 832. Confronted by Meffrs. Boulanger, Monnet, &c. 833. Their opinions shown to be erroneous by Mr. Scheele, 854.
Weigle's experiments on the origin of it, 839. Found to proceed from the combination of the glacial distilling vessel, 840. How to procure the acid free from it, 842. None formed by mixing sand with a salt containing flour acid, 844. But a great quantity by adding powdered green glais, 845.

Cry stalized powder thrown down from solution of calc of plaster by vegetation, 843. Dehydration in chemistry: how to perform that operation, 573 Crystallisation of alum impeded by vitriolic acid, 847. Solution of metals, its increase accounted for, 574. How to determine the accurate density of spirit of nitre mixed with other liquids, 587. Increase of it in compound substances, 404.

Diphosphatic acid converted into acetic acid by charcoal, 131. Operation to the exclusion of phlogiston from the total combustion of it in some cases, 152. Little phlogiston confounded by the combustion of iron in this kind of air, 153. Of the diphosphatic marine resin, 206, 790, et seq. 1424. Diphosphatic green vitriolic cannot precipitate solution of gold, 256. Quantity of mineral salt taken up by diphosphatic nitrogen filings, 267. Of the solution of diphosphatic calc of iron cannot be crystallized, 457. Diphosphatic green vitriolic decomposed by clay, 684. Diphosphatic acid and material for the nitric acid, 72. How to prepare the diphosphatic spirit of fats, 590, 791. Can fearlessly be condensed into a liquid, 792. Its other properties, ib. Acid of arsenic prepared by its means, 919, 1274. The only volatile of platinum, 1319. Diphosphatic spirit of nitre decomposed by camphor, 1444.

Diphosphoric acid, how prepared, 1254.

Digger, Papin's, described, 567. Effects of it produced by long boiling, ib.

Diphosphoric acid, in chemistry how performed, 565.

Diphosphoric acid: Quantity of ingredients in it, 379, 431. Prepared from vegetable alkali and marine acid, 794.

Diluted. Water prepared by being operated on that operation, 150.

Dilution: how that operation was originally performed, 6 Mr Watt's experiments on the dilution of water, 124. Method of operating the dilution of 574. Phenomena on dilution of inflammable substances, 573. Boerhaave's experiment of the dilution of mercury, 1230.

Diluted verdigris, how prepared, 878. Dissolution of metals, 1317.

**CHEMISTRY.**

**Fixed air:** its specific gravity determined, 431. Of the quantity of it in vegetable alkali, 431. In impure vegetable alkali, 431. Of the quantity contained in mineral alkali, 434. Earth of alum contains a great quantity, 446. Of the quantity of phlogiston in fixed air, 435. Alkaline fumes impregnated with a caustic falt and fixed air, 1020 is not the cause of the explosion of aurum fulminans, 1118. Explodes the colouring matter from lilionium fanguinis, 1173. Water intermixed with it diffuses maligne, 1371.

**Fixed alkali:** left attracted by nitrous acid than falt, 308. Vegetable fixed alkali takes up an equal quantity of all the acids, 452. Exact calculation of the quantity of acid taken up by vegetable fixed alkali, 420. Stone ware prepared by adding the caufic fixed alkali, 592. Fixed falt ammoniac and the fame with a combination of the marine acid and calcareous earths, 797. Combination of falt acid with fixed alkali, 48, 850. Fixed alkali falt how procured, 1016. Vegetable alkali crystallized in various ways, 1057. Changed by combination with marine acid. Combination of fixed alkali with sulphur, 1021. With expreffed oils, 1026. With effential oils, 1047. With phlogiston, 1083. Differences observed between those obtained from different vegetables, 1029. Precipitate folutions of terra ponderofa whether in their fmal or caufic flate, 1054. The caufic fixed alkali throw down an infoluble precipitate from thefe folutions, 1056. Marmor metalicum precipitate unchanged from oil of vitriol by mild vegetable alkali, 1064. A triple falt formed by fixed alkalis, fitleous earth, and flic acid, 1075. The mineral part of the difintegration of the vegetable alkali decomposes cryftals of platina, 1392.

**Flints:** earth of, fuppozed to under go a tranformation by being difolved in an alkaline liquor, 1069. This change denied by Mr Bergman, 1070. The fupponed tranformation found to arise from an admixture of clay, 1071. Cryftals of fint produced artificially by Mr Bergman, 1072. Why the flic acid will not difolve fint diréctly, 1073. Earth of fints most completely precipitated by volatile alkali, 1074. Forms a triple falt with flic acid and fixed alkali, 1075. Difolved by boiling in an alkaline liquor, 1076. 1072. A remarkable attraction for alkaline fairs in the dry way, 1077. It is very rare and fpongy when precipitated, 1078. Why the alkaline folution of fnts sometimes converted into an alkali without heat, 1079. Liquor of fnts decompo-
INDEX.

CHEMISTRY.

Increased by the addition of lead, ib. 484
Fusion: how to perform that operation in chemistry, 544 Difference between the watery and dry fusion, ib. Of the crucibles necessary for the fusion of metals, 555, et seq. See Crucible. Fusions of all metals promoted by bismuth, 1521.

Galls, acid of, how separated from them, 1537. An acid liquor produced from them by distillation, 1538. Its properties, 1539. Galls, juice of animals contains phosphoric acid, 904.

Geoffroy's rule for determining the degrees of chemical attraction, 975. His table of affinities, 553. Investigates the constituent parts of alum, 641. His theory of profound metals, 1165. A beautiful blue salt ammoniac, 1299.

German: a kind of Spatham pondersum found in its neighbourhood, 1060.

Glass: method of engraving on it by means of fluor acid, 2d 857. Glass vessels, when to be used by chemists, 556. Dr Black's remarks on the properties of glasses 538. Affords the silicious crust observed on fluor acid, 840. Violent action of that acid on glasses, 848. Corroded by it and by the ammoniacal salt produced from it, 834. Nitre convertible into glass, 1520. How to prepare glass of antimony, 1577. A beautiful blue glass produced by the cales of regulus of cobalt, 1599.

Glass of lemon: the vessels most capable of rendering its action, 589. Glass-making: Pliny's account of the origin of it, 7.

Glasse, of the materials proper for casting them, 350. Glaser's fili ammonium prepared from vitriolic acid and volatile alkali, 653. See Ammonium.

Glaser's fluid of nitre, 734.

Gmelin, Dr., his experiments on the differences between the chemical substances produced from different vegetables, 1079. On the silves of different plants, 1089. Method of making dulcedine spirit of salt, 1741.

Gold: why its solution is precipitated by grec vitriol, 255. But not by silicious grec vitriol, 256. Way it is precipitated by solution of tin, 272. Various precipitates of it, 273. Bell kind of aqua regia for dissolving it, 481. Quantity of it precipitated by dilution with aqua regia, 482. Its calcines soluble in the vitriolic and nitrous acids, 483. Kirwan's opinion that the metal cannot in any quantity be dissolved in the nitrous acid, 484. Dr Brand's experiments, showing that it may be so in close vessels, 750. Lewis's observation on this experiment, ib. Solution of its calces in spirit of salt, 798. Sublimes along with the acid, ib. The sublimates find the material used for the blood of its Januarius, 800. Is not affected in any way by the arsenical acid, 941. Its nature and properties particularly treated of, 1089. Unites readily with all the metals, 1590. Its colour debated by all the metals except copper, ib. Said to be lighter than the calce, 1591. Markably with tin, 1592. Dr Lewis's account of the bad effects of this metal upon it, ib. Mr Alchermes's experiments in opposition, 1593. Could not removed brittles by the fumes of tin, 1593. Nor by the addition of the metal itself in small quantities, ib. Nor with the addition of copper, 1594. Maleability of gold entirely destroyed by a small quantity of regulus of arsine, 1595. Surprising tenacity of its parts, 1596. Is not liable to rust 1597. Mr Boyce's experiment to show its fusibility, 1598. Of its solution in aqua regia, 1599. This solution of a corrosive nature, 2100. May be crystallized, ib. Of the precipitation of gold, 2101. Separated from other metals by green vitriol, 2102. Explodes with prodigious force in some cases, 2103. See Aquirum fulvis. Solution of the gold in sulphur, 1127. Medical virtues of gold entirely imaginary, 1128. Solution in essential oil not permanent, ib. Dissolved permanently in ether, and crystallized by its means, 1259. Revived by its solution in aqua regia by mixing it with spirit of wine, ib. A method thus afforded of taking it from other metals, ib. Have to reforrifice its colour when lost, 1370. Mercury fixed by amalgamation with gold, 1234. Wheat to lose its malleability and to be red with platina, 1536. How to detect this fraud if it should be praticed, 1537.

Golden calce: its distillation adduced as a instance of Mose's sill in chemistry, 279.

Golden sulphur of antimony, how prepared, 1263.

Golden vessels recommended for keeping the flour acid, 857.
Heliot procures from flowers of zinc inflammable air: metallic calces reduced by it, 149. Revival of lead from minorum by it, 344. Quantity of inflammable air produced from iron, 454. Why none is produced from the nitrous solution of iron, 456. Charcoal entirely convertible into it, 1451. Inflammable spirit produced from radical air, 1544. Sulphureous inflammable vapours produced from it, 1154. Inflammation: difference betwixt its heating and ignition, 153. Bodies decomposed by its igniting, 1133. Its effects of it upon nickel, 1150. Inflammable air contains sulphur, 210. Hermes Trismegistus, the same with Siphnus, an Egyptian, the founder of chemistry, 315. Higgins, Mr., his experiments on human calculus, 1453, et seq. His observations on the nitric acid, 1472. Metathesis, 1472. How they are reduced by heat, 1475. Löwerts, 1475. Discovered the true composition of volatile alkali, 1553. Homberg's experiments on specific gravities compared with those of Hohenheim, 1473. Inflammable air: The still experiment of them accounted for, 351, 899. An oil obtained by Homberg supposed to come from the flowers of zinc, 1424. The nitrate discovered by him, 1426. How he discovered his pyrolysis, 1425. Left: the method of preparing it, 1416. See Pyrophorus. Discovered that marine air corrodes glass, 1452. How it affects the cow for that purpose, 699. January, St., a fulminate of marine acid and gold shown for his blood, 805. Ice a quantity of heat left in the melting of it, 42. Fely the mucilage of animal fluidities, 1454. All of them reducible to this by long boiling, ib. Is the true animal substance ib. Forms a very strong cement, ib. Ignited bodies all equally hot, 118. Ignite an universal effect of fire, 130. Difference between ignition and inflammation, 133. Neo aquificum the growth of that plant a sign of aluminous ores in the ground, 639. Inflammable and vitriolic acid obtained from solution of copper in vitriolic acid, 465, 471. Inflammable fluidities, their nature and properties, 316. Principles into which they are resolved by burning, ib. By dilution, 517. Their phenomena with different acids, 318. Some singular productions, 473. Vitriolic acid obtained from it, 474, et seq. Nitrous acid, 477, et seq. Marine acid, 824. An inflammable spirit extracted from sugar of lead, 878. Inflammable vapour arising from the decomposition of hepaur sulphur, 1025. Volatile alkalines combined with them, 1035. Of their division and chemical properties, 1296, et seq. Precipitate spontaneously from the vitriolic acid, 698. Iron contained in the retin produced from the reducible of vitriolic ether, 824. Cannot be diffolved by concentrated, though it will by diluted, nitrous acid, 759. Diffolves and produces inflammable air with marine acid, 803. Volatilizes by this acid, 806. Its solution used in medicine, 807. Combined with acetic acid, 823. With acid of tartar, 835. With the acid of arsenic, 948. Its nature and properties, 1017. Has great tenacity of parts, 1157. Is a combustible sublimate, 1159. Is the only metal capable of it being welded, 1160. Contracts in fuse, and expands again on becoming cold, 1161. Is diffolved by all metals except lead and mercury, 1162. Becomes brittle by being brandished for some time in that fluid, ib. Can scarce be united to zinc, ib. Has a strong attraction for arsenic, ib. Is the basis of Prussian blue, 1165. Cured alkali from solution of it, 1166. Precipitated by the colouring matter of Prussian blue from its solution by aerial acid, 1191. Nitre alkaliized by it, 1206. Its filings take fire spontaneously with sulphur, 1207. Unites with platinum, 1247. Iron filings particularly treated, how prepared, 873. Jowitte, Dr.: a general account of his and Dr. ilack's theory of heat, 35. His theory explained by Dr. Crawford, 36. Italy: of the first alum-works set up there, 659. Fius: gallin, yields phyllocodium, 130. Kimckel, His new method of preparing an alkaline constituent of the nitrous acid, 130. Kirwan, His objections to the doctrines of Mr. Kirwan, 247. His method of preparing an alkaline constituent of the nitrous acid, 130. The precipitation of zinc opinions concerning the identity in certain cases, 519. Chemical air is produced by dissolving iron in the vitriolic acid, 456. Solution of the calces of copper in the vitriolic acid, 1543. The solution of the dephlogiophilic calces reduces to crystallize, 457. Propriety of iron diffused in nitrous acid, 458. In the marine acid, 462. CaIces of iron assume a red colour when precipitated from their solution in the marine acid, 463. Produce green vitriolic by combination with vitriolic acid, 696, 697. For 435, is of opinion that gold cannot be diffolved in nitric acid, 484. Millave of Morsen concerning a superabundance of acid in alun, and concerning 20. Objections to his doctrine concerning the specific gravity, &c. of different fluidities, 241, et seq. To his calculation of the quantity of heat into a fulminating paste, 240. Knoekel: forms a fulminating calx of silver, 716. Lamp-Furnace: Mr. Lewis's description, 611. Is not capable of giving a stagnation, 430. Of Fahrenheit, ib. Language: a specimen of a new chemical one, 552. Its strange appearance in attempting to account for the phenomenon of fulminating silver, 1744. Lapis-ponderosus, considered as a metallic earth by Mr. Bergmann, 567. Lead: experiments by which Mr. ilack was led to the discovery of it, 41. This heat cannot be measured, 73. Expansion of water, ib. Coleman, and the like, 1541. Explained by the theory of latent heat, 108. Air bubbles in ice produced by part of the latent heat of the water, 110. Vapour formed by the absorption of heat, 1540. Lavoisier denies the existence of phlogiston, 137. His arguments drawn from the increased weight of metals by calcination, 138. His theories, 2d 510. His experiments from the dephlogiophilic calxes, 510. heraus's experiments on the increased weight of metallic solutions, 513. His experiments in attempts to explain the same results, 516. Not well founded, 527. Account of some of his experiments on the increased weight of metallic solutions, 513. His experiments explaining the change of heat, 516. His experiments on the nitric acid, 473. His new method, 1540. Lead: quicksilver produced from it in certain cases, 126. Water may be made sufficiently hot to melt lead, 131. Why the vitriolic acid cannot act upon it without a boiling heat, 137. Precipitates of lead, 237. Searl: decomposed in various ways by means of it, 392. In what cases solution of lead is precipitated by other metals, 309. The solution in marine acid decomposed by vitriolic salt, 310. Revival of lead by means of inflammable air, 314. Why it is useful in expellation, 331. Precipitation of it by nickel, 362. Vessels capable of relining the glass of lead, 289. Lead vessels most proper for the preparation of oil of vitriol, 627. Cannot be diffolved in the vitriolic acid, 702. A beautiful white for painting in water prepared from lighthouse

by means of spirit of salt, 737 How to procure the dephlogisticated kind, 738, 1475 Lavater's account of the constituent parts of nitrous acid, 1473 Mr. Cavendish's account, 1474 How to get carbonic fire by means of it, 1476 Remarkable effects of it, on blood, 1477 Mr. Schickel's experiments on various substances, 1534 Volatile alkali prepared from nitrous acid and tin, 1543.

Some latest experiments of Dr. Priestley, have shown, that though nitrous acid is produced from the decomposition of dephlogisticated and phlogisticated air, by taking the electric spark in the mixture, it is likewise produced by the more rapid decomposition of combustion, when inflammable air is made use of instead of the phlogisticated kind. In this case, the mixture, if not allowed to happen to exist in the mixture, it is not in the least affected by the process, but remains after the combustion of the others, just as it was before they were added or obtained, that by the addition of phlogisticated air, the quantity of nitrous acid produced is so far from being augmented, that it is much diminished. The acid in these processes always appears to be extremely volatile, insomuch that some part of it constantly escapes. No liquor at all was condensed when the expilions were made in quick succession, even though the vessel never became hotter than the hand. In another process, the atmospheric air was perfectly excluded, while the pure phlogisticated air was prepared and was obtained from one of the materials employed, viz. precipitate per fr. In this experiment he found, that a considerable quantity of fixed air was produced, and that the water became acid by the abstraction of it. He concludes, therefore, on the whole, that a mixture of dephlogisticated and fixed air always produces an acid by combustion; but that, when they are in their nascent state, the acid air is generated; when both are completely formed previous to the experiment, the nitrous acid appears.

CHEMISTRY

The salt formed by a combination of the phosphoric acid with mineral alkali is found to be an useful purgative, and as such is now brought into practical use. Melors Struve and Marquart are said to have discovered, that the gastric juice of animals is composed of the phosphoric acid and volatile alkali; and Mr. Struve has composed a liquid from these two ingredients which acts in a similar manner on alimentary matters.

Finding the base of vegetable acids obtained from a mixture of pure acid contained in fugar along with an empyreumatic spirit of fall, 476
Finding of its specific oil, 478
By dry distillation, which has been purified and examined by Mr. Schöpf, eight ounces and four refulpes of liquid were obtained in this manner from 16 of fine fugar.
About six drachms of water came over first; after which the acid puffemns; the vapours, which condense into a rivulet on the sides of the receiver. It had a pungent and agreeable smell, and tasted empyreumatic. By repeated distillations from pure clay, its smell became mild, and it acquired an apparent increase of acidity. With vegetable alkali, it formed a salt tafing like that of Sulphur, and flowing into needle-like crystals, soluble with difficulty in cold water, but not at all in spirit of wine. It did not delique in the air; but decrепitated in the fire, and did not melt on hot coals. With the mineral alkali yellow crystals were formed resembling Rochelle salt in taste, easily soluable in water, and not deliquing in the air. Volatile alkali a sharp saline liquor, which acidises, and a white saline mass on evaporation; and a saline mineral mass was produced by uniting it with calcareous earth. Magnesia and earth of alum from gumn compounds. When concentrated, it dissolved the calx of gold, and even gold-leaf; but had no effect on filter, mercury, or their calxes. With it, a yellow solution, which shot into aich white crystals of an astrangent taste. A blood-red solution, which shot into green crystals was obtained from iron. Copper was dissolved, into a green liquor, which did not crystallise. Regulus of antimony was also dissolved, and the solution was of a greenish colour. Zinc was partly dissolved into a green liquor, and partly corroded. Solutions of it were red, 1421
The crystals of iron gave a green precipitate with alkalis, a black or dark blue one with Prussian alkali, and a white one with marine acid. In common pyrites of lead, a yellow precipitate with fixed alkali; with vitriolic alkali, a powder soluble again in the precipitant; vitriolic and marine acids, and an infusion of galls, threw down a white powder, but no precipitate ensued on adding nitrons of iron.
Solution of zinc gave a white precipitate with infusion of galls, alkalis of all kinds whatever, volatil, or phlogisticated, as well as by the vitriolic acid. Tin was partially dissolved, and the solution precipitated by an alkali, and an infusion of galls, but not by alkali of the mineral acids. Lead was precipitated of a white colour by vitriolic and marine acids, and of a grey colour by infusion of galls.

Whether this acid or that of sugar is the basis of vegetable acids, 996. Product of acid of tartar by dry distillation, 997. Of the spirits of vinegar, see Spirit of vinegar. On an ounce of cream of tartar were poured 10 ounces of boiling water, and the mixture allowed to remain in a jar covered with a lead slab, 998. In which a small hole was made with a pin. At the end of three months it was considerably diminished; and contained a quantity of thick, tough, white, and opaque subcarbonate of tartar, which neither effervesced with acids nor alkalis, and, when burnt, the ashes were found to contain only a very small quantity of acid fuming alkalis, 999. The experiment was repeated by Mr. Corvinus with some variation. He kept a solution of cream of tartar in a heat between 102° and 30° of Reaumur’s scale; removing the faine pellicles which formed on the surface as fast as they appeared, and redissolving them in water. By continuing the digestion for several months, the liquor became at last evidently alkaline: and he thus obtained 216 grains of a brown alkali from two ounces of cream of tartar. Mr. Batherel reported for nine months a solution of the heat of last alkali. The following experiment was made by Dr. Reid. He kept a solution of two ounces of cream of tartar in eight ounces of water; taking care to replace the water which evaporates but without removing the crusts which formed upon the surface. At the end of this time he found that the liquor was no longer acid, but began to turn the syrup of violets green. In 15 months it became strongly alkaline; and left, when evaporated, an oily residuum which effervesced with acids, and weighed 468 grains. On treating in the same manner a solution of terra foliates tartar, the liquor began to change to a green colour; and in two months, and in four, the decomposition seemed to be complete. At the end of a year he filtered and evaporated the liquor to dryness, by which means he obtained the salt grains of fixed alkali. The same quantity of terra foliate tartar decomposed immediately by distillation, yielded only 36 grains more of alkali, and subjected to the same treatment by a similar treat. For two years. The latter he observed to be a much more powerful antiseptic than tartar; for which reason it seems to reside decomposed in a proportionate degree. He supplies oil to be the principal cause of the defraction of these acids; and it is employed to separate the fixed from the vitriolic acid, in comparison with tartar, seems to be the cause of the want of capacity in it to undergo the decomposition just mentioned. A solution of 2 oz. of tartar and fixed alkali acid and 10 oz. of tartar with fixed alkalies, 1058. By this method the alkali is obtained, readily, and in such a quantity that its division by the colouring matter of Prussian blue, 1288. How affected by dephlegmated marine gas, 1485.

CHEMNITZ,
CHEMNITZ, (Martin) a famous Lutheran divine, the disciple of Melancthon, was born at Britzen in Brandenburg, in 1522. He was employed in several important negotiations by the princes of the same communion; and died in 1589. His principal work is the Examen of the Council of Trent, in Latin.

CHEMOSIS, a disease of the eyes, proceeding from an inflammation; wherein the white of the eye swells above the black, and overtops it to such a degree, that there appears a fort of gap between them. Others define it to be an elevation of the membrane which surrounds the eye, and is called the white; being an affection of the eye, like white-flush.

CHENOPODIUM, Goose-foot, or Wild Crunch: A genus of the digynia order, belonging to the pentandria class of plants; and in the natural method ranking under the 20th order Heloraee. The calyx is pentaphyllous and pentagonal; no corolla; one seed lenticular, superior. There are 18 species, 13 of which are natives of Britain. The most remarkable are the following: 1. The bonus hericus, or common English mercury, found growing naturally in shady lanes in many places in Britain. It has large triangular, arrow-pointed, entire leaves; upright, thick, fiddlestalk garnished with triangular leaves, and terminated by clove spikes of spatalous yellowish-green flowers in June and July, which are succeeded by ripe seeds in August. 2. The scoparia, belvidere, or annual mock-cypress, which is of a beautiful pyramidal form resembling a young cypress tree. 3. The botryae, or oak of Jerusalem. 4. The ambroisoides, or oak of Cappadocia. All these are very easily propagated from seeds; and will thrive best in a rich light earth. Most of the species have an aromatic smell. A species which grows near the Mediterranean is used by the Egyptians in fällada, on account of its salty aromatic taste. From the same plant kelp is made in other countries.—The first species, or English mercury, was formerly used as sip-nach; but is now disused, as being greatly inferior to that herb. As an article of the materia medica, it is ranked among the emollient herbs, but rarely made use of in practice. The leaves are applied by the common people for healing flux wounds, cleansing old ulcers, and other like purposes. The roots are given to sheep that have a cough. Goats and sheep are not fond of the herb; cows, hores, and fwine, refuse it. —The second species, or belvidere, is a plant much esteemed in China. The following are the properties attributed to it in the Chinese Herbal. After having said that it is about the end of March or beginning of April that the belvidere springs up from the earth; that its suckers or shoots rise to the height of eight or nine inches, in shape of a child's fist half full; that it afterwards extends itself, and sends forth a number of branches loaded with leaves like thofe of flax; and that, as it grows, its branches arrange themselves naturally in the form of a beautiful pyramid; it adds, that its leaves, yet tender, abound with juice, and have a very agreeable taste; that it may be eaten as a salad with vinegar, to which a little ginger has been added; that being prepared like other leguminous plants, and baked with meat, it gives it an agreeable and pleasing flavour: that, when in its full beauty, its leaves become hard and unfit for the table; but that nourishment is then found in its root, which serves as a resource in times of famine and scarcity. When the belvidere has attained to its natural size, the Chinese separate its principal stalk from the rest, and put it into a ley of ashes, which cleans and fottens it, and frees it from all impurities of the bark. After this bath, it is exposed to the sun; and when dry it is baked and seasoned. With regard to the root, which has something of a violet-colour, they strip off the skin by filaments, which may be boiled and eaten, but what is particularly sought after, is the root itself; of which, when reduced to powder, they collect only what remains in the bottom of the vessel, and form it into small leaves that are baked by being held over the flame of boiling oil. People of a delicate taste will scarcely be tempted to admit this dish at their tables; but it is not useful to point out to the poor peafants, that in cafes of necesfity, they may always have recourse, without danger, to this useful food? In such cases, they will be indebted to the Chinese for having made the attempt, which, for the most part, is dangerous. The Chinese Herbal cites the example of four mountaineers, who having lived on nothing but the leaves, roots, and stalks, of the belvidere, with which their country abounded, had nevertheless enjoyed perfect health to a very great age.

CHEPELIO, an island in the bay of Panama and province of Darien, in South America, situated about one hundred leagues from the city of Panama, which it supplies with provisions. W. Long. 61° 57'. N. Lat. 9°.

CHEPSTOW, a market town of Monmouthshire in England, feated on the river Wye near its mouth, in W. Long. 2° 40'. N. Lat. 51° 40'.

CHEQ., or CHERP., the prince of Mecca, who is, as it were, high priest of the law, and sovereign pontiff of all the Mahometans of whatever sect or country they be. See CALIPH.

The grand signor, sophis, moguls, khan of Tartary, &c. send him yearly presents, especially tapestry to cover Mahomet's tomb withal, together with a magnificent tent for himself, and vast sums of money to provide for all the pilgrims during the 17 days of their devotion.

CHERASCO, a strong and considerable town of Italy, in Piedmont, and capital of a territory of the same name, with a (former) citadel, belonging to the king of Sardinia, where he retired in 1706, during the siege of Turin. It is feated at the confluence of the rivers Sturia and Tanaro, upon a mountain. E. Long. 7° 55'. N. Lat. 44° 35'.

CHERBURG, a fea-port town of France, in Normandy, with a harbour and Augustine Abbey. It is remarkable for the sea-fight between the English and French fleets in 1692, when the latter were beat, and upwards of twenty of their men of war burnt near Cape la Hogue. The British landed here in August 1758, and took the town, with the fhips in the bafon, demolished the fortifications, and ruined the other works which had been long carried on for enlarging the harbour and rendering it more safe and commodious. Within these few years it has been attempted again to improve the harbour, and rebuild the works; but after considerable progress had been made, a great part of them suddenly gave way, and the enterprise is
CHEREM, among the Jews, is used to signify a species of annihilation. See ANNihilation.

The Hebrew word cherem signifies properly to destroy or exterminate, devote, or anathema.

Chermes is like wise sometimes taken for that which is consecrated, vowed, or offered to the Lord, so that it may no longer be employed in common or profane uses. No devoted thing that a man shall devote unto the Lord, of all that he hath of man and beast, and of the field of his possession, shall be sold or redeemed; every devoted thing is most holy to the Lord: none devoted, which shall be devoted of men, shall be redeemed, but shall surely be put to death. There are some who assert that the perfons thus devoted were put to death; whereas Jephtha's daughter is a memorable example. Judges xi. 29.

Chermes is also used for a kind of excommunication in use among the Jews. See NIDDU.

Cherson, or Charrzlu, a town of Turkey in Asia, capital of Curdistan, and the seat of a beglerbeg, E. Long. 45° 15'. N. Lat. 35° 0'.

Cherilus, of Samos, a Greek poet, flourished 479 years before Christ. He sung the victory gained by the Athenians over Xerxes, and was rewarded with a piece of gold for every verse. His poem had afterwards the honour of being rehashed yearly with the works of Homer.

Cherleria, in botany; a genus of the trigynia order, belonging to the decandria class of plants; and in the natural method ranking under the 22d order, Caryophyllaceae. The calyx is pentaphyllous; there are five nectaria, blind, and petal-like; the antheres alternately barren; the capsule is trilocular and three-valved.

Cherlesquior, in Turkish affairs, denotes a lieutenant-general of the grand signior's armies.

Chermes, in zoology, a genus of insects belonging to the order of insecta hemiptera. The rostrum is situated on the breast; the feelers are longer than the thorax; the four wings are deflected; the thorax is gibbous; and the feet are of the jumping kind. There are 17 species; and the trivial names are taken from the plants which they frequent, as the Chermes gra- minus, or graps-bug; the chermes ulmi, or elm-bug, &c. The chermes fleas, or fig-tree bug, one of the largest of the genus, is brown above and greenish beneath. The antennae, likewise brown, are large hairy, and one third longer than the thorax. The feet are yellowish; the wings large, twice the length of the abdomen. They are placed so as to form together an acute roof. The membrane of which they consist is thin and very transparent; but they have brown veins, strongly marked, especially towards the extremity. The rostrum of this chermes is black, and takes its rise from the lower part of the thorax, between the first and second pair of feet. It is an insect to be met with in great numbers upon the fig-tree. The larva has six feet. It is like the insect, when provided with wings, its form is oblong, and its motion slow.

The chrysalis differs from it by two flat buds that spring from the thorax and inclose the wings, afterwards seen in the perfect insect. These chrysalids are frequently met with on plants; and the two places of their thorax give them a broad uncouth appearance and a heavy look. When the little chrysalids are going to be metamorphosed, they remain motionless under some leaves which they fix themselves upon. Their skin then divides upon the head and thorax, and the perfect insect comes forth with his wings, leaving the poul of his chrysalis open and rent anteriorly upon the leaf. These kind of bugs are often found beneath the leaves of the fig-tree. The perfect insect is furnished with four wings, large in proportion to its body, veined, and placed in the form of a roof; and with them it flies. It has, moreover, the faculty of leaping pretty briskly, by means of its hinder-legs, which play like a spring. When it is attempted to catch the chermes, it makes its escape rather by leaping than flying. Some of these insects have a manufaeture worthy of notice. Several species are provided at the extremity of their body with a small sharp-pointed implement; but which lies concealed, and that they draw out in order to deposit their eggs, by making a puncture in the plant that suits them. By this method the fig-tree chermes produces that enormous football, which is found at the summit of the branches of that tree, and which is formed by the extravasation of the juices occasioned by the punctures. The young larvae shelter themselves in cells contained in the tumour. The white down, under which the larva of the pine-chermes is found, seems to be produced much in the same manner.

That of the box-tree chermes produces no tubercula like those; but its punctures make the leaves of that tree bend and grow hollow in the shape of a cup, which by the union of those infected leaves produces at the extremity of the branches a kind of knobs, in which the larvae of that insect find shelter. The box-chermes, as well as some others, has yet another peculiarity, which is, that the larva and its chrysalis eject at the anus a white sweet-tasted matter, that foists under the touch, and is not unlike manna. This subfidence is found in small white grains within the balls formed by the box-leaves, and a stiring of the same matter is often seen depending from the anus of the insect.

Chermes Mineral. See Kerme.

Cherry-Island, an island in the northern ocean, lying between Norway and Greenland, in E. Long. 20° 5'. N. Lat. 75° 0'.

Cherry-Tree, in botany. See Prunus.

Cherso, an island in the gulph of Venice, with a town of the same name near Crete, belonging to the Venetians. The air is good, but the soil rocky; however, it abounds in wine, cattle, oil, and excellent honey. E. Long. 15° 5'. N. Lat. 45° 8'.

Chersonesus, among modern geographers, the same with a peninsula; or a continent almost encompassed round with the sea, only joining to the main land by a narrow neck or isthmus. The words is Greek, χερσονήσις; of χερσός, land, and νήσος, island; which signifies the same. In ancient geography, it was applied to several peninsulas: as the Chersonesus Aurea, Cimbrica, Taurica, and Thracia, now thought to be Malacca, Jutland, Crimea Tartary, and Romania.

Cherit, Petrosilex, Lapis Cornetus, the Hornstone of the Germans; a species of flone clasified by Cronstedt among the siliceous earths. It is of a corf:
fer texture than the common flint, as well as softer; for which reasons it is not capable of such a fine pol- 
lish. It is faintly translucent at the edges, or when broken into very thin pieces. It is found of different 
colours, viz. white, whitish yellow, flesh-coloured, and 
greenish. According to Mr Kirwan, it runs in veins 
through rocks, from whence its name is derived; its 
specific gravity being from 2.59 to 2.700. In the fire 
it whitens and decrepitates like files, but is generally 
sufficient per se. Mineral alkali does not totally dif 
solve it in the dry way, but borax and microcosmic 
foam with effervescence. Its appearance is droller and 
less transparent than flint. The reddish pet 
roflex, used in the court de Lauragais's porcelain 
manufactory, and there called field-jeat, contained 72 
per cent. of files, 20 of argill, and 6 of calcareous earth.

Cromledt observes that there are not as yet any 
certain characters known by which the cherubs and 
jaspers may be distinguished from one another, though 
they can easily be so by touch; the cherubs appearing 
of a fine sparkling texture when broken; but the Jasper 
being grained, dull, and opaque, and having the ap- 
pearance of a dry clay. The cherub is also found form- 
ing larger or smaller veins, or in nodules like kernels 
in rocks; whereas the Jasper, on the contrary, some 
times constitutes the principal part of the highest and 
most extended mountains. The cherub is likewise 
found plentifully in the neighbourhood of stony lime- 
stones, as flints are in the frazis of chalk.

The connection between these bodies is not yet dis 
covered; but it is impollible to establish any essential 
difference between them, from the circumstance of 
flints and agates being generally found in single, loofe, 
and irregular nodules, and hardly in rocks like the 
cherub; for near Conblantimo the agate ftones runs in 
a vein across the rock, of the fame hardness, and as fine 
and transparent, as those agates found in round 
noahules at Deux Ponts.

CHERTZEY, a market town of Surrey in England, 
about seven miles west from Kingston upon Thames. 
W. Long. 50°, N. Lat. 51° 25'.

CHERUB, (plural, CHERUBIM); a celestial spirit, 
which in the hierarchy is placed next to the seraphim. 
See HIERARCHY.

The term cherub, in Hebrew, is sometimes taken for 
a calf or ox. Ezekiel sets down the face of a cherub 
as synonymous to the face of an ox. The word cher- 
ub, in Syriac and Chaldee, signifies-to till or plow, which 
is the proper work of oxen. Cherub also signifies 
strong and powerful. Grotius says, that the Cherubim 
were figures much like that of a calf. Buech显示 likewise, 
that the cherubim were more like to the figure of an ox 
than to any thing besides; and Spener 
is of the same opinion. Lastly, St John, in the 
Revelations, calls cherubim beasts. Josephus says, that the Cherubim 
were extraordinary creatures of a figure un- 
known to mankind. Clemens of Alexandria be- 
lieves, that the Egyptians imitated the cherubim of 
the Hebrews in the representations of their phalxins 
and their hieroglyphical animals. All the several 
discriptions which the scripture gives us of cherubim 
differs from one another; but all agree in representing 
them as a figure composed of various natures, as a 
man, an ox, an eagle, and a lion. Such were the cherubims described by Ezekiel. Those which Isaiah 
2
CHE [ 641 ] C HE

CHE

CHESS, an ingenious game performed with different pieces of wood, on a board divided into 64 squares or houses; in which chance has so little a share, that it may be doubted whether a person ever lost a game but by his own fault.

Each gamester has eight dignified pieces, viz. a king, a queen, two bishops, two knights, and two rooks, also eight pawns: all which, for distinction's sake, are painted of two different colours, as white and black.

As to their disposition on the board, the white king is to be placed on the fourth black house from the corner of the board, in the first and lower rank; and the black king is to be placed on the fourth white house on the opposite, or adversary's end of the board. The queens are to be placed next to the kings, on houses of their own colour. Next to the king and queen, on each hand, place the two bishops; next to them, the two knights; and last of all, on the corners of the board, the two rooks. As to the pawns, they are placed, without distinction, on the second rank of the house, one before each of the dignified pieces.

Having thus disposed the men, the onset is commonly begun by the pawns, which march straight forward in their own file, one house at a time, except the first move, when it can advance two houses, but never moves backwards: the manner of their taking the adversary's men is side-ways, in the next house forwards; where having captivated the enemy, they move forward as before. The rook goes forward or crofs-ways through the whole file, and back again. The knight skips backward and forward to the next house, save one, of a different colour, with a sliding march, or a leap, and thus kills his enemies that fall in his way, or guards his friends that may be exposed on that side. The bishop walks always in the same colour of the field that he is placed in at first, forward and backward, alofe, or diagonally, as far as he lifts.

The queen's walk is more universal, as she takes all the steps of the before mentioned pieces, excepting that of the knight; and as to the king's motion, it is one house at a time, and that, either forward, backward, dopping, or side-ways.

As to the value of the different pieces, next to the king is the queen, after her the rooks, then the bishops, and last of the dignified pieces comes the knight. The difference of the worth of pawns, is not so great as that of noblemen; only, it must be observed, that the king's bishop's pawn is the best in the field, and therefore the skilful gamester will be careful of him.

It ought also to be observed, that whereas any man may be taken, when he falls within the reach of any of the adversary's pieces, it is otherwise with the king, who, in such a case, is only to be saluted with the word check, warning him of his danger, out of which it is absolutely necessary that he move; and, if it so happen that he cannot move without exposing himself to the like inconvenience, it is check-mate, and the game is lost. The rules of the game are,

1. In order to begin the game, the players must be seated opposite to each other, and afterwards the pieces must be brought out to support them. The king's, queen's, and bishop's pawns, should be moved first, that the game may be well opened; the pieces must not be played out early in the game, because the player may thereby lose
A. Castling, is to cover the king with a castle; which is done by a certain move which each player has a right to whenever he thinks proper.

B. To queen, is to move a pawn into the adversary's back row, which is the rule at this game when the original one is lost.

c. When the King is blocked up so as to have no move at all.
A player should never cover a check with a piece that a pawn pushed upon it may take, for fear of getting only the pawn in exchange for the piece.

A player should never crowd his adversary up with pieces, for fear of giving a stalemate inadvertently, but always should leave room for his king to move.

By way of corroborating what has been already said with respect to this game, it is necessary to warn a player against playing a timid game. He should never be too much afraid of losing a rook for an inferior piece; because although a rook is a better piece than any other except the queen, it seldom comes into play to be of any great use till at the end of the game; for which reason it is often better to have an inferior piece in play, than a superior one to stand still, or moving to no great purpose. If a piece is moved, and is immediately drove away by a pawn, it may be reckoned a bad move, because the adversary gains a double advantage over the player, in advancing at the same time the other is made to retire; although the first may not seem of consequence between equal players, yet a move or two more left after the first makes the game scarcely to be recovered.

There never wants for a variety at this game, provided the pieces have been brought out regular; but if otherwise, it often happens that a player has no where to play.

Many indifferent players think nothing of the pawns, whereas three pawns together are strong; but four, which constitute a square, with the alinement of other pieces, well managed, make an invincible strength, and in all probability may produce a queen when very much wanted. It is true, that two pawns with a space between are no better than one; and if there should be three over each other in a line, the game cannot be in a worse way. This shows that the pawns are of great consequence, provided they are kept close together.

Some middling players are very apt to risk losing the game in order to recover a piece; this is a mistake; for it is much better to give up a piece and attack the adversary in another quarter; by so doing, the player has a chance of snatching a pawn or two from, or gaining some advantage over, the adversary, whilst his attention is taken up in parrying this piece.

If the queen and another piece are attacked at the same time, and that by removing the queen the piece must be lost; provided two pieces can be gained in exchange for the queen, the queen should be given up, it being the difference of three pieces, and consequently more than the value of the queen. By losing the queen, the game is not thrown into that disorder which it would otherwise have been: in this case it would be judicious to give the queen for even a piece, or a pawn or two; it being well known among good players, that he who begins the attack, and cannot maintain it, being obliged to retire, generally loses the game.

A player should never be fond of changing without reason, because the adversary, if he is a good player, will ruin his situation, and gain a considerable advantage over him. But rather than lose a move, when a player is stronger than the adversary, it is good play to change, for he thereby increases his strength.

When the game is almost drawn to a conclusion, the player should recollect that his king is a capital piece, and consequently should keep him in motion; by so doing he generally gets the move, and often the game.

As the queen, rook, and bishop, operate at a distance, it is not always necessary in the attack to have them near the adversary's king.

If a man can be taken with different pieces, the player should take his time, and consider which of those pieces is the best to take it with.

If a piece can be taken almost at any time, the player should not be in a hurry about it, but try to make a good move elsewhere before he takes it.

A player should be cautious how he takes his adversary's pawn with his king, as it often happens to be a safe-guard to it.

After all that has been said, it is still necessary for us to advise those who would play well at this game, to be very cool and attentive to the matter in question: for it is impossible that any person in the universe can be capable of playing at chess if they think that they are played elsewhere. To learn to play at this game are,

1. If a player touches his man, he must play it, and if he quits it, he cannot recall it.

2. If by mistake or otherwise a false move is played, and the adversary takes no notice of it till he hath played his next move, it cannot be recalled by either of the parties.

3. If a player misplaces the men, and he plays two moves, it is at the option of the adversary to permit him to begin the game or not.

4. If the adversary plays or discovers a check to a player's king, and gives no notice of it, the player may let him stand still till he does.

5. After the king is moved, a player cannot castle.

Sarasin has an express treatise on the different opinions of the original of the Latin schach, whence the French echecs, and our chess, is formed. Menage is also very full on the same head. Lencelavus takes it to come from Ufeches, famous Turkish robbers; P. Sirmond, from the German Scehch, "theft:" and that from calculus. He takes chess to be the same with theadius latrunculorum of the Romans, but mistakenly. This opinion is countenanced by Vollius and Salmasius, who derive the word from calculus, as used for latrunculus. G. Tolosanus derives it from the Hebrew shach, vallavit et mat moritun; whence check and checkmate. Fabricius says, a celebrated Persian astronomer, one Schatrenfcha, invented the game of chess; and gave it his own name, which it still bears in that country. Nicod derives it from shachque, or shaghe, a Moorish word for lord, king, and prince. Bochart adds, that shach is originally Persian; and that shachmat, in that language, signifies the king is dead.—The opinion of Nicod and Bochart, which is likewise that of Scriverius, appears the most probable.

Mr Twiss mentions a small treatise on chess, written, as he supposes, about 400 years ago; at the end of which is a representation of a round chess-board, with directions for placing the men upon it. In this the knight can cover the 64 squares on the board at as many moves. The board is divided into these 64 parts by four concentric circles, having an empty space in the middle; and each of these is divided into 8 parts. Number 1 is placed in the outermost circle; number 2 in the third circle counting inwards, in the division to

4 M 2
Chefs. the right hand of the former; number 3 is placed in the outermost circle, in the division to the right hand of 2; 4 in the third circle counting inwards to the right hand of three; and thus alternately from the first to the third, and from the third to the first circle, till the round is completed by 16 on the third circle to the left hand of 1. Number 17 is then placed on the division of the innermost circle to the right hand of 1; 18 on the second circle counting inwards, to the right hand of 17; and thus alternately from the second to the fourth circles, until the round is completed by 32, directly below number 1. Number 33 then is placed on the third circle directly to the right hand of number 2; 34 on the fourth circle, to the right hand of 4; and thus alternately between the third and fourth circles, until the round is again completed by 48 on the fourth circle, directly below number 33. The numbers are now placed in a retrograde fashion; 50 on the outer circle in that division immediately to the right hand of 1; 51 on the third circle, to the left hand of 2, and directly below number 32; 52 is then placed on the outer circle, immediately on the left hand of 1: 53 on the third circle directly to the left hand of 16; and thus alternately on the first and third circles, until the last round is completed by 64 between the numbers 3 and 5. On this round check-board, supposing the black king to be placed in number 49 on the fourth circle, the queen stands on number 17 at his left hand; the bishops in 32 and 2; the knights 18 and 47; the castles in 3 and 50; the pawns on 19, 4, 49, 64, and 46, 51 32, 1. The white king will then stand in 25, opposite the black queen; the white queen in 40 opposite to the black king, and so on. In playing on a board of this kind, it will be found that the power of the castle is double to that in the common game, and that of the bishop only one half; the former having 16 squares to range in, and the last only four. The king can castle only one way; and it is very difficult to bring the game to a conclusion.

With regard to the origin of the game at chefs, we are much in the dark. Though it came to us from the Saracens, it is by no means probable that they were the original inventors of it. According to some it was invented by the celebrated Grecian hero Diomedes. Others say, that two Grecian brothers, Lcedo and Tyrrenno, were the inventors; and that being much professed with hunger, they fough to alleviate the pain by this amusement. It is certain, however, that it is a game of very ancient standing, and in former ages has been very fashionable in every part of Europe; though in this country it is not very common, probably on account of the intense application of thought required to play at it. It has long been a favourite of the Icelanders and other northern people. There is little difference between their game and ours.

The game of chefs has been generally practised by the greatest warriors and generals; and some have even suppos'd that it was necessary for a military man to be well professed in this game. It is a game which has something in it peculiarly interesting. We read that Tamerlane was a great chefs-player, and was engaged in a game during the very time of the decisive battle with Bajazet the Turkish emperor, who was defeated and taken prisoner. It is also related of Ali Amin the khalif of Bagdad, that he was engaged at chefs with his freedman Kuthar at the time when Ali Amin's forces were carrying on the siege of that city with so much vigour that it was on the point of being carried by assault.

Dr Hyde quotes an Arabic history of the Saracens, in which the khalif is said to have cried out when warned of his danger, Let me alone, for I see check-mate against Kuthar! We are told that Charles I. was at chefs when news were brought of the final intention of the Scots to fell him to the English; but to little was he discomposed by this alarming intelligence, that he continued his game with the utmost composure; so that no person could have known that the letter he received had given him information of any thing remarkable. King John was playing at chefs when the deputies from Rouen came to acquaint him that their city was besieged by Philip Augustus; but he would not hear them until he had finished his game.

The following remarkable anecdote we have from Dr Robertson in his History of Charles V. John Frederic, elector of Saxony, having been taken prisoner by Charles, was condemned to death. The decree was intimated to him while at chefs with Ernst of Brunswick, his fellow-prisoner. After a short pause, and making some reflections on the irregularity and injustice of the emperor's proceedings, he turned to his antagonist, whom he challenged to finish the game. He played with his usual ingenuity and attention; and having beat Ernst, expressed all the satisfaction that is commonly felt on gaining such victories. He was not, however, put to death, but set at liberty after five years confinement.

In the Chronicle of the Moorish kings of Granada we find it related, that in 1396, Mehemed Balbafeizd upon the crown in prejudice of his elder brother, and palled his life in one continual round of difasters. His wars with Castile were invariably unsuccessful; and his death was occasioned by a poisoned veil. Finding his cafe desperate, he dispatched an officer to the fort of Salobrena to put his brother Juzaf to death; but left that prince's adherents shou'd form any obstacle to his son's succession. The alcaide found the prince playing at chefs with an alfiqu*i or priest. Juzaf begged hard for two hours respite, which was denied him; and at last with great reluctance the officer permitted him to finish the game; but before it was finished a messenger arrived with the news of the death of Mehemed, and the unanimous election of Juzaf to the crown.

We have a curious anecdote of Ferrand count of Flanders; who having been accouled to amuse himself at chefs with his wife, and being constantly beaten by her, a mutual hatred took place; which came to such an height, that when the count was taken prisoner at the battle of Bovines, she suffered him to remain a long time in prison though she could easily have procured his releas.

The game of chefs has undergone considerable variations since it was first invented. We have it on good authority, that among the eastern nations, the piece now called the queen was formerly called the vizir or king's minifter, and that the powers of the queen herself were but very small. The chefs-boards used by Tamerlane were larger, and contained many more squares,
CHE [ 645 ]

CHE, squares, than those at present in use. Carrera invented two new pieces to be added to the eight commonly in use. One of these, which he calls campione, is placed between the king's knight and castle, the other, named conture, between the queen's knight and castle, has the move of the bishop and knight united. This invention, however, did not favor its author. In another of this kind, the two additional pieces are called the centurion and decurion: the former, situated between the king and his bishop, in its move the same with that of the queen, but only for two squares; the latter moves as the bishop, but only one square at a time. This, like the former, died with its inventor. The chefs-board of Tamerlane was a parallelogram, having eleven squares one way and twelve the other. In the Memoirs of the late Marshal Keith, we find it related, that he invented an amusement something similar to that of chefs, with which the king of Prussia was highly entertained. Several thousand small statues were call by a founder; and these were ranged opposite to each other as if they had been drawn up in an army; many of the different movements with them as in real service in the field.

A very complicated kind of game at chefs was invented by the late duke of Rutland. At this the board has 14 squares in breadth and 10 in height, which make in all 140 houses: and there are 14 pawns on each side, which may move either one, two, or three squares the first time. The other pieces were the king, queen, two bishops, two knights, a crowned castle uniting the move of the king and castle, and a common castle. On the other side of the king was a concubine, whose common move united that of the castle and knight, two bishops, a single knight, a crowned castle, and a common castle. On the other side of the king was a concubine, whose common move united that of the castle and knight, two bishops, a single knight, a crowned castle, and a common castle. In this game the pawns are of very little use; and by the extent of the board, the knights lose much of their value, which consequently renders the game more defective and less interesting than the common one.

There is an amusing variety at the game of chefs, in which the king with eight pawns engages the whole set, by being allowed to make two moves for every one of his adversary. In this he is almost certain of coming off victorious; as he can make his first move into check, and the second out of it. Thus he can take the queen when she stands immediately before her king, and then retreat; for he cannot remain in check. He cannot be check-mated unless his adversary has preserved his queen and both castles.

Chess-Trees, taquetis d'anuere; two pieces of wood bolted perpendicularly, one on the starboard, and another on the larboard, side of the ship. They are used to confine the claeu, or lower corners of the main-sail; for which purpose there is a hole in the upper part, through which the rope passes that usually extends the claeu of the sail to windward. See Tack.

The chefs-trees are commonly placed as far before the main-mast as the length of the main-beam.

CHEST, in commerce, a kind of measure, containing an uncertain quantity of several commodities.

A chef of sugar, e. g. contains from ten to fifteen hundred pounds; a chef of glass, from two hundred to three hundred feet; a chef of coffee, from two and an half to three hundred weight; of indigo, from one and an half to two hundred weight, five score to the hundred.

CHEST, or Thorax. See Anatomy, Part IV.

CHESTER, commonly called West-Chester, to distinguish it from many other Chester, in the kingdom; the capital of Cheshire, in England. It is a very ancient city, supposed to have been founded by the Romans; and plainly appears to have been a Roman station by the many antiquities which have been and are still discovered in, and about the town. It was among the last places the Romans quitted; and here the Britons maintained their liberty long after the Saxons had got possession of the rest of their country. At present it is a large well-built wealthy city, and carries on a considerable trade. Mr Pennant calls it a city without parallel, on account of the singular structure of the four principal streets. They are as if excavated out of the earth, and sunk many feet beneath the surface; the carriages drive far beneath the level of the kitchens on a line with ranges of shops. The houses are mostly of wood, with galleries pendants, and covered walls before them; by which not only the shops, but those who are walking about the town, are hid, that one would imagine there were scarce any inhabitants in it, though it is very populous. But though by this contrivance such as walk the streets are screened from rain, &c., yet the shops are thereby rendered dark and inconvenient. The back courts of all the houses are on a level with the ground; but to go into any of the four principal streets, it is necessary to descend a flight of several steps.

Chester is a bishop's see. It was anciently part of the diocese of Litchfield; one of whose bishops removing the seat of his see hither in the year 1075, occasioned his successors to be frequently styled bishops of Chester. But it was not erected into a distinct bishopric until the general dissolution of monasteries, when king Henry VIII. in the year 1541, raised it to this dignity, and allotted the church of the abbey of St Werburgh for the cathedral, styling it the cathedral church of Christ and the blessed Virgin; adding the bishopric to the province of Canterbury: but soon after he disjoined it from Canterbury, and added it to the province of York. When this abbey was dissolved, its revenues were valued at L. 1005: 3: 11. This diocese contains the entire counties of Chester and Lancaster, part of the counties of Welfmoreland, Cumberland, and Yorkshire, two chapellies in Denbyshire, and five parishes in Flintshire; amounting in all to 256 parishes, of which 101 are impropriations. This bishopric is valued in the king's books at L 420: 1: 8, and is computed to be worth annually L.2700; the clergy's tenths amounting to L.435: 12: 6. To this cathedral belong a dean, two archdeacons, a chancellor, a treasurer, six prebendaries, and other inferior officers and servants. W. Long, 3. o. N. Lat. 53. 12.

Chester-le-Street, the Cunusacre of the Saxons: a small thoroughfare town between Newcastle and Durham, with a good church and fine spire. In the Saxon times this place was greatly respected on account of the relics of St Cuthbert, deposited here by bishop Eardulf, for fear of the Danes, who at that time (about 884) ravaged the country. His shrine became.
became afterwards an object of great devotion. King Athelstan, on his expedition to Scotland, paid it a visit, to obtain, by intercession of the saint, success on his arms; beloowed a multitude of gifts on the church; and directed, in case he died in his enterprise, that his body should be entered there. At the time that this place was honoured with the remains of one of great privileges, and always thought themselves exempt from all military duty, except that of defending the body of their saint. Chester-le-Frreet may be considered as the parent of the fee of Durham; for when the relics were removed there, the fee in 995 followed them. Tanner says, that probably a chapter of monks, or rather secular canons, attended the body at this place from its first arrival; but bishop Beke, in 1286, in honour of the saint, made the church collegiate, and established here a dean and suitable ecclesiastics; and, among other privileges, gives the dean a right of fishing on the Were, and the rythe of fish.

New Chester, a town in the flate of Pennsylvania, and capital of a county of that name. It is seated on the Delaware, and has a fine capacious harbour, admitting vessels of any burden. W. Long. 74. 7. N. Lat. 40. 15.

CHESTERFIELD, a market town of Derbyshire in England, pleasantly situated on a hill between two small rivers. It has the title of an earldom; and a considerable market for corn, lead, and other country commodities. The houses are, for the most part, built of rough stone, and covered with slate. W. Long. 1. 25. N. Lat. 53. 20.

CHESTERFIELD (Earl of). See STANHOPE.

CHEVAL de FRIZE, a large piece of timber pierced, and traversed with wooden spikes, armed or pointed with iron, five or six feet long. See Plate CXXXVI.

The term is French and properly signifies a Frizeland horse; as having been first invented in that country. It is also called a Turnpike or Turniquet.

Its use is to defend a paillage, keep a breach, or make a rethrenchment to stop the cavalry. It is sometimes also mounted on wheels, with artificial fires, to roll down in an assault. Errard observes, that the prince of Orange used to inclose his camp with chevaux de Frise, placing them one over another.

CHÉVALER, in the manage, is said of a horse, when, in paillage upon a walk or trot, his off foreleg croixes or overlaps the near fore-leg every second motion.

CHÉVALIER, a French term, ordinarily signifying a Knight. The word is formed of the French cheval, "horse;" and the barbarous Latin cavallus.

It is used, in heraldry, to signify any cavalier, or horsemann armed at all points; by the Romans called cataphractus equus: now out of use, and only to be seen in coat-armour.

CHEVAUX de FRIZE. See CHEVAL de FRIZE.

CHEVIN, a name used in some parts of England for the CHUB.

CHEVIOT (or TIVIO) HILLS, run from north to south through Cumberland; and were formerly the borders or boundaries between England and Scotland, where many a bloody battle has been fought between the two nations; one of which is recorded in the ballad of Chevy-chase. These hills are the first land discovered by sailors in coming from the east into Scotland.

CHEVISANCE, in law, denotes an agreement or composition, as an end or order set down between a creditor and his debtor, &c. In the statutes, this word is most commonly used for an unlawful bargain or contract.

CHEVREAU (Urban), a learned writer, born at Lundun in 1613. He distinguished himself in his youth by his knowledge of the belles lettres; and became secretary of state to queen Christina of Sweden. Several German princes invited him to their courts; and Charles-Lewis, the elector palatine, retained him under the title of counsellor. After the death of that prince, he returned to France, and became preceptor to the duke of Maine. At length retiring to Lundun, he died there in 1701, aged 88. He was the author of several books; and amongst others, of an Universal History, which has been often reprinted.

CHÉVRON, or CHEVERON, in heraldry. See HERALDRY.

CHEWING-BALLS, a kind of balls made of aloe-tidea, liver of antimony, bay-wood, juniper-wood, and pellitory of Spain; which being dried in the sun, and wrapped in a linen cloth, are tied to the bit of the horse to chew; they create an appetite; and it is said, that balls of Venice-cracle may be used in the same manner with good success.

CHEYKS. See BENGAL, No 17.

CHEYNE (Dr George), a physician of great learning and abilities, born in Scotland in 1671, and educated at Edinburgh under the great Dr Pitcairn. He parted his youth in close study, and with great perseverance: but coming to settle at London, when about 30, and finding the younger gentry and free-livers to be the most easy of access and most susceptible of friendship, he changed on a sudden his former manner of living in order to force a trade, having observed this method to succeed with some others. The consequence was, that he grew daily in bulk, and in intimacy with his gay acquaintance; swelling to such an enormous size, that he exceeded 32 stone weight; and he was forced to have the whole side of his chariot made open to receive him into it; he grew short-breathed, lethargic, nervous, and feborheic; so that his life became an insufferable burden. In this deplorable condition, after having tried all the power of medicine in vain, he resolved to try a milk and vegetable diet; the good effects of which quickly appeared. His size was reduced almost a third; and he recovered his strength, activity, and cheerfulnes, with the perfect use of all his faculties. In short, by a regular adherence to this regimen, he lived to a mature period, dying at Bath in 1742, aged 72. He wrote several treatises that were well received; particularly, "An Essay on Health and Long Life;" and "The English Malady, or a Treatise of Nervous Diseases," both the result of his own experience. In short, he had the greatest reputation in his own time, both as a practitioner and as a writer; and most of his pieces passed thro several editions. He is to be ranked among those physicians
Some physicians who have accounted for the operations of medicines and the morbid alterations which take place in the human body upon mechanial principles. A spirit of piety and of benevolence, and an ardent zeal for the interests of virtue, are predominant throughout his writings. An amiable candour and ingenuousness are also discernible, and which led him to retract with readiness whatever appeared to him to be confiderable in what he had formerly advanced. Some of the metaphysical notions which he has introduced into his books, may, perhaps, justly be thought fanciful and ill-grounded; but there is an agreeable vivacity in his productions, together with much openness and frankness, and in general great perspicuity.

CHIABRERA (Gabriel), esteemed the Pindar of Italy, was born at Savona in 1552, and went to study at Rome. The Italian princes, and Urban VIII. gave him public marks of their esteem. He wrote a great number of poems; but his lyric verses are most admired. He died at Savona in 1638, aged 86.

CHIAN EARTH, in pharmacy, one of the medicinal earths of the ancients, the name of which is preferred in the catalogues of the materia medica, but of which nothing more than the name has been known for many ages in the shops.

It is a very dense and compact earth; and is sent hither in small flat pieces from the island of Chios, in which it is found in great plenty at this time. It stands recommended to us as an astringent. They tell us, it is the greatest of all cosmetics; and that it gives a whiteness and smoothness to the skin, and prevents wrinkles, beyond any of the other substances that have been celebrated for the same purposes.

CHIAOUS, a word in the original Turkish, signifying "envoys," are officers to the number of five or six hundred in the grand signior's court, under the command of a chaisoos bashi. They frequently meet in the grand vizir's palace, that they may be in readiness to execute his orders, and carry his dispatches into all the provinces of the empire. The chaisoos bashi assists the divan, and introduces those who have business there.

CHIAPA, a capital of a province of the same name in Mexico, situated about 300 miles east of Acapulco. W. Long. 98° 6'. N. Lat. 16° 30'.

CHIAPA DE LOS INDIOS, a large and rich town of North America, in Mexico, and in a province of the same name. The governor and most of the inhabitants are originally Americans. W. Long. 98° 35'. N. Lat. 16° 20'.

CHIAPAS, a town of Mexico, in a province of the same name, with a bishop's see. Its principal trade consists in chocolate-nuts, cotton, and sugar. W. Long. 98° 35'. N. Lat. 16° 20'.

CHIARA (Joseph), a celebrated Italian painter, was the disciple of Carlo Maratti; and adorned the churches and palaces of Rome with a great number of fine paintings. He died of an apoplexy in 1727, aged 73.

CHIARI, a town of Italy, in the province of Brescia, and territory of Venice, 7 miles west of Brescia, and 27 miles from Milan. Here the Imperialists gained a victory over the French in 1701. E. Long. 18° 18'. N. Lat. 45° 50'.

CHIARO-SCURO. See Claro-Obscur.

CHIAVENNA, a handsome, populous, and large town of Switzerland, in the country of the Grisons. It is a trading place, especially in wine and delicate fruits. The governor's palace and the churches are very magnificent, and the inhabitants are Roman Catholics. It is fleated near the lake Como. E. Long. 9° 29'. N. Lat. 46° 15'.

CHIAUSI, among the Turks, officers employed in executing the vizirs, bailawks, and other great men: the orders for doing this, the grand vizir sends them wrapped up in a black cloth; on the reception of which, they immediately perform their office.

CHICANE, or CHICANERY, in law, an abuse of judiciaty proceeding, tending to delay the cause, to puzzle the judge, or impose upon the parties.

CHICANE, in the schools, is applied to vain philosophies, distinctions, and subtleties, which protract disputes, and obscure the truth.

CHICHESTER, the capital city of the county of Sussex in England, was built by Ceila, the 2d king of the South Saxons, and by him called Cijian Caefter. It is surrounded with a wall, which has four gates, answering to the four cardinal points; from which run two streets, that cross one another in the middle and form a square, where the market is kept, and where there is a fine stone piazza built by bishop Read. The space between the west and south gates is taken up with the cathedral church and the bishop's palace. It has five parish-churches; and is seated on the little river Lavant, which washes it on all sides except the north. This city would have been in a much more flourishing condition if it had been built by the sea-side; however, the inhabitants have endeavored to supply this defect in some measure, by cutting a canal from the city down into the bay. The principal manufactures of the town are malt and needles. The market of Chichester is noted for fish, wheat, barley, malt, and oats; the finest lobster in England are bred in the Lavant; and it is observable, that this river, unlike most others, is very low in winter, but in summer often overflowing its banks. Chichester is a city and county of itself; it is governed by a mayor, recorder, aldermen, commoncouncil without limitation, and four justices of the peace chosen out of the aldermen; and it sends two members to parliament. It is a bishop's see. The cathedral church was anciently dedicated to St Peter. It was new built by Radulph, the twenty-fifth bishop; but being destroyed by fire, it was again built by Sessidius the twenty-ninth bishop. This see hath yielded to the church two sants, and to the nation three lord chancellors, two almoners, and one chancellor to the university of Oxford. Anciently the bishops of Chichester were confessors to the queens of England. This diocese contains the whole of the county of Sussex (excepting 22 parishes, peculiarities of the archbishop of Canterbury), wherein are 250 parishes, whereof 172 are appropriated. It hath two archdeaconesses, viz. of Chichester and Lewes: is valued in the king's books at L.677:1:5, and is computed to be worth annually L.2600. The tenth of the whole clergy is L.257:2:03. To the cathedral belong a bishop, a dean, two archdeaconesses, a treasurer, a chancellor, thirty-two prebendaries, a chanter, twelve vicars-coral, and other officers. W. Long. 50° N. Lat. 50° 50'.

CHICK, or CHICKEN, in zoology, denotes the young
young of the gallinaceous order of birds, especially the common hen. See \textit{Phasianus}.

\textit{Chick-wed}, in botany. See \textit{Alpine}.  
\textit{Chick-en-fox}. See (Index subjoined to) \textit{Medicine}.  
\textit{Chickling-pea}, in botany, a name given to the \textit{Lathyrus}.

\textit{Chicuítos}, a province of South America, in the government of Santo-Cruz de la Sierra. The chief riches consist of honey and wax; and the original inhabitants are very voluptuous, yet very warlike. They maintained bloody wars with the Spaniards till 1690; since which, some of them have become Christians. It is bounded by la Plata on the N. E. and by Chili on the W.

\textit{Chidley}, or \textit{Chimley}, a market-town of Devonshire, situated in W. Long. 4. 0. N. Lat. 51. 0.  
\textit{Chief}, a term signifying the head or principal part of a thing or person. Thus we say, the chief of a party, the chief of a family, &c. The word is formed of the French \textit{chef}, "head;" of the Greek \textit{kephalē}, "head;" though Menage derives it from the Italian \textit{capo}, formed of the Latin \textit{caput}.

\textit{Chief}, in heraldry, is that which takes up all the upper part of the escutcheon from side to side, and represents a man's head. In \textit{chief}, imports something borne in the chief part or top of the escutcheon.

\textit{Chief-tain}, denotes the captain or chief of any class, family, or body of men. Thus the chiefs or chieftains of the Highland clans, were the principal noblemen or gentlemen of their respective clans. See \textit{Clans}.

\textit{Chicles}, a strong town of Turkey in Europe, in the Morea. It was taken by the Venetians in 1685; but after that the Turks retook it, with all the Morea. E. Long. 22. 21. N. Lat. 26. 50.

\textit{Chigi} (Fabio), or Pope Alexander VII. was born at Siena in 1599. His family finding him a hopeful youth, sent him early to Rome, where he soon engaged in a friendship with the marquis Pallavicini, who recommended him so effectually to Pope Urban VIII. that he procured him the post of Inquisitor at Malta. He was sent vice-legate to Ferrara, and afterward nuncio into Germany; there he had an opportunity of displaying his intriguing genius; for he was mediator at Munster, in the long conference held to conclude a peace with Spain. Cardinal Mazarin had some resentment against Chigi, who was soon after made a cardinal and secretary of state by Innocent X. but his resentment was sacrificed to political views. In 1655, when a pope was to be chosen, Cardinal Sacchetti, Mazarin's great friend, finding it impossible for him to be raised into St Peter's chair because of the powerful opposition made by the Spanish faction, desired Cardinal Mazarin to content to Chigi's exaltation. His request was granted, and he was elected pope by the votes of all the 64 cardinals who were in the conclave: an unanimity of which there are but few instances in the election of popes. He showed uncommon humility at his election, and at first forbade all his relations to come to Rome without his leave; but he soon became more favourable to his nephews, and loaded them with favours. It is affirmed that he had once a mind to turn Protestant. The news-papers in Holland bestowed great encouragements upon him; and acquainted the world, that he did not approve of the cruel persecutions of the Wal-
Children. In the genealogical history of Tuscany, wrote by Gamarini, mention is made of a nobleman of Sienna, named Pichi, who of three wives had 150 children; and that, being sent ambassador to the pope and the emperor, he had 48 of his sons in his retinue. In a monument in the church yard of St. Innocent, at Paris, erected to a woman who died at 88 years of age, it is recorded, that she might have seen 288 children directly issued from her. This exceeds what Hakewell relates of Mrs Honeywood, a gentlewoman of Kent, in England born in the year 1527, and married at 16 to her only husband R. Honeywood, of Charing, Esq; and died in her 93d year. She had 16 children of her own body; of which three died young, and a fourth had no issue: yet her grandchildren, in the second generation, amounted to 114; in the third, to 228; though in the fourth, they fell to 9. The whole number the might have seen in her life-time, being 367. 

\[16 + 114 + 228 + 9 = 367\]

So that she could say the same as the ditto does of one of the Dalburg's family at Basil:

\[1 + 2 + 3 + 4 + 5 + 6\]

\[Ut moment, natce, plangere, filiolam.\]

Management of Children See Infant.

Overlaying of Children is a misfortune that frequently happens; to prevent which, the Florentines have contrived an instrument called arreceto. See Arrecesso.

Children are, in law, a man's issue begotten on his wife. As to illegitimate children, see Bastard.

For the legal duties of parents to their children, see the articles Parent and Bastard.

As to the duties of children to their parents, they arise from a principle of natural justice and retribution. For to those who gave us existence, we naturally owe subjection and obedience during our minority, and honour and reverence ever after: they who protected the weakness of our infancy, are entitled to our protection in the infirmity of their age; they who by sublimity and education have enabled their offspring to prosper, ought, in return, to be supported by that offspring, in case they find in need of assistance. Upon this principle proceed all the duties of children to their parents, which are enjoined by positive laws. And the Athenian laws carried this principle into practice with a scrupulous kind of nicety: obliging all children to provide for their father when fallen into poverty; with an exception to spurious children, to whose whole chastity had been prostituted with consent of their father, and to whom he had not put in any way of gaining a livelihood. The legislature, says baron Montesquieu, considered, that, in the first case, the father, being uncertain, had rendered the natural obligation precarious; that in the second case, he had fulfilled the life he had given, and done his children the greatest of injuries, in depriving them of their provision; and that, in the third case, he had rendered their life (so far as in him lay) an insupportable burden, by furnishing them with no means of subsistence.

Our laws agree with those of Athens, with regard to the first only of these particulars, the cafe of spurious issue. In the other cases, the law does not hold the tie of nature to be dissolved by any misbehavior of the parent; and therefore a child is equally justifiable in defending the person, or maintaining the cause of the father, as of a bad parent; and is equally compulsable, if of sufficient ability, to maintain and provide for a wicked and unnatural progenitor, as for one who has shown the greatest tenderness and paternal piety. See further the article Filial Affection.

CHILI, a province of South America, bounded by Peru on the north, by the province of La Plata on the east, by Patagonia on the south, and by the Pacific ocean on the west, lying between 75 and 85 degrees of west longitude, and between 25 and 45 degrees of south latitude; though some comprehend in this province Patagonia and Terra del Fuego.

The first attempt of the Spaniards upon this country was made by Almagro in the year 1535, after he and Pizarro had completed the conquest of Peru. He set out on his expedition to Chili with a considerable body of Spaniards and auxiliary Indians. For 200 leagues he was well accommodated with every necessity by the Indians, who had been subjects of the emperors of Peru: but reaching the barren country of Charcas, his troops became discontented through the hardships they suffered; which determined Almagro to climb the mountains called Cordilleras, in order to get the fonder into Chili; being ignorant of the invaluable mines of Potosi, contained in the province of Charcas where he then was. At that time the Cordilleras were covered with snow, the depth of which obliged him to dig his way through it. The cold made such an impression on his naked Indians, that it is computed no less than 10,000 of them perished on these dreadful mountains, 150 of the Spaniards sharing the same fate; while many of the survivors lost their fingers and toes through the excess of cold. At last, after encountering incredible difficulties, Almagro reached a fine, temperate, and fertile plain on the opposite side of the Cordilleras, where he was received with the greatest kindness by the natives. These poor savages, taking the Spaniards for deputies of their god Viracocha, immediately collected for them an offering of gold and silver worth 200,000 ducats: and soon after brought a present to Almagro worth 300,000 more. Their offerings only determined him to conquer the whole country as soon as possible. The Indians among whom he now was, had acknowledged the authority of the Peruvian incaes, or emperors, and consequently gave Almagro no trouble. He therefore marched immediately against those who had never been conquered by the Peruvians, and inhabited the southern parts of Chili. These savages fought with great resolution, and disputed every inch of ground: but in five months time the Spaniards had made such progress, that they must infallibly have reduced the whole province in a very little time, had not Almagro returned to Peru, in consequence of a commission sent him from Spain.

In 1540, Pizarro having overcome and put Almagro to death, sent into Chili, Baldio, or Valdivia, who had learned the rudiments of war in Italy, and was reckoned one of the best officers in the Spanish service. As he penetrated southwards, however, he met with much opposition; the confederated caciques frequently gave him battle, and displayed great con-
rage and resolution; but could not prevent him from penetrating to the valley of Maipocho, which he found incredibly fertile and populous. Here he found the city of St Jago; and finding gold mines in the neighbourhood, forced the Indians to work in them; at the same time building a castle for the safety and protection of his new colony. The natives, exasperated at this slavery, immediately took arms; attacked the fort; and, though defeated and repulsed, set fire to the outworks, which contained all the provisions of the Spaniards. Nor were they discouraged by this and many other defeats, but still continued to carry on the war with vigour. At last, Valdivia, having overcome them in many battles, forced the inhabitants of the vale to submit; upon which he immediately set them to work in the mines of Quilotta. This indignity offered to their countrymen redoubled the fury of those who remained at liberty. Their utmost efforts, however, were as yet unable to stop Valdivia's progress. Having crossed the large rivers Maullie and Hata, he traversed a vast tract of country, and founded the city of La Concepcion on the South-sea-coast. He erected fortresses in several parts of the country, in order to keep the natives in awe; and built the city called Imperial, about 40 leagues to the southward of Concepcion.

The Spanish writers say that the neighbouring valley contained 80,000 inhabitants of a peaceable disposition; and who were even so tame as to suffer Valdivia to parcel out their lands among his followers, while they themselves remained in a state of inactivity. About 16 leagues to the eastward of Imperial, the Spanish general laid the foundations of the city Villa Rica, so called on account of the rich gold mines he found there. But his ambition and avarice had now involved him in difficulties from which he could never be extricated: He had extended his conquests beyond what his strength was capable of maintaining. The Chileans were still as fierce as ever of recovering their liberties. The horses, fire-arms, and armour of the Spaniards, indeed, appeared dreadful to them; but thoughts of endless slavery were still more so. In the course of the war they had discovered that the Spaniards were vulnerable and mortal men like themselves; they hoped, therefore, by dint of their superiority in numbers, to be able to expel the tyrannical usurpers. All these nations joined in this resolution, the Spaniards had certainly been exterminated; but some of them were of a pacific and fearful disposition, while others considered servitude as the greatest of all possible calamities. Of this last opinion were the Araccans, the most intrepid people in Chili, and who had given Valdivia the greatest trouble. They all rofe to a man, and chose Capañican, a renowned hero among them, for their leader. Valdivia, however, received notice of their revolt sooner than they intended he should, and returned with all expedition to the vale of Aracca; but before he arrived, 14,000 of the Chileans were there assembled under the conduct of Capañican. He attacked them with his cavalry, and forced them to retreat into the woods; but could not obtain a complete victory, as they kept continually falling out and harrying his men. At last Capañican, having observed that fighting with such a number of undisciplined troops only served to contribute to the defeat and confusion of the whole, divided his forces into bodies of 1000 each. Thefe he directed to attack the enemy by turns; and, though he did not expect that a single thousand would put them to flight, he directed them to make as long a stand as they could; when they were to be relieved and supported by another body; and thus the Spaniards would be at last wearied out and overcome. The event fully answered his expectations. The Chileans maintained a fight for seven or eight hours, until the Spaniards, growing faint for want of refreshment, retired precipitately. Valdivia ordered them to police a pafs at some distance from the field, to stop the pursuit; but this design being discovered to the Chileans by the treachery of his page, who was a native of that country, the Spaniards were surrounded on all sides, and cut in pieces by the Indians. The general was taken and put to death; some say with the tortures usually inflicted by thole savages on their prisoners; others, that he had melted gold poured down his throat; but all agree, that the Indians made flutes and other instruments of his bones, and preferred his skull as a monument of their victory, which they celebrated by an annual festival. After this victory the Chileans had another engagement with their enemies; in which also they proved victorious, defeating the Spaniards with the loss of near 3000 men; and upon this they bent their whole force against the colonies. The city of Concepcion, being abandoned by the Spaniards, was taken and destroyed: but the Indians were forced to raise the siege of Imperial; and their progres was at last stopped by Garcia de Mendoza, who defeated Capañican, took him prisoner, and put him to death. No defeat, however, could dierip the Chileans. They continued the war for 50 years; and to this day they remain unconquered, and give the Spaniards more trouble than any other American nation. Their most irreconcilable enemies are the inhabitants or Aracceans and Tucapel, those to the south of the river Bobio, or whose country extends towards the Cordilleras —

The manners of these people greatly resemble those of North America, which we have already desribed under the article America; but seem to have a more warlike disposition. It is a constant rule with the Chileans never to sue for peace. The Spaniards are obliged not only to ask the first combatants, but to purchase it by presents. They have at last been obliged to abandon all thoughts of extending their conquests, and reduced to cover their frontiers by erecting forts at proper distances.

The Spanish colonies in Chili are dispersed on the borders of the South-sea. They are parted from Peru by a defart 80 leagues in breadth; and bounded by the island of Chiloe, at the extremity next the straits of Magellan. There are no settlements on the coasts except that of Baldavia, Concepcion Island, Valparaiso, and Coquimbo or La Serena, which are all sea-ports. In the inland country is St Jago, the capital of the colony. There is no culture nor habitation at any distance from these towns. The buildings in the whole province are low, made of unburnt brick, and modestly thatched. This practice is observed on account of the frequent earthquakes; and is properly adapted to the nature of the climate, as well as the indolence of the inhabitants.

The climate of Chili is one of the most wholesome
in the whole world. The vicinity of the Cordilleras
may be resolved into as many triangles as it has sides. Chiliarcha
The author of l'Art de Venerer, p. 44, has brought this
instance to show the distinction between imagination
and conceiving.

CHILIACHRA, or CHILIARCHUS, an officer in
the armies of the ancients, who had the command of
the fleet. May 1st.

CHILIARCHUS, in church-history. See MILLENA-
Rians.

CHILLINGWORTH (William), an eminent di-
vine of the church of England, was born at Oxford
in 1602, and bred there. He made early great pro-
minence in his studies, being of a very quick genius.
He was an expert mathematician, as well as an able
divine, and a very good poet. Study and conver-
sation at the university turning upon the controver-
sy between the church of England and that of Rome,
on account of the king's marriage with Henrietta daugh-
ter to Henry IV. king of France, Mr Chillingworth
forsook the church of England, and embraced the
Roman religion. Dr Laud, then bishop of London,
hearing of this, and being greatly concerned at it,
wrote Mr Chillingworth; who expressing a great deal
of candour and impartiality, that prelate continued to
correspond with him. This set Mr Chillingworth on
a new inquiry; and at last determined him to return
to his former religion. In 1634 he wrote a confu-
sation of the arguments which had induced him to go
over to the church of Rome. He spoke freely to his
friends of all the difficulties that occurred to him;
which gave occasion to a groundless report, that he
had turned Papist a second time, and then Protestant
again. His return to the communion of the church
of England made a great noise, and engaged him in
several disputes with those of the Roman persuasion.
But in 1635 he engaged in a work which gave him
a far greater opportunity to confute the principles of
the church of Rome, and to vindicate the Protestant
religion, under the title of 'The Religion of Protes-
tants a safe way to Salvation.' Sir Thomas Covent-
ry, lord keeper of the great seal, offering him pre-
ferment, Mr Chillingworth refused to accept it on ac-
count of his scruples with regard to the subscription
of the 39 articles. However, he at last surmounted these
scruples; and being promoted to the chancellorship
of the church of Sarum, with the prebend of Brix-
worth in Northamptonshire annexed to it, he there
remained with the usual subscription. Mr Chillingworth
was zealously attached to the royal party; and, in
August 1643, was present in king Charles I.'s army
at the siege of Gloucester, where he advised and di-
rected the making certain engines for assaulting the
town. Soon after, having accompanied the Lord
Hopton, general of the king's forces in the west, to
Arundel castle in Sussex, he was there taken prisoner
by the parliamentary forces under the command of Sir
William Waller, who obliged the castle to surrender.
But his ill health increasing, he obtained leave to be
conveyed to Chichester, where he was lodged at the bish-
op's palace; and, after a short illness, died in 1644.
He hath left several excellent works behind him.

CHILMINAR. See PERSERPOLIS.

CHILO, one of the seven sages of Greece, and
of the ephori of Sparta the place of his birth, flourished
about 556 years before Christ. He was accustomed
Chiloé, an island lying near the coast of Chili, in South America, under the 43rd degree of south latitude. It is the chief of an archipelago of 40 islands, and its principal town is Cañete. It rains here almost all the year, in some places covering the earth with snow, which has rendered it of late years fruitful, was covered with snow, and rendered it habitable.

CHIL TENHAM, a town in Gloucestershire, England, situated at the entrance of the Vale of the Chiltern Hundreds. The air on these heights is extremely salutary, and is deemed excellent in scurvy complaints.

CHILTERN, a chain of chalky hills forming the southern part of Buckinghamshire, England, the northern part of the county being distinguished by the name of the Vale. The air on these heights is extremely healthful: The soil, though stony, produces good crops of wheat and barley; and in many places it is covered with thick woods, among which are great quantities of beach. Chiltern is also applied to the hilly parts of Berkshire, and it is believed has the same meaning in some other counties. Hence the Hundreds lying in those parts are called the Chiltern Hundreds.

Chiltern Hundreds (Stewards of.) Of the Hundreds into which many of the English counties were divided by King Alfred, for the better government, the jurisdiction was originally vested in peculiar courts, but came afterwards to be devolved to the county courts; and so remains at present, excepting with regard to some, as the exchequer, which have been by privilege annexed to the crown.

Chimaera, a port-town of Turkey in Europe, situated at the entrance of the gulf of Venice, in the province of Epirus, about 32 miles north of the city Corfu, near which are the mountains of Chimaera, which divide Epirus from Thessaly. E. Long. 20. 40. N. Lat. 40. 40.

Chimera, a fabulous history, a celebrated monster, springing from Echidna and Typhon. It had three heads; one of a lion, and a goat, and a dragon; and continually vomited flames. The foreparts of its body were those of a lion, the middle was that of a goat, and the hinder parts were those of a dragon. It generally lived in Lydia, about the reign of Jobates, by whose orders Belerophon mounted on the horse Pegasus, overcame it. This fabulous tradition is explained by the recollection that there was a burning mountain in Lydia, whose top was the rest of lions on account of its desert wilderness; the middle, which was fruitful, was covered with goats; and at the bottom the marshy ground abounded with serpents. Belerophon is said to have conquered the Chimæra, because he destroyed the wild beasts on that mountain, and rendered it habitable. Plutarch says that it was the captain of some pirates who adorned their ship with the images of a lion, a goat, and a dragon.

By a chimæra, among the philosophers, is understood a mere creature of the imagination, composed of such contradictions and absurdities as cannot possibly any where exist but in thought.

Chimes of a Clock, a kind of periodical music, produced at equal intervals of time, by means of a particular apparatus added to a clock.

In order to calculate numbers for the chimes, and adapt the chime-barrel, it must be observed, that the barrel must turn round in the same time as the tune; it is to play requires in finging. As for the chime-barrel, it may be made up of certain bars that run athwart it, with a convenient number of holes punched in them to put in the pins that are to draw each hammer: and these pins, in order, to play the time of the tune rightly, must stand upright, or hang down from the bar, some more, some less. To place the pins rightly, you may proceed by the way of changes on bells, viz. 1. 2. 3. 4; or rather make use of the musical notes. Observe what is the compass of your tune, and divide the barrel accordingly from end to end. Thus, in the examples on Plate CXXXVII. each of the tunes is eight notes in compass; and accordingly the barrel is divided into eight parts. These divisions are struck round the barrel; opposite to which are the hammer-tails.

We speak here as if there were only one hammer to each bell, that it may be more clearly apprehended; but when two notes of the same sound come together in a tune, there must be two hammers to the bell to strike it: so that if in all the tunes you intend to chime of eight notes compass, there should happen to be such double notes on every bell, instead of eight you must have sixteen hammers; and accordingly you must divide the barrel, and strike sixteen strokes round it, opposite to each hammer-tail: then you are to divide it round about into as many divisions as there are musical bars, semibreves, minims, &c. in the tune.

Thus the hundredth-palm tune has 20 semibreves, and each division of it is a semibreve: the first note of it also is a semibreve; and, therefore, on the chime-barrel must be a whole division, from five to five, as your may understand plainly, if you conceive the surface of a chime-barrel to be represented by the above figures, as if the cylindrical superficies of the barrel were stretched out at length, or extended on a plane: and then such a table, so divided, if it were to be wrapped round the barrel, would show the places where all the pins are to stand in the barrel; for the dots running about the table are the places of the pins that play the tune.

Indeed, if the chimes are to be complete, you ought to have a set of bells to the gamut notes; so as that each bell having the true sound of fol, la, mi, fa, you may play any tune with its flats and sharps: nay, you may by this means play both the bass and treble with one barrel: and by setting the names of your bells at the
Chimney

the head of any tune, that tune may easily be transferred to the chime-barrel, without any skill in music; but it must be observed, that each line in the music is three notes distant; that is, there is a note between each line, as well as upon it.

CHIMNEY, in architecture, a particular part of a house, where the fire is made, having a tube or tunnel to carry off the smoke. The word chimney comes from the French cheminée, and that from the Latin camina, a chamber wherein is a chimney; "caminata, again, comes from caminius; and that from the Greek σιματος, "a chimney," if σαυρ, are "I burn."

Chimneys are usually supposed a modern invention; but in Italy, and that of Appian, who says, "That of those persons prostrated by the triumvirate, some hid themselves in wells and common ewers, and some on the tops of houses and chimneys;" for he understands "Camnas urbicums, simaria sub teglo posta." Add, that Aristophanes, in one of his comedies, introduces the tops of houses and chimneys; together with the obscurity of the rules of Vitruvius on this head, make us rather conclude the use of chimneys, because of the ancient houses, where the chimneys had entire apartments, induced them to neglect this part of building which the coldness of our climates obliges us to have a principal regard to.

Method of Building CHIMNEYS that will not smoke. Workmen have different methods of drawing up the funnels of chimneys, generally according to their own fancies and judgments, and sometimes according to the customs of places. They are seldom directed by found and rational principles. It will be found for the most part, that the smoking of chimneys is owing to their being carried up narrower near the top than below, or zig-zag, all in angles; in some cases, indeed, it is owing to accidental causes, but for the most part, to those above mentioned. Where they are carried up in pyramid or tapering form, especially if the house be of a considerable height, it is ten to one but they sometimes smoke. The air in the rooms, being rarified, is forced into the funnel of the chimney, and receives from the fire an additional force to carry up the smoke. Now, it is evident, that the further up the smoke flies, the less is the force that drives it, the flower it must move, and consequently the more room in proportion it should have to move in; whereas in the usual way it has less, by the sides of the chimney being gathered closer and closer together.

The method here proposed of carrying up chimneys will be objected to by some thus: The wider a chimney is at the top, the more air the smoke puff out below. This method has proved effectual after all others had failed; and that in a house placed in the worst situation possible, namely, under a high mountain to the southward, from which strong blaits blow down upon it. A vent was carried up without angles, as perpendicular as possible; and was made about three or four inches wider at top than at the bottom: the funnel was gathered in a throat directly above the fire-place, and so widening upwards. Since that time the house has not only ceased to smoke, but when the doors stand open, the draught is so strong that it will carry a piece of paper out at the chimney-head. See more on this subject under the article SMOKE.

CHIMNE-Y-Money, otherwise called Hearth-money, a duty in England on houses. By Stat. 14. Char. II. cap. 2. every fire-hearth, and floor of every dwelling or other house, within England and Wales (except such as pay not to church and poor), was chargeable with 2 s. per annum, payable at Michaelmas and Lady-day to the king and his heirs and successors &c.; which payment was commonly called chimney-money. This tax, being more complained of as burdenome to the people, has been since taken off, and others imposed in its stead; among which that on windows has by some been esteemed almost equally grievous.

CHIMPANZEE, in natural history. See SIMIA.

CHINA, a country of Asia, situated on the most easterly part of that continent. It is bounded on the north by Tartary; from which it is divided, partly by a prodigious wall of 1500 miles in length, and partly by high, croppay, and inaccessible mountains. On the east, it is bounded by the ocean; on the west, by part of the Mogul's empire, and India beyond the Ganges, from which it is parted by other ridges of high mountains and sandy deserts. On the south, it is bounded partly by the kingdoms of Lao, Tonquin, Ava, and Cochín-China, and partly by the southern or Indian sea, which flows between it and the Philippine Islands. There are several ways of computing its length and breadth. According to some of these, it is reckoned 1268, 1600, or 1800 miles in length, and as much in breadth; however, by the best and latest accounts, this vast country is somewhat of an oval form, the breadth being less than the length by little more than a fourth-part. It contains 15 provinces, exclusive of that of Lyam-tong, which is situated without the provisions of the great wall, though under the same dominion. Their names are, 1. Shen-fi; 2. Shan-fi; 3. Pechehi; which are situated on the north side, along the wall. 4. Shan-tong; 5. Kyan-nang; 6. Che-Kyang; 7. Foo-keyn; which are situated along the eastern ocean. 8. Quang-tong; 9. Quang-fii; 10. Yu-nan; 11. Se-chin; which stretch themselves towards the south and south-west. And, 12. Ho-nan; 13. Hu-quand; 14. Quey-chew; 15 Kyang-fii; which take up the middle part. For a particular description of all these, see their proper articles.

The origin of all nations is involved in obscurity and fable; but that of the Chinese is much more so than any other. Every nation is inclined to assume to itself an antiquity to itself, but the Chinese carry theirs beyond all bounds. Indeed, though no people on earth are more exact in keeping records of every memorable
morable transaction, yet such is the genius of the Chinefe for superflition and table, that the first part of their history is utterly concealed by every rational person. What contributes more to the uncertainty of the Chinefe history is, that neither we, nor they themselves, have anything but fragments of their ancient historical books; for about 213 years before Christ, the reigning emperor of Si-wang-ti caused all the books in the empire to be burned, except those written by layyers and physicians. Nay, the more effectually to destroy the memory of every thing contained in them, he commanded a great number of learned men to be buried alive, from their memories, they should commit to writing something of the true memoirs of the empire. The inaccuracy of the Chinefe annals is complained of even by their most respected author, Confucius himself; who also affirms, that before his time, many of the oldest materials for writing such annals had been destroyed.

According to the Chinefe histories, the first monarch of the whole universe (that is, of China), was called Puon-ku, or Puon-kuwa. This, according to some, was the first man; but according to Baycr and Menzelius, two of the greatest critics in Chinefe literature, that have hitherto appeared, the word signifies the highest antiquity. Puon-ku was succeeded by Tien-hoang, which signifies the emperor of heaven. They call him also the intelligent heaven, the supreme king of the middle heaven, &c. According to some of their historians, he was the inventor of letters, and of the Cylic characters by which they determine the place of the year, &c. Tien-hoang was succeeded by Ti-hoang (the emperor of the earth), who divided the day and night, appointing 30 days to make one moon, and fixed the winter solstice to the 21th moon. Ti-hoang was succeeded by Gine-hoang (sovereign of men), who with his nine brothers shared the government among them. They built cities, and surrounded them with walls; made a distinction between the sove reign and subjests; instituted marriage, &c.

The reigns of these four emperors make up one of what the Chinefe called $ki$, "ages," or "periods," of which there were nine before Fo-hi, whom their most sensible people acknowledge as the founder of their empire.

The history of the second $ki$ contradicts almost every thing said of the first; for though we have but just now been told that Gine-hoang and his brethren built cities surrounded with walls; yet, in the succeeding age, the people dwelt in caves, or perched upon trees as it were in nests. Of the third $ki$ we hear nothing; and in the fourth, it seems matters had been still worse, as we are told that men were then only taught to retire into the hollows of rocks. Of the fifth and sixth we have no account. These six periods, according to some writers, contained 90,000 years; according to others, 1,100,730.

In the seventh and eighth $ki$, they tell us over again what they had said of the first; namely, that men began to leave their caves and dwell in houses, and were taught to prepare clothes, &c. Chine-fang, the first monarch of the eighth $ki$, taught his subjects to take off the hair from skins with rollers of wood, and cover themselves with the skins so prepared. He taught them also to make a kind of web of their hair, to serve as a covering to their heads against rain. They obeyed his orders with joy, and he called his subjects people dressed with skins.

His reign lasted 350 years; that of one of his successors, also, named Tien-soo-chih, lasted more than 300; and his family continued for 12 or 18,000 years. But what is most surprising, all these thousands and millions of years had elapsed without mankind's having any knowledge of fire. This was not discovered till towards the close of this period, by one Sougine. After so useful a discovery, he taught the people to dress their viscous; whereas before, they had devoured the flesh of animals quite raw, drank their blood, and swallowed even hair and feathers. He is also said to have been the inventor of fishing, letters, &c.

In the ninth period we find the invention, or at least the origin of letters, attributed to one Tien-hie, who received them from a divine tortoise that carried them on his shell, and delivered them into the hands of Tfan-hie. During this period also, music, money, carriages, merchandise, and commerce, &c were invented. There are various calculations of the length of these $ki$ or periods. Some make the time from Puon-ku to Confucius, who flourished about 479 years before Christ, to contain 279,000 years; others, 2,275,000; some, 2,735,860; others, 3,276,000; and some no less than 96,601,740 years.

These extravagant accounts are by some thought Fabulous to contain obscure and imperfect hints concerning the history ecomomony and creation of the world, &c. Puon-ku, plaines, the first emperor, they think, represents eternity preceding the duration of the world. The succeeding ones, Tien-hoang, Ti-hoang, and Gine-hoang, they imagine, signify the creation of the heavens and earth, and the formation of man. The ten $ki$, or ages, nine of which preceded Fo-hi, mean the ten generations preceding Noah. This may very possibly be the case; for about 300 years before Christ, some Jews travelled into China, who might have made the Mosaic writings known there.

What we have now related, contains the substance of that part of the Chinefe history which is entirely fabulous. After the nine $ki$, or "ages" already taken notice of, the tenth commenced with Fo-hi; and the history, though still very dark, becomes more and more confused and intelligible. Fo-hi was born in the province of Shen-ho.

Reign of His mother walking upon the banks of a lake in that Fo-hi, province, saw a very large print of a man's foot in the sand there; and, being surrounded by an iris or rainbow, became impregnated. The child was named Fo-hi; and, when he grew up, was by his countrymen elected king on account of his superior merit, and styled Yen-iff, that is "the fon of heaven." Fo invented the eight gna, or symbols, confining of three lines each, which, differently combined, formed 64 characters that were made use of to express every thing. To give thes the greater credit, he pretended that he had seen them inscribed on the back of a dragon and a bird. He gave to the form of a dragon, which arose from the bottom of a lake. Having gained great reputation among his countrymen by this prodigy, he is said to have created
Hence we may assign a reason why the emperors of
China always carry a dragon in their banners. He also
inaugurated marriage, invented music, &c. Having es-
tablished a prime minister, he divided the government
of his dominions among four mandarins, and died af-
after a reign of 115 years.

After Fo-hi followed a succession of emperors, of
whom nothing remarkable is recorded, except that in
the reign of Taou, the seventh after Fo-hi, the fun did
not set for ten days, so that the Chinese were afraid of
a general conflagration. This event the compilers of
China supposed to be the fame with that mentioned in
the book of Joshua, when the sun and moon stood still
for about the space of a day. Fo-hi, they
will have to be the same with Noah. They imagine,
that after the deluge, this patriarch remained some time
with his descendants; but on their wicked combina-
tion to build the tower of Babel, he separated himself
from them with as many as he could persuade to go
along with him; and that, still travelling eastward,
he at last entered the fertile country of China, and
laid the foundation of that vast empire—But, leav-
ing these fabulous and conjectured times, we shall pro-
cceed to give some account of that part of the Chinese
history, which may be more certainly depended on.

As the Chinese, contrary to the practice of al-
most all nations, have never sought to conquer other
countries, but rather to improve and content
themselves with their own, their history for many ages
furnishes nothing remarkable. The whole of their
emperors, abstracting from those who are said to have
reigned in the fabulous times, are comprehend-
ed in 22 dynasties, mentioned in the following table.

</table>

This table is formed according to the account of
the Jesuit Du Halde, and is commonly reckoned to be
the most authentic; but according to the abovemention-
ed hypothesis of the compilers of the Universal
History, who make Taou contemporary with Joshua, the
dynasty of Hya did not commence till the year before
Christ 1057; and to accommodate the history to their
hypothesis, great alterations must be made in the dura-
tion of the dynasties.

The most interesting particulars of the Chinese hi-

tory relate only to the incursions of the Tartars, who
at last conquered the whole empire, and who still con-

tinue to hold the sovereignty; though by transferring
the seat of the empire to Peking, and adopting the
Chinese language, manners, &c. Tartary would
seem rather to have been conquered by China, than
China by Tartary. These incursions are said to have
taken place very early; even in the time of the emperor
Shun, successor to Taou abovementioned, in whose
reign the miraculous salsifics happened. At this
time, the Tartars were repulsed, and obliged to re-
tire into their own territories. From time to time,
however, they continued to threaten the empire with
invasions, and the northern provinces were often ac-
tually ravaged by the Tartars in the neighbourhood.

About the year before Christ 213, Shi-whang-ti ha-

d the Chinese empire, and is commonly reckoned to be
the first Chinese emperor that ever sat on the throne.

For this purpose, he ordered all the histori-

cal writings to be burnt, and caused many of the
learned to be put to death, as already men-
tioned. What effect the great wall had in pre-
venting the invasions of the Tartars, we are not
told; but in the tenth century of the Christian era,
the chief of Kiton or Lyau got a footing in China. The
Kitan Tartars were a people of eastern Tartary, who dwelt on the
north and north-east of the province of Pecheli in
China, particularly in that of Layu-tong lying without
the great wall. These people having subjugated the
country between Korea and Kafgar, became much
more troublesome to the Chinese than all the other
Tartars. Their empire commenced about the year
915, in the fourth year of Mo-ti-kyan-tî, second empe-
or of the 14th Chinese dynasty called Hew-iyang. In
946, Mingt-fong, second emperor of the 15th dyna-
sty, being dead, Sheking-tang, his son-in-law, rebelled
against Mingt-fong, his son and successor, whom he de-
prived of his crown and life. This he accomplished
by means of an army of 50,000 men furnished by the
Kitan. Fi-tî, the son of Mingt-Song, being unable to
reclaim the usurper, fled to the city of Ghey-chew; where
shutting himself up with his family and all his valuable
effects, he set fire to the palace, and was burnt to
ashes. On his death, Sheking-tang assumed the title
of emperor; founded the 16th dynasty; and changed his name to that of Kant-fu. But the Kitan general
refusing to acknowledge him, he was obliged to pur-

chase
In 959, they broke the treaty when the traitor became emperor of all China, and, changing his name to Kau-tfu, founded the 17th dynasty. The Tartars, in the meantime, ravaged all the northern provinces without opposition, and then marched into the southern. But being here stopped by some bodies of Chinese troops, the general thought proper to retire with his booty into Tartary. In 962, Kaut-fu, dying, was succeeded by his son In-ti. The youth of this prince gave an opportunity to the eunuchs to raise commotions; especially as to lay siege to a city in the province of Pecheli, besides a yearly present of 300,000 pieces of silk.

This submission served only to inflame the avarice and ambition of the Kitan. In 959, they broke the treaty when least expected, and invaded the empire. Ting-vang, the emperor at that time, opposed them with a formidable army; but through the treachery of his general Lyew-chi-ywen, the Tartars were allowed to take him prisoner. On this, Ting-vang was glad to recover his liberty by accepting of a small tribute. But through the generosity of his general Lyew-chi-ywen, the Tartars were ready to the eunuchs to raise commotions; especially as to lay siege to a city in the province of Pecheli, besides a yearly present of 300,000 pieces of silk.

From this time the Kitan remained in peaceable Kitan dominions till the year 1117, when they invaded the emperor by his grandson, who, being able neither to bear their ravages, nor by himself to put a stop to them, resolved upon a remedy which at last proved worse than the disease. This was to call in the Sung, Nyu-che, or Eastern Tartars, to destroy the kingdom of the Kitan. From this he was dissuaded by the king of Korea, and most of his own ministers; but, disregarding their falutary advice, he joined his forces to those of the Sung. The Kitan were then everywhere defeated; and at last reduced to such extremity, that those who remained were forced to leave their country, and fly to the mountains of the west.

Thus the empire of the Kitan was totally destroyed. Who after nothing to the advantage of the Chinese; for the name of Kim, and invade China. Then began to think of aggrandizing himself and enlarging his empire. For this purpose, he immediately broke the treaties concluded with the Chinese emperor; and invading the provinces of Pecheli and Shen-fi, made himself master of the greater part of them. Whey-tsong, finding himself in danger of losing his dominions, made several advantageous proposals to the Tartar; who, seeming to comply with them, invited him to come and settle matters by a personal conference. The Chinese monarch complied; but, on his return, the terms agreed on seemed intolerable to his ministers; so that they told him the treaty could not be fulfilled, and that the most cruel war was preferable to such an ignominious peace. The Kim monarch, being informed of all that passed, had recourse to arms, and took several cities. Wheytong was weak enough to go in person to hold a second conference; but, on his arrival, was immediately feized by the Tartar. He was kept prisoner until they took a strong guard during the remaining part of his life, and ended his days in 1126, in the defeat of his son, Shamo, having nominated his eldest son Kin-tsong to succeed him.

In 1125 began his reign with putting to death six ministers of state, who had betrayed his father into the hands of the Kim Tartars. The barbarians in the mean time pursued their conquests without opposition. They crossed the Wang-ho, or Yellow River, which a handful of troops might have prevented; and marching directly towards the imperial city, took and plundered it. Then feizing the emperor and his consort, they carried them away captives; but many of their emperors, the principal lords, and several of the minions, preferred to ring death to such an ignominious bondage; killed themselves. The Kin being informed of the empress Meng that she had been divorced, she left her behind. This proved the means of saving the empire: for
China.

for her wisdom and prudence she got the crown placed on the head of Kaut-tong, ninth son of the emperor Wchy-tong; by his divorced empress. Kaut-tong fixed his court at Nanking the capital of Kyang-nan; but soon after was obliged to remove it to Kang-chew in Che-chiang. He made several efforts to recover some of his provinces from the kin, but without effect. He fixed the kin monarch, in the mean time, endeavored to gain the affection of his Chinese-subjects by paying a regard to their learning and learned men, and honouring the memory of Confucius. Some time after, he advanced to Nanking, from whence Kaut-tong had retired, and took it; but, receiving advice that Yol, general of the Song, or Southern Chins, was preparing by long marches to the relief of that city, they left fire to the palace, and retired northward. However, Yol arrived time enough to fall upon their rear-guard, which saddled very much; and from this time the kin never dared to cross the river Kyang. In a few years afterwards the Chinesse emperor submitted to become tributary to the Kin, and concluded a peace with them upon very honourable terms. This submission, however, was of short duration; for, in 1162, the Tartars broke the peace; and, invading the southern province with a formidable army, took the city of Yang-chew. The king, having approached the river Kyang, near its mouth, where it is widest as well as most rapid, commanded his troops to cross it, threatening with his drawn sword to kill those who refused. On receiving such an unreasonable command, the whole army mutinied; and the king being killed in the beginning of the tumult, the army immediately retired.

17 Progrcefs the Kin checked.

From this time to the year 1210, nothing remarkable occurs in the Chinesse history; but this year, Jenghiz-khan, chief of the western Tartars, Moguls, or Mongols, quarrelling with Yol-khan emperor of the Kin; and at the same time the king of Hya, disgraced at being refuse of affiance against Jenghiz-khan, threatened him with an invasion on the west side. Yong-shi prepared for his defence; but in 1211, receiving news that Jenghiz-khan was advancing southward with his whole army, he was seized with fear, and made proposals of peace, which were rejected. In 1212, the Mogul generals forced the great wall; or, according to some writers, had one of the gates treacherously opened to them, to the north of Shanti; and made incursions as far as Peking the capital of the Kin empire. At the same time the province of Lyao-tong was almost totally reduced by several Kitan lords who had joined Jenghiz-khan; several strong places were taken, and an army of 200,000 Kin defeated by the Moguls. In autumn they laid siege to the city of Tay-tong-fu; where, although the governor Hujaku fled, yet Jenghiz-khan met with a considerable resistance. Having lost a vast number of men, and being himself wounded by an arrow, he was obliged to raise the siege and retire into Tartary; after which the Kin retook several cities. The next year, Jenghiz-khan re-entered China; retook the cities which the Kin had reduced the year before; and overthrew their armies in two bloody battles, in one of which the ground was fired with dead bodies for upwards of four leagues.

19 Great wall forced by Jenghiz-khan.

The same year Yong-shi was slain by his general Hojaku; and Sun, a prince of the blood, advanced in his room. After this the Moguls, attacking the empire with four armies at once, laid waste the provinces of Shanhs, Honan, Pechei, and Shantong. In 1214 Jenghiz-khan fat down before Peking; but instead of assaulting the city, offered terms of peace, which were accepted, and the Moguls retired into Tartary. After this departure, the emperor, having his son at Peking, removed his court to P}-en-ling near Kay-tong-fu, the capital of Honan. At this Jenghiz-khan being offended, immediately sent troops to besiege Peking. The city held out to the fifth month of the year Peking ta-1215, and then surrendered. At the same time the Kin.

20 Southern Chins, New attack by the Song.

Jenghiz-khan returned to pursue his conquests in the west of Asia, where he had seven years' during which time his general Muhuli made great progress in China against the Kin emperor. He was greatly afflicted by the motions of Nihong-khan emperor of the Song, or Southern China; who, incensed by the frequent perjuries of the Kin, had declared war against them, and would hearken to no terms of peace, though very advantageous proposals were made. Notwithstanding this, however, in 1220, the Kin, exerting themselves raised two great armies, one in Shenfu, and the other in Shang-ton. The former baffled the attempts of the Song and king of Hya, who had united against them; but the latter, though no fewer than 200,000, were entirely defeated by Muhuli. In 1221, this officer passed the Whang-ho, and died after conquering several cities.

22 Jenghiz-khan deposed by his son Shew. In 1224, the Kin emperor died; and was succeeded by Jenghiz-khan's son Shew, who made peace with the king of Hya; but next year, that kingdom was entirely destroyed by Jenghiz-khan. In 1226, Oktay son to Jenghiz-khan marched into Honan, and beliged Kay-Song-fu, capital of the Kin empire; but was obliged to withdraw into Shensi, where he took several cities, and cut in pieces an army of 30,000 men. In 1227 Jenghis-khan died, after having defied his sons to demand a passage for their army through the dominions of the Song, without which he said they could not safely vanquish the Kin.

After the death of that great conqueror, the war was carried on with various successes; but though the Moguls took above 60 important places in the province of Shensi, they found it impossible to force Tung-quan, which it believed them to do in order to penetrate efficaciously into Honan. In April 1231 they took the capital of Shensi, and defeated the Kin army which came to its relief. Here one of the officers desired prince Toley to demand a passage from the Song through the country of Han-chung-fu. This proposal Toley communicated to his brother Oktay, who approved of it as being conformable to the dying advice of Jenghis-khan. Hereupon Toley, having assembled all his forces, sent a messenger to the Song generals to demand passage through their territoy. This, however, they not only refused, but put the messenger to quarter death; which so enraged Toley that he swore to make them repent of it, and was soon as good as his word. He decamped in August 1231; and having forced the passages, put to the sword the inhabitants of

Wha.
which Toley had obstructed with trees, they were attacked by that prince at a disadvantage, and, after a faint resistance, defeated with great slaughter, and the loss of both their generals, one killed and the other taken. The emperor now ordered the army at Tong-quan and other fortified places to march to the relief of Kay-fong-fu. They assembled accordingly, to the number of 110,000 foot and 15,000 horse; and were followed by vast numbers of people who expected by their means to be protected from the enemy. But many of these troops having deferted, and the rest being encumbered by the fatigues of their march, they diffipated on the approach of their pursuers, who killed all they found in the highways. After this the Moguls took Tong-quan and some other considerable posts; but were obliged to raise the siege of Quey-te-fu and Loyang, by the bravery of the governors.

27

Oktay, at last, notwithstanding his successes, resolved to return to Tartary; and offered the Kin emperor the behest of peace, provided he became tributary, and delivered up to him 27 families which he named. These offers were very agreeable to the emperor; but Suputay, taking no notice of the treaty, pushed on the siege of the capital with more vigour than ever. By the help of the Chinese slaves in his army, the Mogul general soon filled the ditch; but all his efforts seemed only to inspire the besieged with new vigour. The Moguls at that time made use of the frightful and mortality, by which they expected to make the least impression upon the city walls. They raised walls round those they besieged, which they fortified with ditches, towers, and battlements. They proceeded also to tap the walls of the city; but were very much annoyed by the artillery of the besieged, especially by their bombs, which sinking into the galleries, and bursting under ground, made great havoc among the miners. For 16 days and nights the attack continued without intermission; during which time an incredible number of men perished on both sides: at length, Suputay, finding that he could not take the city, withdrew his troops, under pretence of peace conference, being on foot. Soon after, the plague clad them in Kay-fong-fu; and raged with such violence, that in 50 days, 900,000 biers were carried out, besides a vast multitude of the poorer sort who could not afford any.

28

In a short time, two unlucky accidents occurred: a renewal of the war; which now put an end to the empire of the Kin. Gan-yong, a young Mogul lord, having ascertained the government of some cities in Kyang-nan, and killed the officer sent to take possession...
The empire of China was now to be shared between the Song, or Southern Chinese, and the Monguls. It had been agreed upon, that the province of Honan should be delivered up to the Song as soon as the war was finished. But they, without waiting for the expiration of the term, or giving Oktay notice of their proceedings, introduced their troops into Kay-fong-fu, Lo-yang, and other considerable cities. On this the War between the Moguls general resolved to attack them; and repassing the Whang-ho, cut in pieces part of the garrison of Song and Lo-yang, while they were out in search of provisions.

The garrison of Kay-fong-fu likewise abandoned that place; and the Song emperor degraded the officers who had been guilty of those irregularities, sending ambassadors to Oktay, at the same time, to desire a continuance of the peace. What Oktay's answer was we are not told, but the event showed that he was not well pleased; for, in 1235, he ordered his second son prince Kotovan, and his general Chahay, to attack the Song in Se-chwen, while others marched towards the borders of Kyang-nan.

In 1236, the Monguls made great progress in the province of Hu-quant, where they took several cities, and put vast numbers to the sword. This year they introduced paper or silk money, which had formerly been used by Chang-tong sixth emperor of the Kin. Prince Kotovan forced the passages of the district of Hang-chong-fu in the province of Sheni, which he entered with an army of 500,000 men. Here a terrible battle was fought between the vast army of the Monguls and the Chinese troops, who had been driven from the passages they defended. The latter consisted only of 10,000 horse and foot, who were almost entirely cut off; and the Monguls lost such a number of men, that the blood is said to have run for two leagues in a day. After this victory the Monguls marched to Sechwen, which they almost entirely reduced, committing such barbarities, that, in one city, 40,000 people chose rather to put an end to their own lives than submit to such cruel conquerors.

In 1237, the Monguls received a considerable check before the city of Gan-tong in Kyang-nan, the siege of which they were obliged to raise with loss. In 1238 they besieged Lu-chew, another city in the same province. They surrounded it with a rampart of earth and a double ditch; but the Chinese general ordered their intrenchments to be filled with immense quantities of herbs steeped in oil, and then set fire, while the fire flamed upon the top a tower seven stories high. At the same time a furious sally was made; and the Mongul army being thrown into the utmost disorder, were obliged finally to abandon the siege and retire northwards.

In 1239, these barbarians were opposed by a general called Meng-kong, with great success. Who, this and the following year, gained great honour by his exploits. While he lived, the Monguls were never able to make any considerable progress; but his death, in 1246, proved of the greatest detriment to the Chinese affairs; and soon after, the Tartars renewed the war with more vigour and success than ever. In
1825, they re-entered the province of Se-chwen; but still met with vigorous opposition in this quarter, because the Chinese took care to have Se-chwen furnished with good troops and generals. Though they were always beaten, being greatly inferior in number to their enemies, yet they generally retook the cities the Moguls had reduced, as the latter were commonly obliged to withdraw for want of provisions and forage. In 1259, they undertook the siege of Ho-chew, a strong city to the west of Peking, defended by Vang-kyen, a very able officer, who commanded a numerous garrison. The siege continued from the month of February till August; during which time the Moguls lost an immense number of men. On the 10th of August they made a general assault in the night. They mounted the walls before the governor had intelligence; but were soon attacked by him with the utmost fury. The Mogul emperor, Meng-ko, himself came to the salade; but his presence was not sufficient to overcome the valour of Vang-kyen. At the same time the scaling-ladders of the Moguls were blown down by a storm; upon which a terrible slaughter ensued, and among the rest fell the emperor himself. Upon this disaster the Mogul generals agreed to raise the siege, and retire towards Shen-ch. On the death of Meng-ko, Hupilay, or Kublay Khan, who succeeded him, laid siege to Vu-chang-fu, a city not far distant from the capital of the Song empire.

At this the emperor being greatly alarmed, distributed immense sums among his troops; and, having raised a formidable army, marched to the relief of Vu-chang-fu. Unfortunately the command of this army was committed to the care of Kya-te-tau, a man without either courage or experience in war. He was besides very vain and vindictive in his temper; often using the best officers ill, and entirely overlooking their merit, which caused many of them to go over to the Moguls. The siege of Vu-chang-fu was commenced, and had continued a considerable time, when Kya-te-tau, afraid of its being lost, and at the same time not daring to take any effectual step for its relief, made proposals of peace. A treaty was accordingly concluded, by which Kya-te-tau engaged to pay an annual tribute of about 50,000 in silver, and as much in silk; acknowledging likewise the sovereignty of the Moguls over the Song empire. In consequence of this treaty, the Moguls retired after the boundaries of the two empires had been fixed, and repulsed the Yang; but 170 of them having flaid on the other side of the river, were put to death by Kya-te-tau.

This blood that minister totally concealed from the emperor his having made such a shameful treaty with the Moguls; and the 170 soldiers murdered by his order, gave occasion to report that the enemy had been defeated, so that the Song court believed that they had been compelled to retreat by the superior valour and wisdom of Kya-te-tau. This proved the ruin of the empire; for, in 1258, the Mogul emperor sent Hupilay to the Chinese court to execute the terms agreed on with Kya-te-tau. The minister, dreading the arrival of this envoy, imprisoned him near Nanking; and took all possible care that neither Hupilay, nor Li-tung the Chinese emperor, should ever hear anything of him. It was impossible such unparalleled conduct could fail to produce a new war. Hupilay's courtiers immediately prevailed to have Hupilay assassinated in the Song for their treacherous behaviour; and he soon published a manifesto against them, which was followed by a renewal of hostilities in 1263. The Mogul army amounted to 300,000 men; but notwithstanding their numbers, little progress was made till the year 1271.

Syan-yang and Fan-ching, cities in the province of Se-chew, which had been besieged for a long time ineffectually; but this year, an Igur lord advised Hupilay to send for several of those officers out of the west, who knew how to cast stones of 150 pounds weight out of their engines, which made holes of seven or eight feet wide in the strongest walls. Two of these engineers were accordingly sent for; and after giving a specimen of their art before Hupilay, were sent to the army in 1272. In the beginning of 1273 they planted their engines against the city of Fan-ching, and presently made a breach in the walls. After a bloody conflict the suburbs were taken, and soon after the Moguls made themselves masters of the walls and gates of the city. Nevertheless, a Chinese officer, with only 100 soldiers, resolved to fight from street to street. This he did for a long time with the greatest obstinacy, killing vast numbers of the Moguls; and both parties are said to have been led so much overcome with thirst, that they drank human blood to quench it. The Chinese set fire to the houses, that the great beams, falling down, might embarrass the way of their partners; but at last being quite wearied out, and filled with despair, they put an end to their own lives. After the taking of Fan-ching, all the materials which had served at the siege were transported to Seyen-yang. The two engineers posted themselves against a wooden entrenchment raised on the ramparts. This they quickly demolished; and the besieged were so intimidated by the noise and havoc made by the stones cast from these terrible engines, that they immediately surrendered.

In 1274, Pe-yen, an officer of great valour, and endowed with many other good qualities, was promoted to the command of the Mogul army. His first exploits were the taking of two strong cities; after which he passed the great river Kyang, defeated the Song army, and laid siege to Vu-chang-fu. This city was soon intimidated into a surrender; and Pe-yen, by restraining the barbarity of his soldiers, whom he would not allow to hurt any body, soon gained the hearts of the Chinese so much, that several cities surrendered to him on the first summons. In the mean time the treacherous Kya-te-tau, who was sent to oppose Pe-yen, was not allowed to propose peace on the terms he had formerly concluded with Hupilay; but thence being rejected, he was obliged at length to come to an engagement. In this he was defeated, and Pe-yen continued his conquests with great rapidity. Having taken the city of Nanking, and some others, he marched towards Hang-chew-fu, the capital of the Song empire. Peace was now again proposed, but rejected by the Mogul general; and at last the emperors of the Song empire was constrained to put herself, with her son, then an infant, into the hands of Pe-yen, who immediately sent them to Hupilay.

The submission of the empress did not yet put an end to the war. Many of the chief officers swore to
do their utmost to rescue her from the hands of her enemies. In consequence of this resolution they distributed their money among the soldiers, and soon got together an army of 40,000 men. This army attacked the city where the young emperor Dong-fong was lodget, but without success; after which, and several other vain attempts, they roused one of his brothers to the throne, who then took upon him the name of T'ung-tong. He was but nine years of age when he was raised to the imperial dignity, and enjoyed it but a very short time. In 1277 he was in great danger of perishing, by reason of the ship on board which he then was being cast away. The poor prince fell into the water, and was taken up half dead with the fright. A great part of his troops perished at that time, and he soon after made others of submission to Huplay. These, however, were not accepted; for, in 1278, the unhappy T'ung-tong was obliged to retire into a little desert. In 1281, being informed that the barks, which brought to court the tribute of the southern provinces, or carried on the trade of the empire, were obliged to come by sea, and often suffered shipwreck, he cau ted that celebrated canal to be made, which is at present one of the wonders of the Chinese empire, being 300 leagues in length. By this canal above 9,000 imperial barks transport with ease, and at small expense, the tribute of grain, rice, silk, &c. which is annually paid to the court. In the third year of his reign Shih-tu formed a design of reducing the islands of Japan, and the kingdoms of Tonquin and Cochin-china. Both these enterprises ended in failure, but the first remarkably so; for of 100,000 persons embarked in it, only four or five escaped with the melancholy news of the destruction of the fleet, all perished by shipwreck. Shih-tu reigned 14 years, died in the 80th year of his age, and was succeeded by his grandson. The Moguls, having defeated the Chinese in the Ywen family till the year 1367, driven out. when Shun-ti, the last of that dynasty, was driven out by a Chinese named Chu. During this period the Tartars had become encrusted by long prosperity; and the Chineses had been routed into value by their subjection. Shun-ti, the reigning prince, was quite sunk in sloth and debauchery; and the empire, besides, was oppressed by a wicked minister named Ama. In the month of June 1355, Chu, a Chinese of mean extraction, and head of a small party, left out from Huchow, passed the Yang, and took Ta-ping. He then associated himself with some other malcontents, at the head of whom he reduced the town of Tu-chew, in Kiang-nan. Soon after he made himself master of Nanking, having defeated the Moguls who came to its relief. In December 1356, he was able to raise 100,000 men, at the head of whom he took the city of U-chew, in the east borders of Quang-si; and here, assembling his generals, it was resolved neither to commit slaughters nor to plunder. The most formidable enemy he had to deal with was Shen-yew-lang, styled “emperor of the Han.” This man being grieved at the progress made by Chu, equipped a fleet, and raised a formidable army, in order to reduce Nan-chang-fu, a city of Kiang-si, which his antagonist had made himself master of. The governor, however, found means to inform Chu of his danger; upon which that chief cau sed a fleet to be fitted out at Nanking, in which he embarked 200,000 soldiers. As soon as Chen-yew-ling was informed of his enemy’s approach, he raised the siege of Nan-chang-fu, and gave orders for attacking Chu’s naval force. An engagement ensued between a part of the fleets, in which Chu proved victorious; and next day, all the squadrons having joined in order to come to a general engagement, Chu gained a second victory, and burned a part of the enemy’s vessels. A third and fourth engagement happened, in both which Chu gained the victory; and the
the last, Chen-yew-lyang himself was killed, his son taken prisoner, and his generals obliged to surrender themselves, with all their forces and vessels.

In January 1364, Chu's generals proposed to have him proclaimed emperor; but this he declined, and at first contented himself with the title of king of U. In February he made himself master of Vu-chang-fu, capital of Hu-quant; where, with his usual humanity, he relieved those in distress, encouraged the literati, and would allow his troops neither plunder nor destruction. This wife conduct procured him an easy conquest both of Kyang-fu and Ho-quant. The Chinese submitted to him in crowds, and professed the greatest veneration and respect for his person and government.

All this time Shun-ti, with an unaccountable negligence, never thought of exerting himself against Chu, but continued to employ his forces against the rebels who had taken up arms in various parts of the empire; so that Chu found himself in a condition to assume the title of emperor. This he chose to do at Nanking on the first day of the year 1368. After this his troops entered the province of Honan, which they presently reduced. In the third month, Chu, who had now taken the title of Hong-ou, or T'ay-sif, reduced the fortresses of Tong-quan; after which his troops entered Pecheli from Honan on the one side, and Shun-tong on the other. Here his generals defeated and killed one of Shun-ti's officers; after which they took the city of Tong-chew, and then prepared to attack the capital, from which they were now but 12 miles distant. On their approach the emperor fled with all his family beyond the great wall, and thus put an end to the dynasty of Ywen. In 1370 he died, and was succeeded by his son, whom the successor of Hong-ou drove beyond the Kobol or Great Desert, which separates China from Tartary. They continued their incursions, however, for many years; nor did they cease their attempts till 1382, when vast numbers of them were cut down in the Chinese troops.

The 21st dynasty of Chinese emperors, founded in 1368 by Chu, continued till the year 1644, when they were again expelled by the Tartars. The last Chinese emperor was named Whay-tiong, and ascended the throne in 1628. He was a great lover of the sciences, and a favourite of the Christians; though much addicted to the superstitions of the Bonzes. He found himself engaged in a war with the Tartars, and a number of rebels in different provinces. That he might more effectually suppress the latter, he resolved to make peace with the former; and for that end sent one of his generals, named Ywen, into Tartary, at the head of an army, with full power to negotiate a peace; but that traitor made one upon such shameful terms, that the emperor refused to ratify it. Ywen, in order to oblige his master to comply with the terms made by himself, poisoned his host and most faithful general, named Mau-en-long; and then desired the Tartars to march directly to Peking, by a road different from that which he took with his army. This they accordingly did, and laid siege to the capital. Ywen was ordered to come to its relief; but, on his arrival, was put to the torture and strangled; of which the Tartars were no sooner informed, than they raised the siege, and returned to their own country. In 1536, the rebels abovementioned composed four great armies, commanded by as many generals; which, however, were soon reduced to two, commanded by Li and Chang. These agreed to divide the empire between them; Chang taking the western provinces, and Li the eastern ones. The latter seized on part of Shen-ji, and then of Honan, whose capital, named Kay-fung-fu, he laid siege to, but was repulsed with loss. He renewed it six months after, but without success; the besieged choosing rather to feed on human flesh than surrender. The imperial forces coming soon after to its assistance, the general made no doubt of being able to destroy the rebels at once, by breaking down the banks of the Yellow River; but unfortunately the rebels escaped to the mountains, while the city was quite overflowed, and 300,000 of the inhabitants perished.

After this disaster, Li marched into the provinces of Shen-ji and Honan; where he put to death all the mandarins, exacted great sums from the officers in place, and showed no favour to any but the populace, whom he freed from all taxes; by which means he drew so many to his interest, that he thought himself strong enough to assume the title of emperor. He next advanced towards the capital, which, though well garnished, was divided into factions. Li had taken care to introduce before-hand a number of his men in disguise; and by these the gates were opened to him the third day after his arrival. He entered the city in triumph at the head of 300,000 men; whilst the emperor kept himself shut up in his palace, busied only in his perjuries. It was not long, however, before he found himself betrayed; and, under the greatest confusion, made an effort to get out of the palace, attended by about 600 of his guards. He was more surprized to see himself treacherously abandoned by them, and deprived of all hopes of escaping the inflicts of his subjects. Upon this, preferring death to the disgrace of falling alive into their hands, he immediately retired with his empress, whom he tenderly loved, and the princess her daughter, into a private part of the garden. His grief was so great that he was not able to utter a word; but the soon understood his meaning, and, after a few silent embraces, hanged herself on a tree in a silent firing. Her husband flied only to write these words on the border of his vest: "I have been basely deserted by my subjects; do what you will with me, but spare my people." He then cut off the young prince's head with one stroke of his scimitar, and hanged himself on another tree, in the 17th year of his reign, and 36th of his age. His prime minister, queens, and eunuchs, followed his example; and thus ended the Chinese monarchy, to give place to that of the Tartars, which hath continued ever since.

It was some time before the body of the unfortunate monarch was found. At last it was brought before the rebel Li, and by him used with the utmost indignity; after which he caused two of Whay-tiong's sons, and all his ministers, to be beheaded; but his eldest son happily escaped by flight. The whole empire submitted peaceably to the usurper, ex:cc:pt prince U-fan-ghey, who commanded the imperial forces in the province of Lyau-tong. This brave prince, finding himself unable to cope with the usurper, invaded the Tartars...
China.

Tartars to his assistance, and Tiong-te their king immediately joined him with an army of 80,000 men. Upon this the usurper marched directly to Peking; but not thinking himself safe there, plundered and burnt the palace, and then fled with the immense treasure he had got. What became of him afterwards we are not told; but the young Tartar monarch was immediately declared emperor of China, his father Tiong-te having died almost as soon as he set his foot in that empire.

The new emperor, named Shun-chi, or Hsu-chi, began his reign with rewarding U-fan-ghey, by conferring upon him the title of King; and aligned him the city of Si-gnan-fu, capital of Shien-fu, for his residence. This, however, did not hinder U-fan-ghey from repenting of his error in calling in the Tartars, or, as he himself used to phrase it, in sending for lions to drive away dogs." In 1674, he formed a very strong alliance against them, and had probably prevailed if his allies had been faithful; but they treacherously deserted him one after another; which so affected him, that he died soon after. In 1681 Hong-wa, son to U-fan-ghey, who continued his efforts against the Tartars, was reduced to such straits that he put an end to his own life.

During this space, there had been some resistance made to the Tartars in many of the provinces. Two princes of Chinese extraction had at different times been proclaimed emperors; but both of them were overcome and put to death. In 1682, the whole 15 provinces were for a while subdued, that the emperor Kaow-bi, successor to Shun-bi, determined to visit his native dominions of Tartary. He was accompanied by an army of 70,000 men, and continued for some months taking the diversion of hunting. This he continued to do for some years; and in his journeys took father Verbeilt along with him; by which means we have a better description of these countries than could possibly have been otherwise obtained.

This prince was a great encourager of learning and of the Christian religion; in favour of which last he published a decree, dated in 1692. In 1710, however, he revived some obsolete laws against the Christians; nor could the Jesuits with all their art persuade, that the emperor should not put them in China. The causes of this alteration in his resolution are, by the missionaries, said to have been the flanders of the mandarins: but, from the known character of the Jesuits, it will be readily believed, that there was something more at bottom. This emperor died in 1722, and was succeeded by his son Yen-ching; who not only gave no encouragement to the missionaries, but persecuted all Christians of whatever denomination, not excepting even those of the imperial race. At the beginning of his reign he banished all the Jesuits into the city of Canton, and in 1712 they were banished thence into Ma-kau, a little island inhabited by the Portuguese, but subject to China. He died in 1736; but although the Jesuits entertained great hopes from his successor, we have not heard that they have yet met with any success.

Thus we have given an account of the most memorable transactions recorded in the Chinese history. It now remains to describe the present state of the empire and its inhabitants, according to the best and latest accounts.

The climate as well as the soil of this extensive empire is very different in different parts; severe cold being often felt in the northern provinces, while the inhabitants of the southern ones are scarce able to bear the heat. In general, however, the air is accounted wholesome, and the inhabitants live to a great age.

The climate is cold, and the air produces few miasmas. The northern and western provinces have many mountains, which in the latter are cultivated, but in the north are barren, rocky, and incapable of improvement. On the mountains of Chenfi, Honan, Canton, and Fokien, are many forests, abounding with tall, straight trees, of different kinds, fit for building, and particularly adapted for masts and ship-timber. These are used by the emperor in his private buildings; and from these forests enormous trunks are sometimes transported to the distance of more than 300 leagues. Other mountains contain quicksilver, iron, tin, copper, gold, and silver. Formerly these last were not allowed to be opened, lest the people should thereby be induced to neglect the natural riches of the soil; and it is certain, that in the 15th century, the emperor caused a mine of precious stones to be shut, which had been opened by a private person. Of late, however, the Chinese are less scrupulous, and a great trade in gold is carried on by them. Many extravagant fables are told by the Chinese of their mountains, particularly of one in Chen-fi which throws out flames, and produces violent tempests, whenever any one beats a drum or plays on a musical instrument near it. In the province of Fokien is a mountain, the whole of which is an idol, or statue of the god Po. This natural colossus, for it appears not to have been the work of art, is of such an enormous size, that each of its eyes is several miles in circumference, and its nose extends several leagues.

China has several large lakes; the principal one is Lakes and that named Poyang-hou, in the province of Kiang-fi. It is formed by the confluence of four large rivers, extends nearly 100 leagues in length; and, like the sea, its waters are raised into tempestuous waves. The empire is watered by an immense number of rivers of different sizes, of which two are particularly celebrated, viz. the Yang-tze kiang, or son of the sea, and Hoang-ho, the Yellow river. The former rises in the province of Tun-nan, and falls through Hon-guang and Kiang-nan, falls into the sea of China. The latter is of 1200 miles, opposite to the island of Tiong-ming, which is formed by the sand accumulated at its mouth. This river is of immense size, being half a league broad at Nanking, which is near 100 miles from its mouth. The navigation is dangerous, so that great numbers of vessels are lost on it. It runs with a rapid current, forming several islands in its course, which are again carried off and new ones formed in different places, when the river is swelled by the torrents from the mountains. These islands, while they remain, are very useful; producing great quantities of reeds ten or twelve feet high, which are used in all the toneshipping countries for fuel. The Hoang-ho, or yellow river, has its name from the yellow dye it is given by the clay and sand washed down in the time of rain. It rises in the mountains which border the province of Te-tschuen on the west, and after a course of near 600 leagues, discharges itself into the eastern sea not far from the mouth of the Kiang. It is very broad and rapid, but so shallow that it is scarcely navigable.
The Chinese have been at great pains to turn their lakes and rivers to the advantage of commerce, by promoting an inland navigation. One of their principal works for this purpose, is the celebrated canal reaching from Canton to Peking, and forming a communication between the southern and northern provinces. This canal extends through no less a space than 600 leagues; but its navigation is interrupted in one place by a mountain, where passengers are obliged to travel 10 or 12 leagues over land. A number of other canals are met with in this and other provinces, most of which have been executed by the industry of the inhabitants of different cities and towns, in order to promote their communication with the various parts of the empire.

M. Grosler remarks, that, in these works, the Chinese have "surmounted obstacles that perhaps would have discouraged any other people; such, for example, is a part of a canal which conducts from Chao-king to Ning-po." Near these cities there are two canals, the waters of which do not communicate, and which differ ten or twelve feet in their level. To render this place passable for boats, the Chinese have constructed a double glocke of large stones, or rather two inclined planes of stones in an acute angle at their upper extremity, and extend on each side to the surface of the water. If the bark is in the lower canal, they pull it up the plane of the first glocke by means of several capstans, until it is raised to the angle, when by its own weight it glides down the second glocke, and precipitates itself into the water of the higher canal with the velocity of an arrow. It is astonishing that these barks, which are generally very long and heavily laden, never burst asunder when they are raised on this acute angle; however, we never hear of any accident of this kind happening in the passage. It is true, they take the precaution of using for their keels a kind of wood which is exceedingly hard, and proper for resisting the violence of such an effort.

The following remarkable phenomenon in a Chinese river is related by Father Le Couteux, a French missionary. "Some leagues above the village Che-pai (says he), the river becomes considerably smaller, although none of its waters flow into any other channel; and, eight or nine leagues below, it resumes its former breadth, without receiving any additional supply, excepting what it gets from a few small rivulets, which are almost dry during the greater part of the year. Opposite to Che-pai it is so much diminished, that, excepting one channel, which is not very broad, I have passed and repassed it several times by the help of a common pole. I was always surprised to find this river so narrow and shallow in that place; but I never thought of inquiring into the cause of it, until the loss of a bark belonging to a Christian family afforded me an opportunity. In that place where the river diminishes almost of a sudden, it flows with great impetuosity; and where it resumes its former breadth it is equally rapid. At the sixth moon, when the water was high and the wind strong, the bark I have mentioned arriving above Che-pai, was driven on a sand-bank; for between these two places the river is full of moveable sands, which are continually shifting their situation. The master of the boat dropped his anchor until the wind should abate, and permit him to continue his voyage; but a violent vortex of moveable sand, which was cast up from the bottom of the river, laid the bark on its side; a second vortex succeeded; then a third; and afterwards a fourth, which shattered the bark to pieces. When I arrived at the place where this bark had been lost, the weather was mild and serene; I perceived eddies in the current every where around; which absorbed, and carried to the bottom of the river whatever floated on the surface; and I observed, at the same time, that the sand was thrown violently up with a vortical motion. Above these eddies the water was rapid, but without any fall; and in the place below, where the river resumes its usual course, no eddies are to be seen, but the sand is thrown up in the same violent manner; and in some places there are water-falls, and a kind of small islands scattered at some distance from one another. These islands which appear above the surface of the water, are not solid earth, but consist of branches of trees, roots, and herbs collected together. I was told that these boughs rose up from the water, and that no one knew the place whence they came. I was informed, that these mallees, which were 40 or 50 feet in extent on that side on which we passed, were immovable, and fixed in the bottom of the river; that it was dangerous to approach them, because the water formed whirlpools every where around them; that, however, when the river was very low, the fishermen sometimes ventured to collect the boughs that floated on its surface, and which they used for fuel. I am of opinion, that, at the place of the river which is above Che-pai, the water falls into deep pits, from whence it forces up the sand with that vortical motion; and that it flows underground to the other place, eight or nine leagues below, where it carries with it all the boughs, weeds, and roots, which it washes down in its course, and thus forms those islands which appear above its surface. We know there are some rivers that lose themselves entirely, or in part, in the bowels of the earth, and which afterwards arise in some other place; but I believe there never was one known to lose part of its water below its own channel, and again to recover it at the distance of some leagues."
The only method, China.

No. ‘See ', China.

11. public , politories, that peror md into the fourth year, when rice was exceedingly scarce there, the foreign merchants. Form of a lies opposite to the Canton with rice until the supply he had ordered it be, that the Japanese have nothing to spare, or on account of the scarcity of grain in Canton is also bounded by the sea, and has nothing cause of the scarcity of grain in other countries.

This has at all times been a principal city of the empire of Kiang-nan and Che-kyang, to China; and, therefore, the emperor of all offices, nor is he more unlimited in his authority than any other potentate on earth; no sentence of death, pronounced by any of the tribunals can be executed without his consent, and every verdict in civil affairs is subject to be revised by him; nor can any determination be of force until it has been confirmed by the emperor: and, on the contrary, whatever sentence he passes is executed without delay; his edicts are respected throughout the empire as if they came from a divinity; he alone has the disposal of all offices, nor is there any such thing as the purchase of places in China; merit, real or supposed, raifes to an office, and rank is attached to it on ly. Even the succession to the throne is nother hereditary. The emperor of China has a power of choosing his own successor without consulting any

The government of China, according to the Abbe Grolier, is purely patriarchal. The emperor is more unlimited in his authority than any other potentate on earth; no sentence of death, pronounced by any of the tribunals can be executed without his consent, and every verdict in civil affairs is subject to be revised by him; nor can any determination be of force until it has been confirmed by the emperor: and, on the contrary, whatever sentence he passes is executed without delay; his edicts are respected throughout the empire as if they came from a divinity; he alone has the disposal of all offices, nor is there any such thing as the purchase of places in China; merit, real or supposed, raifes to an office, and rank is attached to it on ly. Even the succession to the throne is nother hereditary. The emperor of China has a power of choosing his own successor without consulting any

4 P
China. of his nobility; and can select one not only from among his own children, but even from the body of his people; and there have been several instances of his making use of this right: and he has even a power of altering the succession after it has once been fixed, in case the person pitched upon does not behave towards him with proper respect. The emperor can also prevent the princes of the blood from exercising the title, with which, according to the constitution of the empire, they are invested. They may indeed, notwithstanding this poffesses their hereditary dignity; in which case they are allowed a revenue proportioned to their rank. But they have neither influence nor power, and their assistant is lower than that of the meanest mandarin.

60

Mandarins

The mandarins are of two classes, viz. those of letters, and the inferior fort, styled mandarins of arms. The latter by no means enjoy the fame consideration with the former fort; indeed in China the literati are highly honoured, and to their influence M. Grolier supposes that we may in a great measure attribute the mildness and equity of the government; though he thinks that the balance may incline rather too much in their favour. Several degress, anwering to those of bachelor, licentiate, and doctor, must be passed through before one can attain the dignity of a mandarin of letters; though sometimes, by the favour of the emperor, it is conferred on those who have attained only the two first degrees: but even the persons who have gone through all the three, enjoy at first only the government of a city of the second or third class. When several vacancies happen in the government of cities, the emperor invites to court a corresponding number of the literati, whose names are written down in a list. The names of the vacant governments are then put into a box, raffed so high that the candidates are able only to reach it with their hands; after which they draw in their turns, and each is appointed governor of the city whose name he has drawn.

There are eight orders of those mandarins in China.

1. The chin-tao, from whom are chosen the ministers of state, the presidents of the supreme courts, and all the superior officers among the militia. The chief of this order presides also in the emperor's council, and enjoys a great share of his confidence. 2. The te-hiofe, or man of acknowledged ability, is a title bestowed upon every mandarin of the second rank; and from these are selected the viceroys and presidents of the supreme council in the different provinces. 3. The te-hong-tchou, or school of mandarins, act as secretaries to the emperor. 4. T-chou, or taos. These keep in repair the harbours, royal lodging-houses, and barracks, which belong to the emperor, unless particularly engaged in some other office by his order. 5. The ping-piaou have the inspection of the troops. 6. The tsu-tien-tao have the care of the high-ways. 7. The boa-tao superintend the rivers. 8. The hai-tao inspect the sea-coasts.

Thus the whole administration of the Chinese empire is intrusted to the mandarins of letters; and the homage paid by the common people to every mandarin in office, almost equals that paid to the emperor himself. This indeed flows from the nature of their government. In China it is a received opinion that the emperor is the father of the whole empire; that the governor of a province is the father of that province; and that the mandarin who is governor of a city is also the father of that city. This idea is productive of the highest respect and submission, which is not at all leffened by their great number; for though the mandarins of letters amount to more than 14,000, the same respect is paid to every one of them.

The mandarins of arms are never indulged with any share in the government of the state; however, to attain to this dignity, it is also necessary to pass through the degrees of bachelor, licentiate, and doctor of arms. The accomplishments necessary for a mandarin of arms are, strength of body, with ability and readines in performing the various military exercises, and comprehending the orders requisite for the protection of arms: an examination on these subjects must be undergone before the candidate can obtain the wished for dignity.

The mandarins of arms have tribunals, the members of which are selected from among their chiefs; and among these they reckon princes, counts, and dukes; for these dignities, or something equivalent to them, are met with in China. The principal of these tribunals is held at Peking, and consists of five classes.

1. The mandarins of the rear-guard, called taou-tao. 2. Of the left wing, or fa-tao. 3. Of the right wing, or yeo-tao. 4. Of the advanced main-guard, or te-hong-tao. 5. Of the advanced guard, or tsien-tao. These five tribunals are subordinate to one named tung-tching-tao; the president of which is one of the great lords of the empire, whose authority extends over all the military men in the empire. By his high dignity he could render himself formidable even to the emperor; but to prevent this inconvenience, he has for his affiliate a mandarin of letters, who enjoys the title and exerices the function of superintendant of arms. He must also take the advice of two inspectors who are named by the emperor; and when these have agreed upon the measure, their resolution must be submitted to the revial of an higher court named Ping-pou, which is entirely of a civil nature. The chief of these mandarins is a general of course, whose powers are equivalent to those of our commanders in chief; and below him are other mandarins who act as subordinate officers.

These two classes of mandarins compose what is called the nobility of China; but as we have already hinted, their office is not hereditary; the emperor alone continues or confers it. They have the privilege of remonstrating to the emperor, either as individuals or in a body, upon any part of his conduct which appears contrary to the interests of the empire. These remonstrances are seldom ill received, though the foreign-complies with them only when he himfelf thinks proper. The number of literary mandarins in China is computed at upwards of 14,000; and those of arms at 18,000; the former, however, are considered as the principal body in the empire; and this preference is thought to damp the military ardour of the nation in general, and to be one cause of that weakness in war for which the Chinese are remarkable.

The armies of this empire are proportioned to its vast extent and population; being computed in time military force.
ofi peace at more than 700,000. Their pay amounts to about twopence halfpenny and a measure of rice per day, though some of them have double pay, and the pay of a horsemans is double that of a foot-soldier; the emperor furnishes a horse, and the horsemans receives two measures of small beans for his daily subsistence; the arrears of the army being punctually paid up every three months.

The arms of a horsemans are, a helmet, cuirasses, lance, and fafere; those of a foot-soldier are a pike and fahere; some have fusíces, and others bows and arrows. All these are carefully inspected at every review; and if any of them are found in the least faulty, or otherwise in bad condition, the polifher is instantly punished; if a Chinese, with 30 or 40 blows of a fliick; or, if a Tartar, with as many lashes.

Though the use of gun-power is certainly very old in China, it appears to have been afterwards totally lost, at least fire-arms seem to have been almost entirely unknown some centuries ago. Three or four cannon were to be seen at that time about the gates of Nanking; but not a single person in China knew how to make use of them; fo that, in 1621, when the city of Macao made a present of three pieces of artillery to the emperor, it was found necessary also to fend three men to load them. The utility of these weapons was quickly perceived by the execution which the three cannon did against the Tartars, at that time advanced as far as the great wall. When the invaders threatened to return, the mandarins of arms gave it as their opinion, that cannons were the best arms they could make use of against them. They were then taught the art of caffing cannon by F. Adam Schaal and Verbien, two Jesuit missionaries, and their artillery was increased to the number of 320 pieces; at the same time that they were instructed in the method of fortifying towns, and constructing forteresses and other buildings according to the rules of modern architecture.

The best soldiers in China are procured from the three northern provinces, the others being seldom called forth, but allowed to remain at peace with their families: indeed there is not often occasion for exerting their military talents, unless it be in the quelling of an infurrection, when a mandarin or governor usually accompanies them. They march in a very tumultuous manner, but want neither skill nor agility in performing their different evolutions. They, in general, handle a fafere well, and shoot very dexterously with bows and arrows. There are in China mfr than 2000 places of arms; and through the different provinces there are dispersed 5000 towers or caftles, all of them defended by garrisons. Soldiers continually mount guard there; and on the first appearance of tumult, the nearest sentinel makes a signal from the top of the tower, by hoifting a fflag in the day time, or lighting a torch in the night; when the neighbouring garrisons immediately repair to the place where their presence is necessary.

The principal defence of the empire against a foreign enemy is the great wall which separates China from Tartary, extending more than 1500 miles in length, and of such thickness, that fixed horsemans may easily ride abreast upon it. It is flanked with towers two bow-shots distant from one another; and it is said that a third of the able-bodied men in the empire were employed in constructing it. The workmen were ordered, under pain of death, to place the materials so closely, that not the least entrance might be afforded for any instrument of iron; and thus the work was constructed with such solidity, that it is still almost entire, though 2000 years have elapsed since it was constructed. This extraordinary work is carried on not only through the low lands and valleys, but over hills and mountains; the height of one of which was computed by F. Verbien at 1236 feet above the level of the spot where he stood. According to F. Martini it begins at the gulf of Lea-tong, and reaches to the mountains near the city of Kin on the yellow river; between which places it meets with no interruption except to the north of the city of Suen in the province of Pechell, where it is interrupted by a ridge of houfous and inaccessible mountains, to which it is closely united. It is likewise interrupted by the river Hoang-lo; but for others of an inferior size, arches have been constructed, through which the water itself flows freely. Mr. Bell informs us, that the carriage and carriages are chiefly constructed in the dry climate in which it stands, may remain in the state of nature for many ages. When carried over steep rocks, where no horse can pass, it is about 15 or 20 feet high: but when running through a valley, or crossing a river, it is about 30 feet high, with square towers and embrasures at equal distances. The top is flat, and paved with cut stone; and where it rises over a rock or eminence, there is an arched made by an easy stone-flair. "This wall (our author adds) was begun and completed finished in the short space of five years; and it is reported, that the labourers fford(flag) to clofe for many miles, that they could hand the materials from one to another. This seems the more probable, as the rugged rocks among which it is built must have prevented all use of carriages; and neither clay for making bricks, nor any kind of cement, are to be found among them."

The whole civil government of China is managed by the following courts. 1. The emperor's grand council, composed of all the ministers of state, presidents and auditors of the fix sovereign courts, and of three others, to be afterwards mentioned. This is never assembled but on affairs of the greatest importance; the emperor's private council being substituted to it in all cases of smaller moment. 2. The chief of the other courts furnishes mandarins for the different provinces, watches over their conduct, and keeps a journal of their transactions, and informs the emperor of them, who rewards or punishes according to the report he gets. This second tribunal, which may be called a kind of civil inquisition, is subdivided into four others; the first entrusted with the care of selecting those who, on account of their learning or other good properties, are capable of filling the offices of government; the second

Account of the great wall.
The principal sovereign court to which these four last are subordinate is called Li-pou.

2. Hou-pou, or the grand treasurer, superintends all the finances of the state; is the guardian and protector of the treasuries and dominions of the emperor, keeping an account of his revenues, &c., superintending the management and coining of money; the public magazines, custom-houses; and, lastly, keeping an exact register of all the families in the empire. To adjudge this court, 14 others are appointed throughout the different provinces of the empire.

3. Li-pou, or the court of ceremonies. "It is an undoubted fact (says M. Grolier), that ceremonies form, in part, the bafe of the Chinefe government. This tribunal therefore takes care to support them, and enforce their observance; it inspects also the arts and sciences. It is confulted by the emperor when he design to confer particular honours; takes care of the annual sacrifices offered up by him, and even regulates the entertainments which he gives either to strangers or his own subjects. It also receives and examines foreign embassadors, and keeps in repair the emperor's palaces, as well as those of the princes and viceroyes, and the buildings where the tribunals are held, with the temples, tombs of the sovereigns, and all public monuments. It has besides the superintendence of the streets, public highways, bridges, lakes, rivers, and every thing relating either to internal or foreign navigation. Four inferior tribunals assist in the discharge of these duties; the first drawing the plans of public works: the second, while the sixth has the care of the arms, tents, chariots, barks, and stores necessary for military operations; so that nothing relative to these can be put in execution without the concurrence of all the three tribunals.

To prevent any lawful combination among the tribunals, each has its cenfor appointed. This is an officer whose duty is merely to watch over the proceedings of the court, without deciding upon any thing himself. He affists therefore at all assemblies, reviles all their acts, and without acquainting the court in the least with either his sentiments or intentions, immediately informs the emperor of what he judges to be amifs. He likewise gives information of the behaviour of the mandarins, either in the public administration of affairs, or in their private conduct: nay, sometimes he will not scruple to reprimand the emperor for what he supposes to be erroneous in his conduct.

These censors are never removed from their places but in order to be promoted; and thus, holding their offices for life, they have the greater courage to speak out when they obferve any impropriety or abuse. Their accusation is sufficient to let on foot an inquiry, which generally leads to a proof; in which case the accused is discharged from his office, and never held in any estimation afterwards. The complaints of the censors, however, are generally unites to the importance of their office incorruptible probity and invincible courage. The sovereign may, if he proceeds to rigour, take away their lives; but many of them have patiently suffered death, rather than betray the caufe of truth, or wink at abuses. It is not sufficient therefore to have got rid of one, they must all be treated in the fame manner; the last that might be spared would tread in the fame steps with no lefs resolution than those who went before him. In the annals of no nation do we find an example of such a tribunal, yet it appears to be necessary in all, without exception. We must not, however, imagine, that the privileges of a cenfor gave him a right to forgie his duty to his sovereign, or to communicate to the public the remarks which he takes the liberty of making to him: were he only to give the leaf hint of them to his colleagues, he would be punished with death; and he would share the fame fate did he, in any of his representations, suffer a single word, inconsistent with moderation or respect, to escape him."
Filial piety. The basis of all the civil laws of the Chinese is filial piety. Every mandarin, who is a governor either of a province or city, must instruct the people assembled round him twice a month, and recommend to them the observance of certain salutary rules, which are summed up in a few short sentences, and such as no person can ever be supped of forgetting.

The Chinese are allowed only to have one wife, whose rank and age must be nearly equal to that of their husbands; but they are allowed to have several concubines, whom they may admit into their houses without any formality, after paying the parents a sum of money, and entering into a written engagement to use their daughters well. These concubines, however, are all in subjection to the lawful wife; their children are considered as heirs; they address her as mother, and can give this title to her only. A person that has once been married, whether man or woman, may lawfully marry again, but it is then no longer necessary to study equality of age or condition. A man may choose his second wife from among his concubines; and, in all cases, this new marriage requires very few formalities. A widow is absolute mistress of herself, and can neither be compelled by her parents to marry again, nor to continue in a state of widowhood, contrary to her own inclination. Thole of moderate rank, however, who have no children, do not enjoy the same privilege, as the parents of the former husband can dispose of her in marriage, not only without her consent, but without her knowledge. The law authorizes the disposal of them in this manner, in order to indemnify the relations of the deceased husband for the money they may have cost him. If the wife is left big with child, this cannot take place, until she is delivered; nor can it be done at all if she brings forth a son. There are likewise two exceptions: 1. when the parents of the widow assign her a proper maintenance; and, 2. if the widow embraces a religious life, and becomes a nun.

Divorces, unlawful marriages.

Divorces are allowed in China in cases of adultery, mutual dislike, incompatibility of temper, jealousy, &c. No husband, however, can put away or sell his wife until a divorce is legally obtained; and if this regulation be not strictly observed, the buyer and seller become equally culpable. If a wife, lawfully married, privately withdraws herself from her husband, he may immediately commence an action at law; by the sentence of which she becomes his slave, and he is at liberty to sell her to whom he pleases. On the other hand, if an husband leaves his wife for three years, she is at liberty, after laying her complaint before the mandarins, to take another husband; but if she were to anticipate their consent, she would be liable to a severe punishment.

Marriage is deemed illegal in China in the following cases: 1. If a young woman has been betrothed to a young man, and presents have been given and received by the parents of the intended husband and wife. 2. If in the room of a beautiful young woman another be substituted of a disagreeable figure, or if the daughter of a free man marry his slave; or if any one give his slave to a free woman, pretending to her parents that he is his son or relation. In all these cases the marriage is null and void; and all those who have had any share in making up the match are severely punished.

3. Any mandarin of letters is forbidden to form an alliance with any family residing in the province or city of which he is governor.

No Chinese youth can enter into a state of marriage during the time of mourning for his father or mother; and if promisses have been made before, they cease immediately on that event taking place. After the usual time of mourning is expired, however, the parents of the intended bride are obliged to write to those of the young man, putting him in mind of his engagement.

5. Marriage is also suspended when a family experiences any severe misfortune, and even if a near relation were thrown into prison; though this may be let aside, provided the unfortunate person give his consent.

6. Two brothers cannot marry two sisters; nor is a widower at liberty to marry his son to the daughter of a widow whom he choos for his own wife. A man is also forbidden to marry any of his own relations, however distant the degree of consanguinity may be between them.

In China every father of a family is responsible for the conduct of his children, and even of his domestics; all those faults being imputed to him which it was his duty to have prevented. Every father has the power of selling his son, "provided (says the law) the son has a right of selling himself." This custom, however, is barely tolerated among the middling and inferior ranks; and all are forbidden to sell them to comedians, or people of infamous character, or very mean stations.

In China a son remains a minor during the whole lifetime, and is even liable for the debts contracted by his father, those from gaming only excepted. Adoption is authorized by law, and the adopted child immediately enters into all the rights of a lawful son; only the law gives a right to the father of making a few dispositions in favour of his real children. The children, however, whether adopted or not, cannot succeed to the dignity or titles of their father, though they may to his estate. The emperor alone can confer honours; and even then they must be resigned when the person attains the age of 70; though this renunciation is considered as an advice rather than a law.
Criminal law in China.

The will of a father cannot be set aside in China on account of any informality; nor can any mother in this empire make a will.

Though the Chinese laws authorize slavery, yet the power of the matter extends only to those matters which concern his own service; and he would be punished with death for taking advantage of his power to debauch the wife of his slave.

By the laws of China husbandmen are exempt from the payment of taxes after they have begun to till the earth to the beginning of harvest.

In criminal matters every person accused must be examined before five or six tribunals; and whole enquiries are directed not only against him, but against his accuser, and the witnesses that appear in the cause.

He is, however, obliged to remain in prison during the process; but (says M. Grolier) the Chinese prisons are not horrible dungeons like those of so many other nations; they are spacious, and have even a degree of convenience. One of the mandarins is obliged to inspect them frequently; and this he does with the greatest punctuality, as he must answer for those who are sick. He is obliged to feed them properly treated, to fend for physicians, and to supply them with medicines at the emperor's expense. If any of them die, he must inform the emperor, who perhaps will order one of the higher mandarins to examine whether the former has discharged his duty faithfully or not.

The slightest punishment in China is the bastinado; and the number of blows is to be determined by the degree of the offender's guilt. Twenty is the lowest number; and in this case the punishment is considered as having nothing infamous in it, but being only a simple paternal correction. In this way the emperor sometimes orders it to be inflicted on his courtiers, which does not prevent them from being afterwards received into favour, and as much respected as before. Every mandarin may inflict the bastinado when any one forgets to salute him, or when he acts in judgment in public. The instrument of correction is called pan-tsee, and is a piece of bamboo a little flattened, broad at the bottom, and polished at the upper extremity, in order to manage it more easily with the hand. When the punishment is to be inflicted, the magistrate sits gravely behind a table, having on it a bag filled with small stitches, while a number of petty officers stand around him, each furnished with these pan-tsee, and waiting only for his signal to make use of them. The mandarin then takes out one of the little stitches contained in the bag, and throws it into the hall of audience. On this the culprit is feized and stretched out with his belly towards the ground, his breeches are pulled down to his knees, and an athletic domestick applies five smart blows with his pan-tsee. If the judge draws another small stitch from the bag, another officer succeeds, and befalls more blows; and so on until the judge makes no more signals. When the punishment is over, the criminal must throw himself on his knees, incline his body three times to the earth, and thank the judge for the care he takes of his education.

For faults of a higher nature, the carrying of a wooden collar, called by the Portuguese the canus, is inflicted. This machine is composed of two pieces of wood hollowed out in the middle, which, when put together, leave sufficient room for the neck. These are laid upon the shoulders of the criminal, and joined together in such a manner, that he can neither see his feet nor put his hands to his mouth; so that he is incapable of eating without the assistance of another. This disagreeable burden he is obliged to carry day and night; its weight is from 50 to 200 pounds, according to the enormity of the crime, to which the time of carrying it is also proportioned. For robbery, breaking the peace, or disturbing a family, or being a notorious gambler, it is generally carried three months. During all this time the criminal is not allowed to take shelter in his own house, but is stationed for a certain space of time, either in some public square, the gate of a city or temple, or perhaps even of the tribunal where he was condemned. On the expiration of his term of punishment, he is again brought before the judge, who exhorts him in a friendly manner to amend; and after giving him 20 found blows discharges him.

Bannishment is infliction for crimes of a nature inferior to homicide, and the duration is often for life, if the ment. &c. criminals be sent into Tartary. Some culprits are condemned to drag the royal barks for three years, or to be branded in the cheeks with a hot iron, indicating the nature of their transgressions. But there is no crime between relations more severely punished than any other; and that is accounted the most atrocious where younger brothers or nephews appropriate to themselves beforehand any part of the succession in which they have a right to share with their elder brothers or nephews.

Information against a father or mother, grandfather, or grandmother, uncle or eldest brother, even though mere, of the accusation be just, is punished with 100 blows of informers pan-te, and three years banishment. If the accusation be false, it is punished with death. Deficiency in reward, respect to father, mother, grandfather, or grandmother, is punished with 100 blows of the pan-te; abusive language to these relations is death by strangling; to strike them is punished by beheading; and if any one pretends to hurt or maim them, his flesh is torn from his bones with red hot pincers, and he is cut into 1000 pieces. Abusing an elder brother is punished with 100 blows of the pan-te; striking him, with the punishment of exile.

Homicide, even though accidental, is punished with Capital punishment in China. A rope about six or seven feet in length, with a running noose, is thrown over the criminal's head; and a couple of domesticks belonging to the tribunal pull it strongly in different directions. They then suddenly quit it, and in a few moments give a second pull; a third is seldom necessary, to finish the business. Beheading is accounted in China the most dishonourable of all punishments, and is reserved only for desperate assassins, or those who commit some crime equally atrocious with murder. To be cut in a thousand pieces is a punishment inflicted only upon those criminals or rebellious subjects. It is performed by tying the criminal to a post, scalping the skin from the head, and pulling it over the eyes. The executioner then tears the flesh from different parts of the
China.

unhappy wretch's body; and never quits this horrible employment till mere fatigue obliges him to give over: the remains of the body are then left to the barbarous spectators, who finish what he has begun. Though this punishment, however, has been inflicted by some emperors with all the dreadful circumstances just mentioned, the law orders only the criminal's belly to be opened, his body to be cut into several pieces, and then thrown into a ditch or into the river.

The torture, both ordinary and extraordinary, is used in China. The former is applied to the hands or feet: for the hands, small pieces of wood are applied diagonally between the fingers of the criminal; his fingers are then tied close with cords, and he is left for some time in that painful situation. The torture for the feet is still worse. An instrument, consisting of three or four pieces of wood, is provided, that in the midst being fixed, the others movable. The feet of the criminal are then put into this machine, which, by squeezing them so close that the ankle bones become flat. The extraordinary torture consists in making small gashes in the body, and then tearing off the skin like sheets. It is however not applied to some great crimes, such as treason, or where the criminal's guilt has been clearly proved, and its necessary to make him discover his accomplices.

Notwithstanding those dreadful punishments, M. Grosier is at great pains to prove that the laws of the Chinese, with regard to criminal matters, are extremely mild. "One law (says he) will no doubt appear exceedingly severe and rigorous; it inflicts the punishment of death on those who use pearls. Those who read the history of China will be apt to fall into certain mistakes respecting the penal laws of that nation. Some of its sovereigns have indulged themselves in gratifying sanguinary caprices which were not authorized by the laws, and which have often been confounded with them: but these princes are even yet ranked among the number of tyrants, and their names are still abhorred and detested throughout the whole empire. The Chinese, in their criminal procedure, have a great advantage over all other nations: it is almost impossible that an innocent man should ever become a victim to a false accusation: in such cases the accuser and witnesses are exposed to too much danger. The slowness of the process, and the number of its revisions it undergoes, are another safeguard for the accused. In short, no sentence of death is ever carried into execution until it has been approved and confirmed by the emperor. A fair copy of the whole process is laid before him; a number of other copies are also made out, both in the Chinese and Tartar languages, which the emperor submits to the examination of a like number of doctors, either Tartars or Chinese. When the crime is of great enormity, and clearly proved, the emperor writes with his own hand at the bottom of the sentence, "When you receive this order, let it be executed without delay." In cases where the crime, though punishable by death according to law, is ranked in the ordinary cases, the emperor writes at the bottom of the sentence, "Let the criminal be detained in prison, and executed in autumn," that being the season in which they are generally executed, and all on the same day. The emperor of China never signs an order for the execution of a criminal till he has prepared himself by fasting. Like other monarchs he has the power of giving pardons; but in this respect it is much more limited than any other. The only cases in which the Chinese monarch can remit the punishment inflicted by law, are: 1. To the son of a widow who has not may be married again; 2. To the heir of an ancient family; 3. The dependents of great men or citizens who have done well of their country; and, lastly, the sons, or grandsons of a mandarin, who has become illustrious, and distinguished himself by faithfully discharging the duties of his office. Neither a child, nor a man of very advanced age, can be cited before a tribunal. The son of a very aged father and mother is pardoned, if private property or the public peace be not hurt by giving him a pardon; and if the sons of such a father and mother be all guilty, or accomplices in the same crime, the youngest is pardoned in order to comfort his parents.

In China the accused are always treated with tenderness and lenity, being accounted innocent until their guilt be clearly proved; and even then, liberty is often granted them. A jailor is engaged to behave rigorously towards his prisoners; and the judges must likewise answer at their peril for any additions to the severity of the law: deposition being the slightest punishment inflicted upon them.

Substitution is sometimes allowed by the laws of China; so that the near relation of a guilty person may put himself into the criminal's place, provided, however, that the chastisement be flight, and the accused his ancient friend. The sons, grandsons, wife, and brothers of a banished Chinese, are allowed to follow him into exile; and the relations of all persons are permitted to visit them in prison, and to give them every assistance in their power; to do which good offices they are even encouraged, instead of being prevented.

Every city in China is divided into different quarters, each of which is subjected to the inspection of spies and a certain officer, who is answerable for whatever passes in the place under his jurisdiction. Fathers of families, as we have already observed, are answerable for the conduct of their children and domestics. Neighbours are even obliged to answer for one another, and are bound to give every help and assistance in cases of robbery, fire, or any accident, especially in the night-time. All the cities are furnished with gates, which are barricaded on the commencement of night. Centinels are also posted at certain distances throughout the streets, who keep all who walk in the night, and a number of horsemen go round the ramparts for the same purpose; so that it is almost impossible to elude their vigilance by favour of the darkness. A strict watch is also kept during the day time; and all those who give any suspicion by their looks, accent, or behaviour, are immediately carried before a mandarin, and sometimes even detained until the pleasure of the governor be known.

Private quarrels do not often happen in China, and it is rare that they are attended with a fatal issue. The champions sometimes decide the quarrel with their fists, but most frequently refer the case to a mandarin, who very often orders them both a sound drubbing.

Cafe in which Chinefe monarcl can remit the punishment inflicted by law, are: 1. To the son of a widow who has not may be married again; 2. To the heir of an ancient family; 3. The dependents of great men or citizens who have done well of their country; and, lastly, the sons, or grandsons of a mandarin, who has become illustrious, and distinguished himself by faithfully discharging the duties of his office. Neither a child, nor a man of very advanced age, can be cited before a tribunal. The son of a very aged father and mother is pardoned, if private property or the public peace be not hurt by giving him a pardon; and if the sons of such a father and mother be all guilty, or accomplices in the same crime, the youngest is pardoned in order to comfort his parents.
In all the Chinese cities, and even in some of their ordinary towns, there is an office where money may be borrowed upon pledges at the common rate of interest, which, however, is no less than 30 per cent. Every pledge is marked with a number when left at the office, and must be produced when demanded; but it becomes the property of the office if left there a single day longer than the term agreed upon for the payment of the money. The whole transaction remains an inviolable secret; not even the name of the person who leaves the pledge being inquired for.

In the Chinese roads, great attention is paid by the administration of China to the convenience of travellers. The roads are generally very broad, all of them paved in the southern provinces, and some in the northern; but neither horses nor carriages are allowed to pass along them. In many places valleys have been filled up, and rocks and mountains cut through, for the purpose of making commodious highways, and to prepare them as nearly as possible on a level. They are generally bordered with very lofty trees, and in some places with walls eight or ten feet high, to prevent travellers from going into the fields; but openings are left in proper places, which give a passage into crofs roads that lead to different villages. Covered feats are erected on all the great roads, where travellers may rest themselves from the inclemency of the weather; temples and pagods are also frequent, into which travellers are admitted without payment of the money. When porters are wanted, he furnishes as many as may be necessary, and gives the same number of tickets to the traveller; who returns one to each porter when they have conveyed their loads to an appointed place. These tickets are carried back to the chief, who immediately pays them from the money he received in advance. On all the great roads in China there are several offices of this kind, which have a settled correspondence with others; the travellers therefore have only to carry to one of these offices a list of such things as they wish to have transported: this is immediately written down in a book; and though there should be occasion for two, three, or four hundred porters, they are instantly furnished. Every thing is weighed before the eyes of their chief, and the hire is five pence per hundred weight for one day's carriage. An exact register of every thing is kept in the office; the traveller pays the money in advance, after which he has no occasion to give himself any further trouble: on his arrival at the city he designs, his baggage is found at the corresponding office, and every thing is delivered to him with the most scrupulous exactness.

The custom-houses are here regulated by the general police of the country; and according to M. Grouard, of the viceroys' account, these custom-house officers are the most civil in the world. They have no concern with any delays of people but the merchants, whom they take care not to detain by any rigorous exactions; neither, though they have authority to do so, do they stop travellers till their baggage is examined, nor do they ever require the smallest fee from them. Duties are paid either by the piece or the load; and in the former case credit is given to the merchant's book without asking any questions. A mandarin is appointed by the viceroys of each province to inspect the custom-houses of the whole district; and the mandarins have also the care of the post-offices.

In former times the only money used in China was made of small shells, but now both silver and copper the empire coin are met with. The latter consists of round pieces about nine-tenths of an inch (a) in diameter, with a small square hole in the middle, inscribed with two Chinese words on one side, and two Tartar ones on the other. The silver pieces are valued only by their weight. For the convenience of commerce, the metal is therefore cast into plates of different sizes; and for want of small coin, a Chinese always carries about very large bells of cast iron. According to law these towers should be only five feet, about half a French league, distant from one another.

There is no public post-office in China, though several private ones have been established; but the carriers and offices charged with despatches for the empire have only a right to make use of them. This inconvenience, however excepted, travellers find convenience very easy from one part of China to another. Great numbers of porters are employed in every city, all of whom are distributed under the conduct of a chief, who regulates all their engagements, fixes the price of their labour, receives their hire, and is responsible for every thing they carry. When porters are wanted, he furnishes as many as may be necessary, and gives the same number of tickets to the traveller; who returns one to each porter when they have conveyed their loads to an appointed place. These tickets are carried back to the chief, who immediately pays them from the money he received in advance. On all the great roads in China there are several offices of this kind, which have a settled correspondence with others; the travellers therefore have only to carry to one of these offices a list of such things as they wish to have transported: this is immediately written down in a book; and though there should be occasion for two, three, or four hundred porters, they are instantly furnished. An exact register of every thing is kept in the office; the traveller pays the money in advance, after which he has no occasion to give himself any farther trouble: on his arrival at the city he designs, his baggage is found at the corresponding office, and every thing is delivered to him with the most scrupulous exactness.

(a) The Chinefe foot is longer by one hundredth part than the French, and the inch is divided into ten parts.
Chinese money is gold or silver, the latter being used in the southern provinces, and the former in the northern. The Chinese value silver by the numerical price of the metal. If the price of silver has not fallen below 2000 per piece, the money is employed to buy copper coin; but if the price of silver is more than 1000 per piece, only copper coin is used. This regulates the value of the coin, as well for commerce as for the use of the poor. Copper money is often employed as plain copper. It is forbidden to employ it in manufactures or as currency for daily transactions.

The Chinese government is attentive to preserve an equilibrium between the proportional value of gold and silver; so that the intrinsic value of each may affect the price of copper, and thus regulate the relative value of the coins. The method used is to forbid the exchange of copper for silver, which makes the copper valuable. The same is done for silver.

To keep up a constant circulation of all the coin in the empire, the Chinese government is attentive to preserve an equilibrium between the proportional value of gold and silver; so that the intrinsic value of each may affect the price of copper, and thus regulate the relative value of the coins. The method used is to forbid the exchange of copper for silver, which makes the copper valuable. The same is done for silver.

Commerce in China is under the supervision of the Imperial Treasury. It is regulated by the intrinsic value of metal, and by the value of the metal as currency.

The Chinese government does not enrich a kingdom by commerce alone. It is prejudicial to the empire, as it only furnishes luxury, the high-priced balbbles that accompany it, and the gratification of pride, luxury, and the gratification of vanity.

China.

The satisfaction of both parties. The reconciliation, was of no long duration; for the Russians having soon renewed their disorderly behaviour, an order for their expulsion was issued in 1722, and all intercourse between the two nations forbidden. The differences were once more made up in 1729, and a caravan allowed to go to Peking once in three years, provided it consisted of no more than 100 persons; and that during their stay their expenses should not, as formerly, be defrayed by the emperor of China. The Russians at the same time obtained permission to build a church within the precincts of the caravanary; and that four priests were allowed to reside at Peking for the celebration of divine service; the same indulgence being granted to some Russian scholars, for the purpose of learning the Chinese language, and qualifying themselves for being interpreters between the two nations. This intercourse continued till the year 1755; since which time no more caravans have been sent to China. It was first interrupted by a misunderstanding between the two courts; and though that difference was afterwards made up, no caravans have been sent ever since. The empress of Russia, sensible that the monopoly of the fur trade (which was entirely confined to the caravans belonging to the crown, and prohibited to individuals) was prejudicial to commerce, gave it up in favour of her subjects in 1762; and the centre of commerce between the two nations is now at Kiatoa. Here the trade is entirely carried on by barter. The Russians are prohibited from exporting their own coin; finding it more advantageous to take goods in exchange than to receive bullion at the Chinese standard. The principal exports from Russia are furs of different kinds; the most valuable of which are those of sea-otters, beavers, wolves, foxes, martins, fables, and ermines; the greater part of which are brought from Siberia and the newly discovered islands; but as they cannot supply the demand, there is a necessity for importing foreign furs to Petersburg, which are afterwards sent to Kiatoa. Various kinds of cloth are likewise sent to China, as well as hardware, and live cattle, such as horses, camels, &c. The exports from China are, raw and manufactured silk, cotton, porcelain, rhubarb, musk, &c. The government of Russia likewise reserves to itself the exclusive privilege of purchasing rhubarb. It is brought to Kiatoa by some Bakharian merchants, who have entered into a contract to supply the crown with it in exchange for furs: the exportation of the best rhubarb is forbidden under severe penalties, but yet is procured in sufficient quantities, sometimes by clandestinely mixing it with inferior roots, and sometimes by smuggling it directly. Great part of Europe is supplied with rhubarb from Russia.

The revenue of the emperor of China amounts to more than 47 millions sterling; and might easily be increased, did the sovereign incline to burden his subjects with new impositions. The annual expenses of government are indeed immense, but they are regulated in such a manner as never to be augmented but in cases of the utmost necessity; it even happens very often that administration makes greater savings every year. When this happens to be the case, the surplus serves to increase the general treasure of the empire, and prevents the necessity of new impositions in time of war, or other public calamities. The greater part of the taxes are paid in kind; those, for instance, who breed silk worms, pay their taxes in silk; the husbandmen in grain, the gardeners in fruits, &c. This method, at the same time that it is exceedingly convenient for the subject, is no way detrimental to the public interest. There are numbers of people every where in the service of government, who are thus furnished with food and clothing; so that the commodities collected as taxes are almost consumed in the provinces where they are levied; what remains is sold for the benefit of the emperor, and the money deposited in the imperial treasury. The taxes paid in money arise principally from the customs and sale of salt (which belongs entirely to the emperor), from the duties paid by vessels entering any port, and from other imposts on various branches of manufactures. Excepting these, the trader scarcely contributes any thing to the exigencies of the state, and the mechanic nothing at all; the whole burden of taxation thus falling upon the husbandman. This burden is regulated in proportion to the extent and fertility of his lands; and the greatest care has been taken to manage matters so, that he may neither be overcharged in the imposition nor harassed in the levying of the duties. "The registering of lands (says M. Grodzer), "is often and to no purpose projected in France, but has been long practiced in this empire, notwithstanding its prodigious extent." The levying of taxes in China is as simple as the nature of the thing will admit of. The duties levied from towns and villages are carried to cities of the third class; then they are conducted to those of the second; then to those of the first; and at last to the capital. The levying and imposition of taxes is submitted to the tribunal of finances; and matters are so managed, that besides the consumption in each district for discharging the ordinary expenses of government, something is left by way of reserve for answering accidental demands, and to be ready in cases of necessity. This fund becomes gradually less from the capital to cities of the first, second, and third class. A proper statement of what is paid in the provinces, of what is reserved in the different cities, or contained in the different treasuries of the empire, is subjected to the examination of the grand tribunal of finances. This revives the whole, and keeps an exact account of what is consumed, and of whatever surplus may be left.

Lending money upon interest has been in use in China for about 2000 years. It has often been abolished, and as often established. The interest, as has been already hinted, is no less than 20 per cent, and the year is only lunar. A tenth part of this interest is paid monthly; and concerning neglects of payment, the following laws have been enacted. "However much the debt may have accumulated by months or years, the principal and interest shall remain always the same. Whoever infringes this law shall receive 40 blows of a pan-tpee; or an hundred, if he uses any artifice to add the principal and interest together." This law is explained by the following. "Whoever shall be convicted before a mandarin of not having paid a month's interest, shall receive ten blows, twenty for two months, thirty for three; and in this manner, as far as sixty; that is to say, to the sixth month. The
Many Chinese writers have endeavoured unsuccessfully to show why government should allow such exorbitant interest to be taken for money; but the most satisfactory and rational account seems to be, that the great interest of money prevents the rich from purchasing much land; as landed estates would only embarras and impoverish them, their produce being so much inferior to that of money. The patrimony of a family in China is seldom divided; and it never happens there, as in almost every other country, that wealth and riches are engrossed by one part of the nation, while the other polesce nothing.

Agriculture is by the Chinese considered as the first and most honourable of all professions; so that in this empire the husbandman enjoys many and great privileges, while the merchant and mechanic are much less encouraged. Part of the crop is allowed to be used in distillation; but if the harvest happens to be bad, this operation is prohibited. In China, the tillage of the earth is not only encouraged by law, but also by the example of the emperor, who annually tills the earth with his own hands. The beginning of spring in China is always reckoned to be in the month of February; but it belongs to the tribunal of mathematics to determine the precise day. The tribunal of ceremonies announces it to the emperor by a memorial; in which every thing requisite to be done by him is mentioned with the most scrupulous exactness. The sovereign then names 12 of the most illustrious persons in his court to accompany him, and to hold the plough after he has performed his part of the ceremony. Among these there are always three princes of the blood, and nine presidents of supreme courts; and if any of them are too old and infirm to undergo the fatigue, the substitutes must be authorized by the emperor. The festival is preceded by a sacrifice, which the emperor offers up to Chang-ti (the supreme God); after which he and his attendants prepare themselves by three days fasting and continence. Others are appointed by the emperor, on the evening before the ceremony, to go and prostrate themselves at the sepulchre of his ancestors, and to acquaint them, that, on the day following, he intends to celebrate a grand sacrifice. This is offered up on a small mount a few furlongs distant from the city, which, by the indispensible rules of the ceremony, must be 50 feet in height. The Chang-ti is invoked by the emperor, who sacrifices under the title of sovereign pontiff, and prays for an abundant harvest in favour of his people. He then descends, accompanied by the three princes and nine presidents who are to put their hands to the plough along with him; the field set apart for this purpose being at a small distance from the mount. Forty labourers are selected to yoke the oxen, and to prepare the feed which the emperor is to sow; and which are of five different kinds, viz. wheat, rice, two kinds of millet, and beans. They are brought to the spot in magnificent boxes, carried by persons of the most distinguished rank. The emperor then lays hold of the plough, and turns up several furrows; the princes of the blood do the same, and then the presidents; after which the emperor throws into the furrows the five kinds of feeds already mentioned: lastly, four pieces of cotton-cloth, proper for making drecles, are distributed to each of the labourers, who affit in yoking the oxen and preparing the feeds; and the same presents are made to 40 other persons who have only been spectators of the ceremony.

"We must not (says M. Grolier) judge of the Chinese peasants from those of Europe, especially in what relates to the lights acquired by education. Free schools are very numerous in every province of China, and even some of the villages are not destitute of this advantage. The sons of the poor are there received as readily as those of the rich; their duties and their studies are the same; the attention of the masters is equally divided between them; and from this obscure source talents often spring, which afterwards make a conspicuous figure on the grand stage of life. Nothing is more common in China than to see the son of a peasant governor of that province in which his father had long toiled in cultivating only a few acres. The father himself, if taken from his plough, and elevated to a superior sphere, might, by reviving the instruction he received in his youth, and especially if he be endowed with genius, find himself fully competent for his new employment."

The Chinese have been greatly reproached with the inhuman practice of murdering their children; but although our author cannot deny that they are guilty of this practice, he excuses them by saying, that "the crime when committed in China is commonly owing to the fanaticism of idolatry; a fanaticism which prevails only among the lowest of the people. It is either their infatuated wretches precipitate their children into the river; they imagine that, by doing so, they make an expiatory sacrifice to the spirit of the river. All nations of antiquity almost have disgraced themselves by the like horrid practices; but the Chinese are far from condescending this barbarity on that account. Besides, those criminal sacrifices are never practised but in certain cantons of China, where the people, blinded by idolatry, are the dupes of prejudice, fanaticism, and superstition."

It often happens also, that the bodies of those children which are seen floating on the water have not been thrown into it till after their death; and this is likewise the case with those which are found in the streets, or lying near the public roads. The poverty of the parents suggests this dismal resource, because their children are then buried at the expense of the public. Exploiting of children in public places is a custom tolerated in China; and government employs as much vigilance to have them carried away in the morning, as it bestows care on their education. This is certainly giving people intimation to expose their children in the night-time, and no doubt encourages the practice; but the dictates of humanity are here united to those of found policy. No law in China authorizes mutilation: there are indeed eunuchs in the empire, but their number is much less than what it is generally supposed to be by Europeans. The greater part of the eunuchs belonging to the emperor and empresses have no higher employment than that of sweeping the courts of justice."
Like the capital cities of European kingdoms, Peking, the metropolis of the Chinese empire, is furnished with a gazette, which circulates into the remotest provinces, and which is even considered by administration as an essential part of the political constitution. It is printed daily at Peking, and contains an account of all those objects to which the attention of administration is directed. In this gazette may be seen the names of all those mandarins who are stripped of their employments, and the causes of their disgrace; it mentions also the names of all those delinquents who are punished with death; of the officers appointed to fill the places of the disgraced mandarins; the calamities which have afflicted any of the provinces; the relief given by government; and the expenses incurred by administration for the subsistence of the troops, supplying the wants of the people, repairing or erecting public works; and, lastly, the remonstrances made to the sovereign by the superior tribunals, either with regard to his public decisions or private conduct, and sometimes even with regard to both. Nothing, however, is contained in this gazette that has not immediately come from the emperor, or been submitted to his inspection; and immediate death would be the consequence of inferring a falsehood in this ministerial paper.

No law or sentence, as has already been said, is of any force, until the emperor's seal has been affixed to it. This is about 8 inches square, and is made of fine Jasper, a kind of precious stone much esteemed in China; of which only the emperor is allowed to have a seal. Those given to princes as marks of honour are composed of gold; the seals of the vicerovys and great mandarins, of silver; while those of inferior mandarins and magistrates are made only of lead or copper. The size of these seals is greater or smaller according to the rank their possessors hold in the tribunals or as mandarins; and when any of them happens to be worn out, intimation must be sent to the next superior tribunal; on which a new seal is to be sent into the provinces. The commission of every inspector sent into the provinces must also be confirmed by the emperor's seal. The duty of these officers is to examine into the conduct of governors, magistrates, and private individuals; and instances are recorded of emperors themselves affixing the office of inspectors in some of the provinces. These officers are not only superior to all the magistrates, but even to the vicerovys of the provinces themselves. When a superior magistrate behaves ill to an inferior one, the former instantly becomes the prisoner of the inspector, and is suspended from his office until he has cleared himself from every imputation laid to his charge. The viceroy, however, is allowed to enjoy his office until the report of the inspector has been transmitted to the emperor.

These vicerovys are distinguished by the title of Tông-tou, and are always mandarins of the first class, possessing an almost unlimited power within their districts. They march abroad with all the pomp of royal magnificence, never quitting their palaces, on the most trifling occasion, without a guard of 100 men. A viceroy is the receiver-general of all the taxes collected in the province, transmitting them to the capital, after having reserved what he judges necessary for the demands of his district. All law-suits must be brought before his tribunal; and he has the power of holding sentence of death, but it cannot be put in execution without being first carried to the emperor. Every three years he sends to court a report of the conduct of the mandarins subordinate to him; and according to the informed, those they are either continued or disgraced. Those of whom he makes an unfavourable report are punished in proportion to their delinquency; while, on the other hand, those who have the good fortune to be well reported, are rewarded in a similar proportion.

The principal mandarins are sometimes broke and dismissed from all their employments, while others are only removed some degrees lower. Those who have been degraded ten steps, run a great risk of never being employed again. These degraded mandarins are kept in perpetual remembrance of their misfortune, by being obliged to mention it in every public order they issue forth in their inferior station; thus, "I, such a mandarin, degraded one, two, three, &c. steps, command and order," &c. Over these inferior mandarins the inspector of the province has a very unlimited authority, and can, by his own power, deprive them of their employments for a great offence; nor does he confult the court, excepting where the immediate punishment of the criminal is not necessary. Every one of the mandarins, of whatever rank or denomination, is obliged, once in three years, to give in writing an exact account of the faults he has committed in the execution of his office. If he is a mandarin belonging to any of the four first classes, this confession is examined at court; but if it is made by any of the inferior ones, it must be laid before the provincial tribunal of the governor. Government, however, is not satisfied even with this confession; inquiry is made into the truth of it, and the conduct of the mandarin is scrutinized with the utmost severity, the informations being subjected to the tribunal of mandarins; where they are carefully examined, the merits and demerits of those subject to this political inquisition carefully weighed, and their names are recorded in one of the three classes. The first consists of those for whom rewards and preferment are intended; the second, for whom gentle reproof and admonition are thought necessary; and the third, of those who are to be suspended for some time, or removed altogether, from their offices. Of these last some are allowed to continue; but they receive no salary, and are not only deprived of all their emoluments, but even of their honours. If they have been guilty of any action tending to oppress the people, or to occasion a famine or scarcity among the lower ranks, their punishment is not confined to disfravishment from their offices, but they are also criminally impeached. The family burying-place of every Chinese is sacred; none dares cut down the trees with which it is overshadowed until they become decayed with age; and even then, not until their condition has been attested by a mandarin: but for certain crimes against government or the people, the burying-place of a mandarin is raised to the foundation. No kind of punishment, however, inflicted on a father, is supposed in the least to affect the character of his son; and therefore, when the latter is affected by the emperor concerning his family, he will perhaps coolly
cooly answer, "My father was disgraced for such a crime, my grandfather was beheaded for another," without the acknowledgement being in the least detrimental. On the contrary, by great and important services, it is possible for him to wipe out these stains from the memory of his ancestors.

Though the empire of China is governed by Tartar princes, the latter seem to bellow more much care and attention on the Chinese than their own natural subjects. Should any dispute arise between a Chinese and a Tartar, the former must have greatly deviated from the rules of justice, if he is not acquitted even by those tribunals which are composed of half Chinese and half Tartars. The slightest fault committed by a Tartar mandarin is always severely punished; but the punishment of the greatest is often mitigated if the delinquent be a Chinese; and the same severity is exercised towards those of the military department. Those faults, however, are punished with the greatest severity which hurt the interests of the people: for which reason they seldom fall a sacrifice to that class of petty tyrants who in other countries prey upon and devour them. Every superior mandarin is obliged to inform himself of the faults of his inferiors, and expose them; nay, he would be punished for them himself if he did not.

Very little regard, as we have already had occasion to observe, is paid to hereditary right in China. Even the princes of the blood enjoy no other privilege by birth but that of wearing a yellow girdle; and the names of their children, with the exact time of their birth, are inscribed in a yellow book appropriated to that purpose. Collateral princes are distinguished by an orange girdle, and their children are marked in a book of a red colour. The surnames of the princes of the reigning family are determined by the emperor alone; the rest not being allowed to assume any name that too much resembles those of the Moguls or Chinese. The rank even of the emperor's sons diminishes one degree every generation: so that, at the seventh, only the eldest branch has a title to wear the yellow girdle, the rest being sunk into the rank of plain citizens. An hereditary sovereignty, however, pales from one eldest son to another; and this title cannot be forfeited, unless the possessor be guilty of some crime. In this case the emperor appoints to the succession either one of his younger brothers or a cousin: but these must be always chosen from the same branch, as the lawful branch cannot be deprived of its right without the condemnation of all who compose it. The only hereditary authority of the other princes exists among those troops called the Tartar bands. There they enjoy, without opposition, that rank which they derive from their birth, but in every thing else are on a level with others. They are subjected to a military examination at stated periods, and are always promoted or degraded according to the degree of skill they exhibit. The fame trial is undergone by the heir apparent and his sons; the only indulgence shown them being, that schools are appointed for their particular use. The princes are likewise indulged with a tribunal appropriated for purpose for them, and before which alone they can be tried. An infat offered to a prince decorated with the yellow girdle is punished with death; but if he has omitted to put it on, the aggresor escapes with a basting. A prince may be put to death by the emperor's consent; but he escapes every lighter corporal punishment by paying a fine. Untitled princes have very few privileges superior to those of common citizens; and are generally very poor, unless possessed of some lucrative office. Thus they are sometimes reduced to the necessity of accepting the highest pay of a common soldier in the Tartar bands. When they, or any of their children, however, enter into the marriage state, the emperor usually makes them a present of 100 ounces of silver. He will also relieve them on other occasions, stilt their widows and orphans, &c., but in all this never departs from the most exact rules of economy; so that the mandarins in this respect are much better than the relations of the sovereign himself.

With regard to the ancient religion of China, F. A. F. Avicar informs us, that, after making every possible research, comparing and reasoning upon his observations, he at last concluded, that "the Chinese are a distinct people, who have still preserved the characteristic marks of their origin: a people whose primitive doctrine will be found, by those who take the trouble of investigating it thoroughly, to agree in its essential parts with the doctrine of the chosen people, before Moses, by the command of God himself, had composed the explanation of it to the sacred records: a people, in a word, whose traditional knowledge, when freed from whatever the ignorance or superstitition of later ages has added to it, may be traced back from age to age, and from epoch to epoch, without interruption, for the space of 4000 years, even to the removal of the human race by the grandon of Noah." The king, or canonical books of the Chinese, every where inculcate the belief of a Supreme Being, the author and preserver of all things. Under him they mention the names of Tien, or Heaven; Chang-tien, or Supreme Heaven; Chang-ti, or Supreme Lord; and of Houng-chi, or Sovereign and Supreme Lord: "Names (says M. Grosier) corresponding to those which we use when we speak of God, the Lord, the Almighty, the Most High."

According to the Chinese books, the Supreme Being is the principle of every thing that exists, and the father of all living; he is eternal, immovable, and independent; his power knowes no bounds; his sight equally comprehends the past, present, and the future, penetrating even into the inmost recesses of the heart. Heaven and earth are under his government; all events, all revolutions, are the conquences of his will; he is pure, holy, and impartial; wickedness offends his sight; but he beholds with an eye of complacency the virtuous actions of men. Severe, yet just, he punishes vice in a striking manner even on the throne, and often precipitates from thence the guilty, to place upon it the man who walks after his own heart, whom he hath raised from obscurity. Good, merciful, and full of pity, he relents on the repentance of the wicked; public calamities, and the irregularities of the seafsons, are only salutary warnings, which his fatherly goodness gives to men to induce them to reform and amend.

The performance of religious worship at the proper and appointed times, has given occasion to the great exact-
The facrifices of the Chinese were first offered up in the open fields, or on some mountain, upon what they call the T'ao, which signifies a quantity of flowers thrown together in a round form, or simply a round heap of earth. A double fence, called Kiao, composed of turf and branches of trees, was raised around this; and, in the space left between the two fences, two lesser altars were erected on the right and left; upon which, immediately after the sacrificers offered up the Tien, they sacrificed also to the Chang, or good spirits of every rank, and to their virtuous ancestors. The sovereign alone had a right of sacrificing upon this T'ao; and the custom of sacrificing to inferior spirits, according to the Chinese commentators, may be traced even to the days of Fu-hi himself. The same writers add, that, in addressing themselves to the Chang-ti, they considered him as the sovereign lord of the universe, clothed with all that power which was necessary to satisfy them with regard to the different objects of their requests; but that, in offering up their prayers to the inferior objects of worship, they only implored their protection and mediation with the Chang-ti.

While the empire was confined within narrow bounds, one mountain was sufficient for the sacrifices; but in processes of time it became necessary to consecrate four others. These were situated at the extremities of the empire, and were supposed to correspond with the four quarters of the world; and the prince went successively every year to one of these mountains to offer up sacrifices; taking occasion at the same time to show himself to his people, and to inform himself of their wants. This custom subsisted for a long time; but at length it was found convenient to add a fifth mountain in the centre of the empire; and ever since these have been called the five Yo, or the five mountains of sacrifice. This method of subjecting the emperor to regular annual journeys could not but be attended with many inconveniences. It was found necessary on this account to consecrate some spot in the neighbourhood of his palace, which might be substituted for the Yo upon all occasions when the emperor could not repair to them. An edifice was therefore erected, which at once represented the Kiao, T'ao, and the Hall of Ancestors. This last was a new invention of the edifice, because it was incumbent upon those who offered up sacrifices, first to repair to this hall, and acquaint their ancestors with what they were about to perform; and thither also they returned after sacrificing, to thank the same ancestors for the protection they had received from the Chang-ti; after which they offered up a sacrifice of thanksgiving in honour of them, and performed certain other ceremonies to show their respect. The building contained five separate halls, appropriated to different purposes: originally it had neither paintings nor ornaments of any kind, and a plain arch of nine steps conducted to the principal entrance. Afterwards, however, it was much more richly ornamented, each of the five halls being decorated with columns, over which others were placed that supported the second roof. In succeeding times it was stripped of all its ornaments, with a view to bring back religion to its primitive simplicity. Its four gates were covered with fine moss, representing the branches of which the double fence of the ancient Kiao were formed. The ridge of the roof was covered with the same, and the whole was accompanied by a canal filled with water at the time of offering up the sacrifices. To this a second building was added, which they called the

The critics of Europe may make, seems to furnish a number of texts, which give us reason to consider the Chou-tao, known in Europe, as three united, penetrated, or incorporated into one. According to another book, the emperor formerly offered up a solemn sacrifice every three years to the Spirit, Trinity and Unity, Chin-fan-yeh. The following celebrated text of Lao-tze has long been known in Europe. 'Tao is one by nature: the first begot the second; two produced the third; the three created all things.'

'F' Amiot quotes another passage, which appears to be no less singular. 'He who is, as it were, visible, and cannot be seen, is named Khi; he who may be heard, yet speaketh not to the ears, is called Hi; he whom, in a manner, we feel, yet cannot touch, is named Oiwi.' In vain do we interrogate our senses respecting these three; our reason, which alone can give us any satisfaction, will tell us that they make only one. Above there is no light; below there is no darkness. He is eternal; there is no name which can be given him. He resembles nothing that exists; he is an image without figure; a figure without matter: his light is surrounded by darkness. If we look up to him above, we behold no beginning; if we follow him, we discover no end. From what the T'ao hath been at all times, conclude what he is, viz. that he is eternal: he is the beginning of wisdom.' The commentaries which explain this passage speak in such strong and precise terms, that F. Amiot forbears to quote them, lest he might incur the censure of too many incredulous readers.
Magical practices, the invocation of spirits, and the art of foretelling events by divination, quickly diffused themselves over the empire, and the imbecility of the emperors contributed to propagate the deception. Temples consecrated to spirits quickly reared their heads in every corner of the empire; and two of the monuments celebrated of the facts were so authorized to maintain public worship there after the form which had been prescribed by their master. At the same time they distributed, and sold at a dear rate, images of the imaginary spirits with which they had peopled the heavens and the earth. These were, by their command, worshipped as so many deities independent of the Supreme Being; and, in like manner, several of the ancient emperors were invoked as gods.

Being patronized by the emperors of several dynasties, this sect became more and more powerful. At last they had the impudence to affirm, during the night-time, to one of the gates of the imperial city, a book filled with mystic characters and magical figures. At the break of day they inquired of the emperor whether the sudden appearance of this book, and publicly declared that it was fallen from heaven. This trick easily imposed upon the weak prince. He immediately repaired, with a numerous train, to the spot where the sacred volume appeared; and having taken it into his hands in a respectful manner, carried it in triumph to his palace, where he shut it up in a golden box. Another emperor carried his reverence for the sect to fuch an height of impiety and extravagance, as to order a celebrated Tao-fe to be publicly worshipped under the name of Chang-ti. The sect thus patronized by the princes, and accommodated to the credulity of the vulgar, continued to gain ground in spite of every opposition from the wiser part of the people, and is still very powerful in China. At present they offer up three different victims, a hog, a fowl, and a fish, to a spirit whom they invoke. Various ceremonies, such as bowing, drawing fantastic figures upon paper, making a hideous noise with kettles and drums, are used in their incantations; and though it may readily be believed that they are for the most part unsuccessful, yet their credit is still kept up by those cafes in which they succeed by accident.

The chief of the Tao-fe is invested by government with the dignity of grand mandarin, which is enjoyed by his successors; he resides in a sumptuous palace in a town of Kiang-si; and the superstitious confidence of the people attracts an immense number thither from all parts of the empire. Some arrive in order to be cured of diseases, others to get an insight into futurity. The impostor distributes to them small bits of paper filled with magical characters; and the ignorant wretches depart well satisfied, without grudging the expense of their journey, though ever so long.

A still more pernicious and more widely diffused sect is that of the idol Fo, which came originally from Indian philosophers of the same name. The Tao-fe, had promised to the brother of one Fo of the emperors of China to introduce him to a communication with spirits. The credulous prince having heard of a great spirit named Fo, who resided in India, prevailed on his brother to send an embassado ther. On the arrival of the ambassadors, however, they could find only two worshipers of this deity, both of whom they brought to China. Several images
The bonzes of China were also collected at the same time; and these, together with some canonical books of the Indians, were placed on a white horse, and carried in procession to the imperial city.

This superstition was introduced into China about the 6th year of the Christian era, and soon made vast progress. One of its principal doctrines is that of the metempsychosis, or transmigration of souls, of which M. Grolier thinks he was the inventor, and that Pythagoras, who travelled into several parts of India, had borrowed the doctrine from him. The account given of him by the bouzes is, that finding Pythagoras, at the age of 70, oppressed with infirmities, he called his disciples together, and told them he was unwilling to leave the world without communicating the secret and hidden mysteries of his doctrine; which, were in short, that all things had proceeded from a vacuum of the metempsychous, or transmigration of souls, of which M. Grolier thinks he was the inventor, and that Pythagoras, who travelled into several parts of India, had borrowed the doctrine from him. The account given of him by the bouzes is, that finding Pythagoras, at the age of 70, oppressed with infirmities, he called his disciples together, and told them he was unwilling to leave the world without communicating the secret and hidden mysteries of his doctrine; which, were in short, that all things had proceeded from a vacuum and nothing, and to that they must return. This doctrine produced a corresponding mode of action, or rather of inaction, in those who believed it: for thus the great happiness of man was made to consist in absolute annihilation; and therefore the nearer he could bring himself to this state during life, the happier he was supposed to be.

The common doctrine, however, which admits of a distinction between good and evil, finds more profelytes among the vulgar, whose situation in life will not allow them to spend their time in perpetual idleness. According to this, the righteons will be rewarded and the wicked punished after death. They say also, that the god Po came to save mankind, and to expiate their sins; and that he alone can procure them a happy regeneration in the life to come. Five precepts are likewise inculcated on those who adopt this doctrine: 1. Not to kill any living creature. 2. Not to take away the goods of another. 3. Not to pollute themselves by uncleanliness. 4. Not to lie; and, 5. Not to drink wine. Above all, they recommend to them to perform acts of mercy, to treat their bouzes well, build temples, &c.

The doctrine of metempsychosis has been extended by the Chinese to an infinite number of idols, who are all worshipped on the supposition that the spirit of Po has transmigrated into the animals they represent. These idols, however, seem not to be worshipped with great sincerity; but, like the images of saints in the more superstitious countries of Europe, are beaten and thrown in the dirt when their votaries happen not to obtain their desires, which they impute to the obstinacy or weakness of the idol. Nay, M. Grolier gives an account of one man, who having ineffectually paid a sum of money to the bouzes of a certain idol for the cure of his daughter, brought a formal accusation against the idol itself; and in spite of all that the bouzes could say in its behalf, got its worship suppressed throughout the province.

The bouzes of China are represented as a most avaricious and hypocritical race of men, ready to prostitute every kind of villany, and even to subject themselves to the most intolerable tortures, in order to obtain money from the compassion of the public when they cannot get it in any other way; and an edict of one of the emperors is cited by M. Grolier, by which great numbers of their religious houses were suppressed. In order to perpetuate their sect, they purchase young children, whom they take care to instruct in all the mysteries and tricks of their profession; but excepting this, they are in general very ignorant, and few of them would be able to give any tolerable account of the tenets of their own faith. They are not subject to a regular hierarchy, but acknowledge superiors among them whom they call grand bouzes, who have the first place in all religious assemblies at which they happen to be present; and great profit is derived from certain religious clubs, both of men and women, at which the bouzes are always called to assist. Their wealth is likewise augmented by pilgrimages to certain places where there are temples more or less revered, and where a multitude of absurd ceremonies are performed. These bouzes, as may be easily imagined, are invertebrate enemies to the progress of Christianity, telling the most absurd stories concerning the missionaries; as that they pluck out the eyes of their converts to construct telescopes with, &c. The literal, however, and the more sensible part of the nation, hold them in the greatest contempt.

We shall conclude this detail of the Chinese religion with giving an account of one other superstition, which seems peculiar to the nation. It is named fong-eou, which signifies wind and water. By this they mean the lucky or unlucky situation of a house, burying-place, &c. If any imprudent person has built a house close to that of a Chinese, in such a manner that the angle formed by its roof flanks the wall or roof of the former house, the proprietor ever after lives in terror of utter ruin and destruction from the malignant influence of that angle. An implacable hatred instantly commences between the two families, and often gives rise to a law-suit, which furnishes matter of discussion for some of the superior tribunals. If no redress can be had at law, however, the Chinese is then reduced to the necessity of erecting, on the top of his house, an enormous image of a dragon, or some other monster, with its mouth gaping towards the angle, and, as it were, threatening to swallow it up; after which the apprehensions of the proprietor begin to subside, and tranquillity is restored to the family. In this manner the governor of Kien-chang secured himself from the influence of the church of the Jesuits, which, being built on an eminence, overlooked his palace. Not depending, however, entirely on the good offices of his tutelary dragon, he also took the wise precaution of altering his principal apartments, and raising, at the distance of 200 paces from the church, a kind of large facade three stories high. But unluckily the death of his successor was attributed to this facade; for the mandarin being attacked with a disorder in his breast, which made him spit up a white phlegm, this symptom was thought to be owing to the walls of the facade, which were very white, and which were forthwith painted black. The salutary precaution, however, happened to be taken too late; for the governor died notwithstanding the black colour of the walls.

"We should never have done (says M. Grolier), were we to relate all the superstitious ideas of the Chinese, respecting the lucky and unlucky situation of houses, the quarter which doors ought to face, and the plan
A colony of Jews was established in China about the year 206 B.C.; but they are now reduced to a small number of families at Cai-fong, the capital of the province of Honan. The Mahometans have multiplied much more than the Jews. It is above 600 years since they first entered the empire, where they have formed different establishments. At first their number was augmented only by marriages; but for some time past they have been more particularly attentive to the extending of their faith and propagating their doctrine. The principal means employed for this purpose are, to purchase a great number of children brought up in idolatry, whom their poor parents are glad to part with; and these they circumcise, and afterwards instruct in the principles of their religion. During the time of a famine which desolated the province of Chang-tong, they purchased more than 10,000 of these children; for whom, when grown up, they procured wives, built houses, and even formed whole villages of them. They are now become so numerous, that in the places where they reside they entirely exclude every inhabitant who does not believe in their prophets, and frequent a mosque.

With regard to the manners of the Chinese, they bear no resemblance to those of any other nation; and, if we may believe their historians, they are the same at this day that they were 4000 years ago. The women are condemned almost to perpetual imprisonment within the precincts of their own huts, and are never even seen even by their intended husbands before marriage. He knows nothing of her looks or person but from the account of some female relation or confident, who in such cases acts the part of match-maker; though, if imposed upon either with regard to her age or figure, he can have recourse to a divorce. The same matrons who negotiate the marriage, also determine the fine which the intended husband must pay to the parents of the bride; for in China a father does not give a dowry to his daughter; it is the husband who gives a dowry to the wife. When the day appointed for the marriage is arrived, the bride is placed in a chair or close palanquin, the key of which is committed to the hand of a trustworthy domestic, who must deliver it to none but the husband. The latter, richly dressed, waits at his gate for the arrival of the procession. As soon as it approaches the key is put into his hands; he eagerly opens the chair, and for the first time perceives his bride, or unfortunate. If he is contented with his new bride, the bride descends and enters the house, where the marriage is concluded by feasting and mer­­tain-ent as in other countries; but if the bridegroom is very much disappointed, he suddenly shuts the chair, and sends the bride home to her relations. To get rid of her in this manner, however costs a sum equal to what he originally gave in dowry to obtain her.

The Chinese women, even of the first rank, seldom quit their apartments, which is situated in the most retired part of the house, and in which they are secluded from all society but that of their domestics. The book of ceremonies requires that there should be two apartments in every house; the exterior one for the husband, the interior for the wife. They must even be separated by a wall or wooden partition, the door of which is carefully guarded; nor is the husband at liberty to enter the wife's apartment, or she to quit it, without sufficient reason. According to the same book, the prattling and loquacity of a woman are reckoned sufficient grounds for a divorce. A woman, however, cannot be divorced on any account, if she loses her parents after marriage, or if she has worn three years mourning for the loss of her husband, father, or mother.

A widow of any rank above the common, who has children, seldom enters a second time into the marriage state, though those of the ordinary rank generally do. The poorer part are not at liberty to follow their own inclination; but are sold for the behoof of the parents of the deceased. As soon as the bargain is concluded, a couple of persons bring a chair, which is guarded by a number of sturdy people. In this the widow is shut up, and thus conducted to her new husband.

"Masters (says Mr Grosier), for the most part are very desirous of promoting marriage among their slaves, whatever Mr Pau may say; who, without any foundation, has ventured boldly to assert the contrary. They have even very strong motives to induce them to encourage these marriages; the children produced by them are filled their flames; and besides their becoming new property to them, the fathers and mothers are thus more strongly attached to their service."
is punished with death: and the same punishment is
generally inflicted on the person who debauches a
young woman.

From the accounts we have of the education of chil-
dren in China, one might be apt to conclude, that, in-
stead of being the ignorant superstitious race already
described, they ought to be the most intelligent people
in the world. The book of ceremonies directs the edu-
cation of a child to commence as soon as it is born,
and describes exactly the qualities which its nurse
ought to have. She must speak little, adhere strictly
to truth, have a mild temper, behave with affability to
her equals, and with respect to her superiors. The child
is taught to use the right hand as soon as it can put its
hand to its mouth, and then it is weaned. At six
years of age, if a male, he is taught the numbers most
in use, and made acquainted with the names of the
principal parts of the world; at seven, he is separ-
ated from his father, and no longer allowed to eat with
him, nor to sit down in his presence; at eight, he
is instructed in the rules of good breeding and polite-
ess; at nine, he studies the calendar; at ten he is sent
to a public school, where he learns to read, write, and
count accounts; from ten to fifteen he is taught music,
and every thing that he can do; he is sent to a school,
where he is taught to do sums, and to read and write.
He is instructed in the principles of the world; at
eleven, he is taught geography, and the history of
the different empires; at twelve, he is taught to
read the Chinefe authors with

Another method of initiating children into the
principles of knowledge in this empire is, by selecting
a number of characters expressive of the most common
objects, engraving or painting them separately on
some kind of substance, and, under the thing represented,
putting the name, which points out to the children the
meaning of the word.

As the Chinefe have no proper alphabet, they re-
prent almost every thing by different characters. The
labour of their youth, therefore, is intolerable; being
obliged to study many thousand characters, each of
which has a distinct and proper siglitification. Some
idea of their difficulties may be obtained from what we
are told by F. Martini, who affures us, that he was un-
der the necessitv of learning 60,000 different charac-
ters before he could read the Chinefe authors with tol-
able ease.

The book first put into the hands of the Chinefe
children is an abridgment, which points out what is
a child ought to learn, and the manner in which he
should be taught. This volume is a collection of short
sentences, consisting of three or four verses each, all of
which rhyme; and they are obliged to give an account
in the evening of what they have learned in the day.

After this elementary treatise, they put into their hands
the four books which contain the doctrines of Confu-
cius and Mencius. The sense and meaning of the
work is never explained to them until they have got by
heart all the characters, that is to say, the words in the
book: a method no doubt inconceivably disgusting,
and calculated utterly to destroy the genius of a boy,
if he has any. While they are getting these charac-
ters by heart, indeed, they are likewise employed in
learning to form them with a pencil. For this pur-
pose they are furnished with large leaves of paper, on
which are written or printed with red ink very big.
characters; and all they are required to do is to cover
those red characters with black ink, and to follow ex-
actly their shape and figure: which infensibly accustoms
them to form the different strokes. After this they are
made to trace other characters, placed under the pa-
per on which they write. These are black, and much
smaller than the other. It is a great advantage to the
Chinefe literati to be able to paint characters well; and
on this account they bestowed great pains in forming the
hands of young people. This is of the utmost conve-
fersory to literary students in the examinations which
they are obliged to undergo before they can be ad-
mitted to the first degree. A student, in order to secure
his promotion, is obliged to go through a long series of
examinations, which are headed, viz., that "a candidate
for degrees having,

After the scholar has made himself master of the char-
acters, he is then allowed to compose; but the sub-
ject of his composition is pointed out to him only by
one word. Competitions are likewise established in
China, but most of them are of a private nature.
Twenty or thirty families, who are all of the same
name, and who consequently have only one hall for the
names of their ancestors, agree among themselves to
send their children twice a month to this hall in order
to compose. Each head of a family in turn gives the
subject of this literary contest, and adjudges the prize;
but this costs him a dinner, which he must cause to be
carried to the hall of competition. A fine of about
fifteen pounds is imposed on the parent of each scholar who
appears himself from this exercise.

Besides these private competitions, every student is
obliged to compete at least twice a-year under the in-
spection of an inferior mandarin of letters, styled His-
kan. It frequently happens also, that the mandarins of
letters order these students to be brought before
them, to examine the progress they have made in their
studies, to excite a spirit of emulation among them, and
make them give such application as may qualify them
for any employment in the state. Even the governors
of cities do not think it below their dignity to take
these care upon themselves; ordering all those students
who reside near them to appear before their tribunal:

The author of the best composition is honoured with a prize, and the governor treats all the
candidates on the day of competition at his own ex-
 pense. In every city, town, and village in China,
there are schoolmasters who teach such sciences as
are known in that country. Parents puffed of a certain
fortune provide masters for their children, to attend
and instruct them, to form their minds to virtue, and
to initiate them in the rules of good breeding and the
acquiesced ceremonies, as well as to make them ac-
quainted.
Dres. The education of the Chinese women is confined to giving them a taste for polite, and ACCOMPLISHING them to beauty and elegance; and, if their parents are rich, they are likewise instructed in such accomplishments as may render them agreeable to the other sex.

There is little distinction in China between the ordinary dres of men and women. Rank and dignity are distinguished by certain accouterments: and the person would be severely censured who should presume to assume them without being properly authorized. The dres in general consists of a long veil which reaches to the ground. One part of this veil, viz. that on the left side, folds over the other, and is fastened to the right by four or five small gold or silver buttons, placed at a little distance from one another. The sleeves are wide towards the shoulder, growing narrower as they approach the wrist, where they terminate in the form of a horse shoe, covering the hands entirely, and leaving nothing but the ends of the fingers to be seen. Round their middle they wear a large griddle of silk, the ends of which hang down to their knees. From this griddle is suspended a sheet, containing a knife and two of those small flicks which they use as forks. Below this robe they wear a pair of drawers, in summer made of linen, and in winter of satin lined with fur, sometimes of cotton, and in some of the northern provinces of skin. These are sometimes covered with another pair of white safeties. Their shirts are always very short and wide, of different kinds of cloth, according to the season. Under these they wear a silk net to prevent it from adhering to the skin. In warm weather they have their necks always bare; when it is cold, they wear a collar made of silk, 'fable, or fox's skin, joined to their robe, which in winter is trimmed with sheep's skin, or quilted with silk and cotton.

That of people of quality is entirely lined with beautiful fable skins brought from Tartary, or with the finest fox's skin, trimmed with fable; and in the spring it is lined with ermine. Above their robe they wear also a kind of fur-tout with wide sleeves, but very short, which is lined in the same manner. The emperor and princes of the blood only have a right to wear yellow; certain mandarins have liberty to wear satin of a red ground, but only upon days of ceremony; in general they are clothed in black, blue, or violet. The common people are allowed to wear no other colours but blue or black; and their dres is always composed of plain cotton cloth.

Formerly the Chinese were at great pains to preserve their hair; but the Tartars, who subdued them, compelled them to cut off the greater part of it, and to alter the form of their clothes after the Tartar fashion. This revolution in dres was not effected without bloodshed, though the conqueror at the same time adopted in other respects the laws, manners, and customs of the conquered people. Thus the Chinese are painted as if bald, but they are not so naturally; that small portion of hair which they preserve behind, or on the tops of their heads, is all that is now allowed them.

This they wear very long, and plait like a tail. In summer they wear a kind of cap shaped like an inverted cone, lined with satin, and covered with ratan or osier very prettily wrought. The top terminates in a point, to which they fix a tuft of red hair, which spreads over it, and covers it to the brims. This hair grows between the legs of a kind of cow, and is capable of taking any colour, especially a deep red. This ornament is much used, and any person who chooses may wear it.

The mandarins and literati wear a cap of the same form as the foregoing, only it is lined with red satin, and covered on the outside with white. A large tuft of the finest red silk is fixed over it, which is suffered to hang down or wave with the wind. People of distinction generally use the common cap when they mount on horsecback or during bad weather; being better calculated to keep off rain, and shelter those who wear it from the rays of the sun. In winter they have another cap bordered with sable, ermine, or fox's skin, and ornamented with a tuft of silk like the former. In these fur-trimmings they are very curious, sometimes expending 40 or 50 ounces of silver upon them.

The Chinese people of rank never go abroad without boots made of satin, or some other silk, and sometimes of cotton, but always dyed. They have neither heel nor top, and are made to fit the foot with the greatest exactness. When they travel on horsecback, however, they have others made of the skin of a cow or horse made very pliable. Their boot-stockings are of silk stuff, quilted and lined with cotton, reaching above the top of their boot, and ornamented with a border of velvet or cloth. In summer they wear a cooler kind, and in their houses a sort of slippers made of silk stuff. The common people are contented with black slippers made of cotton stuff. The fan is also a necessary appendage of the Chinese dres, and is reckoned equally necessary with the boots.

The dres of the women consists of a long robe quite close at top, and long enough to cover even their toes, with sleeves so long that they would hang down upon the ground, did they not take care to tuck them up; but their hands are seldom seen. The colour of their dress is entirely arbitrary, but black and violet are generally chosen by those advanced in life. The young ladies, like those of Europe, make use of paint to give a bloom to their complexions; but this, though not the same with the kind used in Europe, agrees with it in the effect of soon wrinkling the skin. Their general head-dres consists in arranging their hair in several curls, among which are interperforated small tufts of gold or silver flowers. According to D. Halde, some of them ornament their heads with the image of a fabulous bird, concerning which many stories are told. This is made of copper or silver gilt, its wings extended and lying pretty close to the head-dres, embracing the upper part of their temples, while the long spreading tail forms a kind of plume on the top of the head. Its body is directly over the head, and the neck and bill hang down, the former being joined to the body by a concealed hinge, in order that it may play freely, and move about on the least motion of the head. The whole bird adheres to the head by means of the claws, which are fixed in the hair.

Ladies of quality sometimes wear several of these birds made up into a single ornament, the workmanship of which is very expensive. Young ladies wear also a
Throughout China of confining the feet of female infants in such a manner that they are never allowed to grow to near their full size. The smallness of their feet is accounted such a valuable beauty, that the Chinese women never think they can pay too dear for it. As soon therefore as a female infant is born, the nurse wraps up its feet in very tight bandages; and this torture must be endured until their feet have ceased to grow. So prevalent is the force of custom, however, that as the child grows up the voluntarily submits to new tortures in order to accommodate the purpose more effectually. Thus the Chinese women are deprived almost entirely of the use of their feet; and are scarce able to walk, in the most awkward hobbling manner, for the shortest space. The shoe of a full grown Chinese woman will frequently not exceed six inches.

The Chinese use white as the colour proper for mourning; and though a son cannot wear this while his father and mother are alive, he can use it no other for three years after their death; and ever afterwards his clothes must be of one colour. The law has forbidden the use of satins and fine cloths to children; and has even prescribed the time when they are first to wear a cap. This is put upon their heads by the master of ceremonies himself, who addresses them in the following manner: "Consider that you now receive the drest of those who have attained to maturity, and that you cease to be children; renounce therefore all childish thoughts and inclinations, assume a grave and serious deportment, apply with resolution to the study of virtue and wisdom, and endeavour to merit a long and happy life." "This ceremony (says M. Grouard), which may appear trifling, is attended with the happiest effects. The Chinese give a kind of importance to every thing which can inspire youth with a taste for morality and a love of good order. It might be useful to mankind at every fixed epoch of their lives, to remind them of those new duties imposed by each successive change; but, by uniting the solemnity of a public ceremony to this instruction, it will make a deeper impression, and remain much longer imprinted on their memories."

Nothing can appear more irksome to an European than the multitude of ceremonies used on all occasions by the Chinese. An invitation to an entertainment is not fapposed to be given with sincerity until it has been renewed three or four times in writing. A card is sent on the evening before the entertainment, another on the morning of the appointed day, and a third when everything is prepared and the guests ready to sit down to the table. The master of the house always introduces his guests into the hall, where he формуles them one after another. He then orders wine to be brought him in a small cup made of silvcr, porcelain, or precious wood, and placed upon a small varnished falver. He lays hold of it with both hands, makes a bow to all the surrounding guests, and advances towards the fore-part of the hall, which generally looks into a large court. He there raises his eyes and the cup towards heaven; after which he pours the wine on the ground. He afterwards pours some wine into a silver or porcelain cup, makes a bow to the most considerable person in company, and then goes to place the cup on the table before him; for in China every guest has a table for himself. The person for whom he intends this honour, however, generally saves him the trouble of placing the cup; calls for wine in his turn, and offers to place the cup on the master's table, who endeavours to prevent him; with a thousand apologies and compliments according to the rules of Chinese politeness. A superior domestick conducts the principal guest to an elbow chair covered with rich flowered silk, where the stranger again begins his compliments, and begs to be excused from sitting in such an honourable seat, which nevertheless he accepts of; and all the rest of the guests do the same, otherwise the ceremonial would be gone through with each of them. The entertainment is concluded by some theatrical representations, accompanied with the music of the country; which, however, would give but little pleasure to an European. Besides the guests, a certain number of people are admitted into the court in order to behold these theatrical representations; and even the women are allowed to view them through a wicket, contrived to that they may behold them without being seen themselves.

The entertainments of the Chinese are begun, not by eating, but by drinking; and the liquor they drink must always be pure wine. The intendant, or 'maître de hotel,' falling down on one knee, first invites the guests to take a glass; on which each of them lays hold, with both hands, of that which is placed before him, raising it as high as his forehead, then bringing it lower down than the table, and at last putting it to his mouth; they all drink together, and very slowly, taking three or four draughts. While they are drinking, the dishes on each of the tables are removed, and others brought in. Each of the guests has twenty-four feet before him in succession; all of them fat, and in the form of ragouts. They never use knives in their repasts; and two small-pointed sticks, ornamented with ivory or silver, serve them instead of forks. They never begin to eat, however, until they are invited by the 'maître de hotel'; and the same ceremony must be gone through every time they are going to take a cup of wine or begin to a new dish. Towards the middle of the entertainment the soup is brought in, accompanied with small loaves or meat-pies. These they take up with their small sticks, steep them in the soup, and eat them without waiting for any signal or being obliged to keep time with the rest of the guests. The entertainment, however, continues in other respects with the utmost formality until tea is brought in, after which they retire from table and amuse themselves in another hall, or in the garden for a short time, until the desert be brought in: This, like the entertainment itself, consists of 24 dishes, which are made up of sweetmeats, fruits differently prepared, hams and salted ducks which have been backed or dried in the sun, with flesh and other kinds of fish. The same ceremonies which preceded the repast are now renewed,
The entertainments begin towards evening, and never end till midnight. A small sum of money is generally given to the domestics: when every one of the guests goes home in a chair preceded by several servants, who carry large lanterns of oil, and on which are inscribed the quality, and sometimes the name, of the master. Without such an attendance they would be taken up by the guard; and the day following they never fail to return a card of thanks to the officer.

Their method of drinking tea is not like that of other nations. A small quantity of bohea, sufficient to tinge the water and render it palatable (for they drink no green), is taken in the morning, and thrown into a vessel adapted to the number in family. This stands till milk warms; in which state it is kept the whole day, and a cup drank now and then without sugar or milk, in order to exhilarate the spirits when exhausted by fatigue: and if a stranger call by accident, or a visitor by appointment, the first thing presented, after the usual ceremonies of meeting, is a very small pipe filled with tobacco of their own growth and a cup; the tea already mentioned, or of some freth made of better quality, together with sweetmeats, &c. Tea is the daily beverage in China, and is drunk by all ranks of people.

Some change has been made in the ceremonial of the Chinese by the Tartar conquest, and some new dishes also introduced by the same means; and here M. Grolier observes, that the Tartars are much better cooks than the Chinese. All their dishes are highly seasoned; and by a variation in the proportions of their spiceries, they are able to form a variety of dishes out of the same materials. None of their viands, however, are more esteemed than flags finews, and the nefs of a particular species of birds, which have the property of giving a most agreeable relish to whatever is mixed with them. Other dishes are introduced at these repasts, which would be disagreeable with us; such as the flesh of wild horses, the paws of a bear, and the feet of several wild animals. The greater part of these provisions are brought preferved in salt from Siam, Camboy, and Tartary.

The wines of China have no resemblance to ours either in taste or quality, being procured from rice and not from the vine. A particular kind of rice is employed for making them, and the grain is steeped for 20 or 30 days in water, into which ingredients of a different nature are successively thrown: they afterwards boil it; and as soon as it becomes dissolved by the heat, it immediately ferments, and throws up a vaporous foam not unlike new wine. A very pure liquor is found under this scum, which is drawn off and put into vessels well glazed; from the remaining yses an inflammable spirit is made, little inferior, and sometimes even superior to the European. Another kind of wine is used by the Chinese, or rather Tartars, called lamb-wine. It is very strong, and has a disagreeable smell; and the same may be believed of a kind of spirit distilled from the flesh of sheep; though this last is sometimes used by the emperors.

These entertainments exceed the bounds of ordinary repasts; the Chinese being naturally sober, and those in easy circumstances living chiefly on pork, for which reason a great number of hogs are bred in the country. Their flesh is much easier of digestion, and more agreeable to the taste, than that of Europe. The Chinese cups are in high estimation. The common people live very poorly; being satisfied, in time of scarcity, with the flesh of dogs, horses, cats, and rats, which last are sold publicly in the streets.

There are several public festivals annually celebrated in China. One is that already mentioned, in which the emperor tills the ground with his own hands. This is also celebrated on the same day throughout the empire. In the morning the governor of every city comes forth from his palace crowned with flowers, and, after his chair amidst the noise of different instruments which precede it; a great number of people attending, as is usual on such occasions. The chair is surrounded by litters covered with silk carpets, on which are represented either some illustrious persons who have supported and encouraged agriculture, or some historical painting on the same subject. The streets are hung with carpets, triumphal arches are erected at certain distances, lanterns everywhere displayed, and all the houses illuminated. During the ceremony a figure resembling a cow, made of baked earth, with gilt horns, is carried in procession, and of such enormous magnitude that 40 men are scarce sufficient to support it. A child follows with one foot naked and the other shod, who is called the spirit of labour and diligence, and keeps continually beating the image with a rod to make it advance. Labourers, with their implements of husbandry, march behind; and the procession is closed by a number of comedians and people in masks. The governor advances towards the eastern gate, and returns in the same manner. The cow is then stripped of its ornaments, a prodigious number of earthen calves taken from its belly and distributed among the people; after which the large figure is broken in pieces and distributed in the same manner. The ceremony is ended by an oration in praise of agriculture, in which the governor endeavours to excite his hearers to the practice.

Other two festivals are celebrated in China with still more magnificence than that above described. One of them is at the commencement of the year; the other is called the feast of lanterns. During the celebration the former, all business, whether private or public, is suspended, the tribunals are shut, the posts stopped, presents are given and received, and visits paid. All the family assemble in the evening, and partake of a feast to which no stranger is admitted; though they become a little more sociable on the following day. The feast of lanterns ought to take place on the 15th day of the first month, but usually commences on the evening of the 14th, and does not end till that of the 16th. At that time every city and village, the shores of the sea, and the banks of all the rivers, are hung with lanterns of various shapes and sizes; some of them being seen in the courts and windows of the poorest houses. No expense is spared on this occasion; and some of the rich people will lay out eight or nine pounds sterling on one lantern. Some of these are very large composed of fix wooden frames either neatly painted or gilt, and filled up with pieces of fine transparent silk, upon which are painted flowers, animals, and human figures; others are blue, and made of a transparent kind of horn. Several lamps, and a great
great number of wax candles, are placed in the inside: to the corners of each are fixed fire-creapers of silk and satin of different colours, with a curious piece of carved work on the top. They are likewise acquainted with our magic lantern, which they sometimes introduce in this festival. Besides this they have the art of forming a snake 60 or 80 feet in length, filled with lights from one end to the other; which they cause twist itself into different forms, and move about as if it was a real serpent. During the same festival all the varieties of the Chinfe fire-works, so justly admired, and which, some time ago at least, surpassed everything of the kind that could be done in Europe, are exhibited.

Every public ceremony in China is carefully rendered as striking as possible. A viceroy never quits his palace but with a royal train, drested in his robes of ceremony, and carried in a chair elegantly gilt, which is borne upon the shoulders of eight domesties; two drummers marching before the guards, and bearing upon copper basons to give notice of his approach. Eight other attendants carry standards of wood varnished, upon which are incribed in large characters all his titles of honour. After these come 14 flags with the symbols of his office; such as the dragon, tyger, phoenix, flying tortoise, &c. Six officers follow, each bearing a piece of board in shape like a large towel, on which are written in large golden characters the qualities of the mandarin himself: two others carry, the one a large umbrella of yellow silk, and the other the cover in which the umbrella is kept. The first guards are preceded by two archers on horseback; the latter are followed by others armed with a kind of weapons composed of hooked blades, fixed perpendicularly to long poles ornamented with four tufts of silk, placed at a small distance above one another. Behind these are two other files of soldiers, some of whom carry large maces with long handles; others iron maces in the shape of a snake; others are armed with huge hammers; while those behind them carry long battle-axes in the form of a crescent: others follow, who have battle-axes of another kind; and behind these are some with the hooked weapons already described.

Behind these come soldiers armed with triple-pointed spears, arrows, or battle-axes; having in front two men who carry a kind of box containing the viceroy's deal. Then come two other drummers to give notice of his approach. Two officers follow, having on their heads felt-hats, adorned with plumes of feathers, and each armed with a cane to recommend regularity and good order to the surrounding multitude. Two others bear maces in the form of gilt dragons. These again are followed by a number of magistrates and officers of justice; some of whom carry whips or flat sticks, while others have chains, hangers, and Silk fars. Two standard-bearers and a captain command this company, which immediately precedes the governor. His chair is surrounded by pages and footmen, and an officer attends him who carries a large fan in form of a crescent: he is followed by several guards differently armed, together with ensigns and other officers, who are also followed by a great number of domestics all on horseback, carrying various necessaries for the use of the mandarin. If he marches in the night-time, instead of flambeaus, as are customary in Europe, large lanthorns, exceedingly pretty, are carried before him:

The emperor marches with still more magnificence, in proportion to his superior quality. The trumpets used in his procession are about three feet long, eight inches in diameter at the lower extremity, and pretty much resembling a bell in shape: their sound is peculiarly adapted to that of the drums. His cavalcade is closed by 2000 mandarins of letters and as many of arms. Sometimes the great mandarins, as well as the emperor, travel in barks. Their attendance is then somewhat different, but the magnificence almost the same. The honours paid to a viceroy who has governed a province with equity are exceedingly great on his departure from it. He has scarcely left the capital of the province when he finds on the highway, for the space of two or three leagues, tables ranged at certain distances, each of which is surrounded with a long piece of silk that hangs down to the earth. On these wax candles are placed even in the open day; perfumes are burnt upon them; and they are loaded with a profusion of victuals and various kinds of fruits, while tea and wine are prepared for him on others. The people throw themselves on their knees as he passes, and bow their heads even to the earth; some shed tears, or pretend to do so; some present him wine and sweet meats; others frequently pull off their boots and give him new ones. These boots, which he has perhaps used only for a moment, are considered as a valuable monument: these first taken are preserved in a cage over the gate of the city; the rest are carefully kept by his friends.

Hitherto our author, M. Grober, has seemed inclined to give a favourable idea of the Chinese, and to cause us look upon them as many degrees superior to ourselves in the practice of virtue and morality; but when he comes to give an account of their dealings in trade, he is then obliged to confess that they are as dishonest and knavish a race as any that exist. "The most frequented fairs of Europe (says he) afford but a faint idea of that immense number of buyers and sellers with which the large cities of China are continually crowded. We may almost say, that the one half are employed in over-reaching the other. It is, above all, against strangers that the Chinese merchants exercise, without any sense of shame, their insatiable rapacity. Of this F. du Halde gives a striking example, which might be supported by many others: The captain of an English vessel bargained with a Chinese merchant at Canton for several bales of silk, which the latter was to provide against a certain time. When they were ready, the captain went with his interpreter to the house of the Chinife merchant to examine whether they were found in good condition. On opening the first bale, he found it according to his wish, but all the rest were damaged and good for nothing. The captain on this fell into a great passion, and reproached the merchant in the severest terms for his dishonesty. The Chinife, after having heard him for some time with great coolness, replied, 'Blame, Sir, your knave of an interpreter: he assured me that you would not inspect the bales.' "

"The lower classes of people are, above all, very dexterous..."

CHI

China. terous in counterfeiting and adulterating every thing they fell. Sometimes you think you have bought a capon, and you receive nothing but skin; all the rest has been scooped out, and the place so ingeniously filled, that the deception cannot be discovered till the moment you begin to eat it. The counterfeit hams of China have been often mentioned. They are made of a piece of wood cut in the form of a ham, and coated over with a certain kind of earth which is covered with hog's skin. The whole is so curiously painted and prepared, that a knife is necessary to detect the fraud.

Mr Oktav, that having one day observed a blind man carrying about for sale some of those trees called by the Chinese Fe-kei, he purchased one, which to appearance had fine red and white flowers; but in a closer examination, he found that the flowers were taken from another tree, and that one calyx was so neatly fitted into the other, with nails made of bamboo, that he should scarcely have discovered the deceit, had not the flowers begun to wither. The tree itself had buds, but not one open flower.

"The robbers in China signalize themselves also by their dexterity and ingenuity, which they display in their profession. They seldom have recourse to acts of violence, but introduce themselves into a house either privately or by forming some connection with the family. It is as difficult in China to avoid robbery as it is to apprehend the criminal in the fact. If we are delirious of finding among the Chinese open eyes of temper, benevolence, friendship, and, lastly, virtue, we shall not seek for it in cities, but in the bosom of the country, among that class of men who have devoted themselves to labour and agriculture. A Chinese rustic often discovers moral qualities which would add a lustre to the character of men of the most exalted rank. It appears that rural life naturally inspires sentiments of benevolence; by continually receiving the gifts of nature, the mind is enlarged, and men are infensibly accustomed to diffuse them to those around them."

The internal commerce of China is much greater than that of all Europe; but its foreign trade is by no means equal to that of any of the grand European powers. Its internal commerce is greatly facilitated by the vast number of canals and rivers which intersect the country, among that class of men who have devoted themselves to labour and agriculture. A Chinese rustic often discovers moral qualities which would add a lustre to the character of men of the most exalted rank. It appears that rural life naturally inspires sentiments of benevolence; by continually receiving the gifts of nature, the mind is enlarged, and men are infensibly accustomed to diffuse them to those around them."

The commercial articles of China are exchanged for exchange which they procure at Cambaya or Siam, produces them cent. per cent. Their trade with the Moluccas brings only about 50 per cent. Their profit is more considerable about Batavia, and the Dutch spare no pains to invite them to traffic at their settlement. The Chinese traders go also, tho' not very frequently, to Acheen, Malacca, Bantam, Patan and Lucca, belonging to Siam and Cochinchina; from whence they bring gold and tin, together with some objects of luxury for the table. A great obstacle to the foreign commerce of the Chinese is their indifference about marine affairs, and the bad construction of their vessels. This they themselves acknowledge: but say, that any attempt to remove it would be derogating from the laws, and subverting the constitution of the empire.

The burying-places in China are always situated at a small distance from a city or town, and generally under some edifice, having pines or cypress trees usually planted around them. The form of the tombs is various, according to the different provinces, and the situation of those for whom they are intended. The coffins of the poor are placed under a shade covered with thatch, or inclosed in a small building of brick in the form of a tomb. The tombs of the rich are shaped like a horse-shoe, well whitened, and finished with great taste; but those of the mandarins and people of quality are much more magnificent and elegant. A vault is first constructed, in which the coffin is shut up; over this vault is raised a pyramid of earth well beat together, about 12 feet in height and 10 in diameter. A layer of lime and sand laid over this earth makes a kind of plaster, which renders the whole very durable and solid; various kinds of trees being planted around it in regular order. Before it is placed a large and long table of white marble, on the middle of which are set a cenotaph accompanied with two vases, and the same number of candles, with a profusion of workmanship. Besides this, a great number of figures, representing officers, courtiers, soldiers, saddled horses, camels, lions, tortoises, &c. are ranged round the tomb in different rows; which, F. du Halde assures us, produce a very striking effect.

When a Chinese dies in a province in which he was born, his children have a right, in their indigent state, to transport the body to the burying place of their ancestors. A son who should be wanting in this respect, would be disgraced, and his name never placed in the hall of his ancestors. This is a vault built, as common to all the branches of the same family; and to which they all repair at a certain season of the year. Sometimes they amount to seven or eight thousand persons, of whose fortune, dignity, and rank in society, are all very different; but there no distinction of rank is known: age only gives precedence, and the oldest always takes place at all the rest, though he should be the poorest in the company. When building, the Chinese do not set a table fet against the wall, upon which is generally seen the image of one of their ancestors, who has filled some office of distinction in the empire with honour to himself, or who has been rendered illustrious by his talents and abilities. Sometimes it only contains the names of men, women, and children belonging to the family inscribed upon tablets, together with their age, the day of their death, and the dignities they enjoyed at that time. These tablets are ranged in two rows upon steps, and are only about a foot high each. In the spring, and sometimes in the autumn, the relations of the deceased repair to this hall, where the only privilege enjoyed by the richest is that of preparing an entertainment, and treating the whole family at their own expenses: but they never allow themselves to taste a bit of any thing until an offering has been first made to their ancestors. This does not, however, exclude them from visiting the real tomb of their ancestors once or twice a year, generally in the month of April. At this time they pluck the weeds and bushes from around the tomb, renew their expressions of
of grief, and conclude by placing upon it wine and provisions, which serve to dine their affitants.

The funeral ceremonies are considered by the Chinese as the most important of any. A few moments after a person has expired, he is dressed out in his richest attire, and adorned with every badge of his dignity; after which he is placed in the coffin. The preparation of a coffin, in which his body may be included after death, is one of the chief objects of attention to a Chinese during his life, and great expense is often thrown out upon it; inasmuch that the poor will give all they are worth, and the rich expend a thousand crowns, nay, a thousand times the coffin, when purchased with all this labour and expense. The coffin is deposited in a tomb appropriated for it, not far from which there are tables arranged in different halls, and on which the affitants are entertained with great splendour. The entertainment is sometimes followed by fresh marks of homage to the corpse; but these are often changed into thanks to the eldest son, who, however, answers only by signs. But if the deceased was a grandee of the empire, a certain number of his relations never leave the tomb for a month or two. There they reside in apartments strictly provided for them, and every day renew their marks of grief in company with the children of the deceased. The magnificence of these funeral ceremonies is proportioned to the wealth or dignity of the deceased. That of one of the brothers of the emperor was attended by 16,000 people, each of whom had a particular office assigned him relating to the ceremony.

The manner of interment is as follows: First they sprinkle some lime in the bottom of the coffin; then they lay the body in it, taking care to place the head on a pillow, and to add a great deal of cotton that it may remain more steady, and be prevented from shaking. In this manner the body remains exposed seven days; but the time may be reduced to three, if any weighty reason makes it necessary; and, during this interval, all the relations and friends, who are purposefully invited, come and pay their respects to the deceased, the nearest relations remaining in the houfe. The coffin is exposed in the hall of ceremony, which is then hung with white, but some pieces of black or violet coloured silk are here and there interpersed, as well as some other ornaments of mourning. Before the coffin is placed a table, on which stands the image of the deceased, or a carved ornament inscribed with his name: and these are always accompanied with flowers, perfumes, and lighted wax candles.

In the mean time those who enter the hall are accustomed to salute the deceased as if he were still in life. They prostrate themselves before the table, and knock their foreheads severally against the earth; after which they place on the table some perfumes and wax candles provided for the purpose. The fublation which they have made to the deceased is returned by the eldest son accompanied by his brothers. The latter come forth from behind a curtain, which hangs on one side of the coffin, creeping along the ground until they reach the spot where those fand whom they are going to salute; after which, without rising up, they return to the place from whence they came. The women are also concealed behind the same curtain, from whence they every now and then send forth dillmal cries.

After a number of ceremonies and invitations, the funeral procession at last commences. A troop of men march in a file, carrying different figures made of paste-board, and representing lions, tigers, horses, &c. Others follow, marching in two files; some of which carry standards, some flags or censers filled with perfumes; while melancholy and plaintive airs are played by others on different musical instruments. These musicians immediately precede the coffin, which is covered with a canopy, in form of a dome, of violet-coloured silk: its four corners are ornamented with tufts of white silk very neatly embroidered, and covered at the top with net-work. The coffin is placed on the bottom of this machine, and is carried by 64 men. The eldest son, clothed in a frock of canvas, having his body bent and leaning on a staff, follows near the coffin; and behind him his brothers and nephews, but none of them clothed in canvas. Then come the relations and friends, all clad in mourning, and followed by a great number of chairs covered with white stuff, which contain the wives and female slaves of the deceased. These make great show of sorrow by their doleful cries; but M. Grosier observes, that in spite of all they can do, the lamentations of the Chinese are so methodical, that an European would be apt to conclude that they were the effects of art rather than the natural effusions of a mind agitated and oppressed with grief. When they arrive at the burying-place, the coffin is deposited in a tomb appropriated for it, not far from which there are tables arranged in different halls, and on which the affitants are entertained with great splendour. The entertainment is sometimes followed by fresh marks of homage to the corpse; but these are often changed into thanks to the eldest son, who, however, answers only by signs. But if the deceased was a grandee of the empire, a certain number of his relations never leave the tomb for a month or two. There they reside in apartments strictly provided for them, and every day renew their marks of grief in company with the children of the deceased. The magnificence of these funeral ceremonies is proportioned to the wealth or dignity of the deceased. That of one of the brothers of the emperor was attended by 16,000 people, each of whom had a particular office assigned him relating to the ceremony.

Mourning continues in China for three years; and during all this time they are obliged to abstain from the use of flesh and wine; nor can they affift at any entertainment of ceremony, or attend any public assembly. At first they are not even permitted to go abroad; and when they do so, they are carried in a chair covered with a white cloth. Sometimes the filial piety of the Chinese is carried to such a length, that they preserve the bodies of their deceased fathers in their houses for three or four years; and those who do so impose also upon themselves a great number of other duties, using no other seat during the day but a stool covered with white serge, and no other bed but a plain mat made of reeds, which is placed near the coffin.

According to M. Grosier, the only diversions of the Chinese are those of hunting and fishing, dancing not being practised, and gaming forbidden by law. Fishing is considered by them rather as an object of commerce and industry than amusement. They catch fish by various methods; using nets in their great fisheries, but lines in the private. In certain provinces also they use a certain kind of bird, whose plumage greatly resembles that of a raven, but with a much longer bill, very sharp and hooked. This method of fishing is practised in boats, of which great numbers may be seen on the river about fun-rising, with the fishing-birds perched on their prows. These birds are taught to catch fish almost in the same manner that dogs pursue game. The fishermen, after making several turns with their boats, beat the water strongly with one of their oars: This serves as a signal to the birds, who instantly plunge into the water, and diving, swallow as many fish as they can, and, when full, swim to their boats, which are kept by the fishermen, who take them aboard with their catch.
small fish as they can, repairing immediately afterwards to the boat, and carrying a large one by the middle in their bill. The small ones are prevented from falling into the flounder by a ring placed on purpose to confine its gullet: and thus the fisherman by stroking its neck with the head downwards, makes the bird dig-gorge all those fish it has swallowed. When they have done fishing, the rings are taken off, and the birds allowed to feed. When the fish happens to be too large for a single bird, the others have facility enough to afflit it; one taking it by the tail, another by the head, &c. and thus they transport it to their matter.

Another method of fishing, practised only in China, is as follows: They nail a board, about two feet in breadth, which is covered with a white flining kind of varnish, upon the edges of a long narrow boat, from one end to the other. This board is placed in such a manner as to slope almost imperceptibly to the water. It is used only in the night-time, and is always turned towards the moon, that the reflection of light from the luminary may increase the splendor of the varnish. The fish, in sporting, often mistake this varnished board for water; and endeavours to throw themselves into it, fall into the boat.

The soldiers have a particular method of fishing with a bow and an arrow; the latter of which is fixed to a bow by a string, both to prevent it from being lost, and to enable them to draw out the fish which the arrow has pierced; others make use of tridents to catch large fish which are sometimes found in the mud.

Besides these diversions, the Chinafes have some strolling players, but no regular theatres; they have wise musicians and singers, but no operas, or indeed any public spectacle worthy of notice.

The language of the Chinafes is not only very ancient, but, in M. Grofier's opinion, is still spoken as in the most early ages without variation. His reason for this opinion are, 1. We do not perceive in history, nor even in the most fabulous traditions, a single fact tending to occasion any doubt of the language spoken by the ancient Chinafes, being different from that used at present. 2. China has never changed its inhabitants; and if revolutions have occasioned any mixture of new languages, it appears that the ancient language has always been predominant, and that the new settlers have learned and spoken it, as the Marchew Tartars after their conquest. 3. The most intelligent and discerning of the literati agree, that the first chapters of the Chow-king were written under the reign of Yao 2300 years before Christ; and in these, several speeches of the first emperors are related word for word; and it is not probable that the language of these princes was different from that of the historian. 4. A compliment paid to Yao by one of his subjects, with the answer of that prince, are still preferred, as well as two fongs composed under the same reign. 5. The most ancient inscriptions in China are all in the language spoken throughout the empire at this day. 7. The Chinafes have borrowed nothing from other nations; and their attachment to their own customs, and to antiquity, must undoubtedly be very unfavourable to any innovation. The language spoken by the vulgar, indeed, must have undergone some changes; but these may be accounted trivial, affecting only the pronunciation; which indeed appears to be varied in some few instances. It is certain, however, that the Chinese players act theatrical pieces which were written 1000 years ago, and that these are still understood throughout the empire.

The language of China has no alphabet; all the words which compose it consist of one syllable only, and are very few in number. These always remain the same, and continue monosyllables even when two are joined together, being united in the same manner as the French words bon and jour are united to form bon-jour. These monosyllables never form but one word. When written by a European, they begin with the letters ch, tch, f, g, or j, h, k, ng, or ts, ou; the final letters being a, e, o, or u, n, gu. The middle of Chinese words consists of vowels and consonants producing only one sound, and pronounced always as monosyllables. The whole primary words of the language are in number only about 300, though some dictionaries make them 484. The sense of these words, however, is varied by the accents and changes of the voice in pronouncing them almost ad infinitum. Two principal accents are known in China; the ping, that is even, without elevating or depressing the voice. This is divided into tfeng, eller, and toh, obscure; or rather open and mute. The accent is labialized into chong, sharp, tin, grave, and for re-entering. The tone is changed when one raises the voice at the end of a word, as when the negative no is pronounced with great emphasis and force; it is kiu. When one depresses the voice with an air of timidity. When the accent is jou, the voice is drawn back as it were into the throat; and the aspiration which takes place on certain words beginning with the letters e, e, t, s, still adds to these varieties.

By these differences in pronunciation the signification of the words is totally changed: thus the word tebu pronounced by lengthening the u, and with a clear tone of voice, signifies matter or lord: if it is pronounced in an uniform tone by lengthening the u, it signifies hog; when pronounced lightly, and with rapidity, it signifies kitchen; and when clotted with a firm and high voice depressed towards the end, it signifies hill. By the conjunction and modification of these different monosyllables, a Chinaf can express every thing he has occasion for; and it may be easily seen what variety must result from this art of multiplying words. The Chinaf language therefore has words expressive of the smallest variation of circumstance, and which cannot be expressed in the European languages without a circumlocution. Thus, instead of the five words, calf, bull, ox, heifer, cow, every time that a cow has a calf she acquires a new name in the language of this empire; and still another when she becomes barren. An ox fed for sacrifice has a particular name, which is changed when he goes to the altar. In like manner, a whole dictionary might be composed of the words that are employed to express the different parts of the emperor's palace, and those that are in a manner consecrated to it; others being employed when the palaces of princes or mandarins are spoken of. Thus the number of their characters are augmented beyond all bounds, so that the greater part of their literati spend all their lives in studying them.

In the Chinaf there are four different languages. 1. The kou-ouen, or classical language. This is not
China.

spoken at present, though it is generally believed to have been the language of the early ages. It is so
cunic, and the ideas are so crowded, that it is very
difficult to be understood; however, the literati, who
can read and understand it, are much delighted with it.

2. The K'ouen-chang is the language used in compo-
positions where a noble and elevated style is requisite.
It is never spoken, but certain sentences and compli-
mentary expressions are sometimes borrowed from it.
It approaches near to the laconic brevity and majestic
sublimity of the K'ouen, and is equally proper for every
kind of subject, excepting only the ambiguities of
metaphysics, and the formal rugged diction used in treat-
ing of the abstract sciences.

3. The K'uaan-ka is the language of the court,
of people in office, and of the literati. It admits of ly-
gynymous expressions to moderate the brevity of
monosyllables; of pronouns and relatives; prepositions,
adsverbs, and particles; to supply the want of cafes,
moods, tenses, and numbers, which have place in other
languages.

4. H'iang-tan is a kind of corrupted language, or
provincial dialect, spoken by the lower classes in China;
and of which every province, city, and almost every
village, has its own. Besides the sense of the words,
which is changed in a great variety of places, they are
so altered by diversity of pronunciation as to be almost
unintelligible.

There are five kinds of writing mentioned by the
Chinese literati; the most modern of which is a me-
thod of tracing out the characters with a pencil. This
is difficult, and requires much experience; at any rate,
it distinguishes the characters greatly, and is therefore
only used in the preference of physicians, prefaces to
books, and inscriptions of fancy. The tracing of
characters with neatness and accuracy, however, as we
have already had occasion to observe, is greatly admi-
red in China. They are often preferred to the most
elegant painting; and some will give a most exorbitant
price for a page of an old book, if it happens to be
neatly written. They pay particular attention to well-
formed characters even in the most common books; and
if any of the leaves happen to fall off, will replace
them with the greatest attention. To apply them to
any vile purpose, tread them under foot, &c. would be
reckoned an unpardonable violation of decency and
politeness; nay, it often happens, that workmen, such
as masons and joiners, dare not tear a printed leaf
of paper fixed to the wall.

Punctuation was not formerly used in China, nor are
points as yet employed in works of an elevated style,
or such as are to be presented to the emperor. Poety
is seldom any object of attention, though the taste
for it seems to be pretty general in China. Their ver-
cification has its rules, and is not less difficult than that
of other nations. Only the most harmonious, ener-
getic, and picturesque words, are to be employed, and
they must always be used in the same sense in which
they were used by the ancients. Each verse can
contain only a certain number of words; all of which must
be ranged according to the rules of quantity, and ter-
minate in rhyme. The number of verses in a joprophe
is not determined; but they must be uniform, and
present the same distribution of rhymes. The small
number of poetical expressions contained in the Chi-

ne speech has rendered it necessary to extend the po-
etical licence to a great length in this respect. The Chi-
nese poets are allowed to employ a blank verse in every
four. They are acquainted with most kinds of poetry in
the usual senses. They have fancies, ode, elegies, idylls,
elegies, epigrams, epitaphs; and even want lyrics. The
common people have also ballads and songs peculiar to
themselves. Some of the most distinguished of the
literati have even thought it of importance enough to
turn the most celebrated maxims of morality, with the
rules of civility, into verse. Their poetry is seldom
gracured by any kind of obscenity; and indeed any
such thing would be severely punished by government.
That severe attention with which every thing tending
to corrupt the morals is watched in China, prohibits
not only poems of this kind, but likewise romances of
all sorts. The police, however, permits such novels as
have an useful tendency, and in which nothing is
introduced prejudicial to found morality. Every au-
thor who writes against government is punished with
death, as well as all those who have had any hand in
the printing or distribution of his works.

The art of making paper and printing have been Chi-
inese long known among the Chinese. That kind of paper
now in use was first manufactured about 145 years be-
fore the Christian era. Before that period they used
cloth, and various kinds of silk stuff, instead of paper;
and to this day they still prefer a cushion of writing
the praiseful of the dead upon large pieces of silk, which
are suspended on ornamented coffins and carried in
funeral processions; and of ornamenting their apart-
ments with maxims and moral sentences written in the
same manner. In ages still more early, they wrote
with a kind of style upon pieces of bamboo, or even
upon plates of metal. The first paper was invented by
a mandarin. He took the bark of trees, hemp, and
old pieces of silk-stuff, boiling them together until they
were reduced to a kind of paste, of which he formed his
paper; which by degrees was brought to perfection,
and the art of whitening and giving it a lustre found
out. A great number of different substances are now
used in this empire for making paper; such as the
bamboo, reed, hemp, the bark of the plant called kau-chu,
and of the mulberry tree; hemp, the straw of wheat and rice, parchment, the cords of the
silk warp, and several other substances unknown in
Europe. In this manufacture the bark of trees and
shrubs is used, and the woody substance of the bamboo
and cotton tree, after it has been macerated and redu-
ted to a thin paste. Most of the Chinese paper, how-
ever, is attended with the disadvantage of being very
susceptible of moisture, readily attracts the dust, and
worms insensibly get into it; to prevent which inconve-
niences, it is necessary to beat the books often, and ex-
pose them to the sun. That made of cotton is the
prettiest, and most used of any. All of them, however,
are much more and smoother than ours; which is abso-
lutely necessary for their method of writing with a pen-
cil, in order that it may run with freedom, which it
could not do upon ours. It is formed into sheets of an
enormous size; so that it would be no difficult matter
to procure from the manufactories of this empire sheets
of paper 30 or 50 feet long.

The Chinese ink came originally from Corea; and it
was not until the year 900, that they hit upon the me-

Of their
poetry.

ink.
The Chineze method of printing is exceedingly different from ours; and indeed it would be in a manner impossible to have movable types for such a number of characters as their language requires. The whole work which they intend to print is therefore engraved upon blocks of wood; and their method of proceeding is as follows. They first employ an excellent writer, who transcribes the whole upon very thin paper. The engraver glues each of the leaves of the manuscript upon a piece of plank made of any hard wood; and he then traces over with a graver the strokes of the writing, carves out the characters in relief, and cuts down the intermediate part of the wood. Thus each page of a book requires a separate plank; and the excessive multiplication of these is no doubt a very great inconvenience, one chamber being scarce sufficient to preserve those employed for a single book. The advantages are, that the work is thus free from typographical errors, and the author has no occasion to correct the proofs. Thus also the booksellers in China have decided advantage over those of Europe, as they are able by this method of printing to throw off copies according to their sale, without running the risk of being ruined by too large an addition. In this method the beauty of the work depends entirely upon the skill of the writer previously employed. The engraver must be exceedingly dexterous, and imitate every stroke so exactly, that it is sometimes difficult to distinguish a printed work from one that is only written.

The method of printing in China is not by a press as in Europe, as neither their wooden planks nor their soft paper could sustain so much pressure. They first place the plank level, and then fix it in that position. The printer is provided with two brushes, and, with the hardest, daubs the plank with ink; and one daubing is sufficient for four or five leaves. After a leaf has been adjusted upon the plank, the workman takes the second brush, which is softer than the former, and of an oblong figure, and draws it gently over the ink, pressing it down a little, that it may receive the ink. The degree of pressure is to be regulated by the quantity of ink upon the plank: and in this manner one man is able to throw off almost 10,000 copies a day. The ink used for printing is different from that formerly described, and which is used in writing. The leaves, on account of the thinness of the paper, are printed only upon one side; on which account each leaf of a book is double, so that the fold stands uppermost, and the opening is towards the back, where it is stitched. Hence the Chinese books are not cut on the edges, but on the back. They are generally bound in grey pasteboard, which is very neat; and those who wish to have them more elegantly done, get the pasteboard covered with satin, flowered taffety, and sometimes with gold and silver brocade. Their books are neither gilt nor coloured on the edges like ours.

The art of manufacturing silk, according to the best Vaish authorities, was communicated by the Chinese to the city of Persians, and from them to the Greeks. The art has been known in this empire from the remotest antiquity; and the breeding of silk-worms and making of silk was one of the employments even of the empresses in very early ages.

The most beautiful silk in the whole empire is that of Tche-kiang, which is wrought by the manufactories of Nankin. From these are brought all the stuffs used by the emperor, and such as he distributes in presents to his nobility. A great number of excellent workmen are also drawn to the manufactories of Canton by the commerce with Europe and other parts of Asia. Here are manufactured ribbons, flockings, and buttons. A pair of silk flockings here cost little more than 6s. sterling.

The quantity of silk produced in China seems to be almost inexhaustible; the internal consumption alone being incredibly great, besides that which is exported in the commerce with Europe and the rest of Asia. In this empire all who possess a moderate fortune wear silk clothes; none but the lower class of people wear cotton stuffs, which are commonly dyed blue. The principal stuffs manufactured by them are plain and flowered gauzes, of which they make summer dresses, damask of all colours; stripped and black silk; napped, flowered, striped, clouded, and pinked taffeties; crapes, brocades, pluch, different kinds of velvet, and a multitude of other stuffs unknown in Europe. They make particular use of two kinds; one named tounse, a kind of satin much stronger, but, which has less lustre, than that of Europe; the other a kind of taffety, of which they make drawers and linings. It is worked dexterously, and is yet so pliable that it may be rumpled and rubbed between the hands without any crease; and even when washed like cotton-cloth, it loses very little of its lustre. They manufacture also a kind of gold brocades, but of such a slight nature, that they cannot be worn in clothes; they are fabricated by wrapping fine slips of gilt paper round the threads of silk.

Porcelain is another great branch of Chinese manufacture, and employs a vast number of workmen. The finest is made in a village called Kung-te-ching in the province of Kiang-su. Manufactories have also been erected in the provinces of Po-kien and Canton, but their produce is not esteemed, and one which the emperor caused to be erected at Peking, in order to be under his own inspection, miscarried entirely.

The Chinese divide their porcelain into several classes, according to its different degrees of fineness and beauty. The whole of the first is reserved for the use of the emperor, so that none of it ever comes into the hands of other persons, unless it happen to be cracked or otherwise damaged in such a manner as to be unworthy of being presented to the sovereign. Among that sent to the emperor, however, there is some porcelain of an
tions, viz. that in former ages the musicians could make brute animals leap at the sound of their instruments. Our author, M. Grolier, indeed, does not quote any Chinese author who affirms that the ancient music could make trees dance, or stones arrange themselves into a city; but he quotes them, alleging "that the musicians could call down superior spirits of every age from the ethereal regions; raise the manes of departed beings; inspire men with a love of virtue; and lead them to the practice of their duty." Effects of this supernatural kind are attributed to the sacred music by the inspired writers; as in the case of Saul, out of whom an evil spirit departed at the sound of David's harp; and of Elihu, who was inspired with the spirit of prophecy at the sound of a musical instrument. It is probable therefore, that the relations both of the Greeks and Chinese are founded upon facts of this kind; and we cannot from thence infer, that the music of early ages was at all superior to that which followed. According to those who have employed much time in these researches, the ancient Chinese were acquainted with the division of the octave into twelve semitones; and that before the time of Pythagoras, or even Mercury himself; that the lyre of Pythagoras, his invention of the diatonic tetrachords, and the formation of his grand sytem, were merely borrowed from the ancient Chinese. In short, it is maintained, that the Greeks, even Pythagoras himself, did nothing but apply to firings that theory which the Chinese had before formed, and applied to pipes.

At present the Chinese are not acquainted with the use of our musical notes; they have not that diversity of signs which distinguish the different tones, and the gradual elevation or depression of the voice, nor anything to point out the various modifications of sound to produce harmony. They have only a few characters to mark the principal notes; and all the airs they learn are repeated merely by rote. The emperor Kang-hi was therefore greatly astonished at the facility with which an European could catch and remember an air the first time he heard it. In 1679 he sent for Fathers Grimaldi and Pereira, to play some tunes on the harpsichord, of which they had before made him a present. He was greatly entertained with their music, but altogether astonished when he found that F. Pereira could take down a Chinese air while the musicians were playing it, and then repeat the whole without omitting a single note. Having made several trials of this kind in order to satisfy himself, he bestowed the highest encomiums upon the European music, and the means furnished by it to facilitate and leaven the labour of the memory. "I must confess (says he) that the European music is incomparable, and that the like of this F. Pereira is not to be found in my whole kingdom."

The Chinese have always distinguished eight different musical instruments; and they believe that nature, in order to produce these, formed eight different kinds of animal and vegetable bodies. The order in which they divide these sounds, and the instruments they have contrived to produce them, are, 1. The sound of skin produced by drums. 2. That of stones produced by the king. 3. The sound of metal by bells. 4. That of baked earth by the braten. 5. Of silk by the kin and che. 6. Of wood
wood by the *yu*, and *tebon*. 7. Of the bamboo by the *kuen*, and different flutes. 8. That of a gourd by the *cheng*.

The drums were originally composed of a box made of baked earth, and covered at the extremities with the skin of some animal; but on account of the brittleness of baked earth, wood was soon substituted in its stead. Greater part of these instruments are shaped like our barrels, but some are cylindrical.

The instruments formed of the founorous stones are called *king*, distinguished into *tsa-king* and *pien-king*. The *tsa-king* consists only of one stone, and therefore produces only one note. The *pien-king* consists of 16 stones suspended together, and thus forming an instrument capable of producing all the tones admitted into the mimic of the ancient Chinese. They are cut and flattened into the form of a carpenter's square; their tone is flattened by diminishing their thicknesses, and is made sharper by abridging their length.

The bells in China have always been made of a mixture of tin and copper. They are of different sizes; and those of the ancients were not round, but flatted, and in the smaller part resembing a crescent. An instrument, corresponding to the *king* already mentioned, is composed of 16 bells of different sizes. Some of these bells used on public occasions are of enormous magnitudes. One at Peking is described as 13½ feet in diameter, 12½ in height, and 42 in circumference; the weight being upwards of 120,000 pounds. It is used for announcing the hours or watches of the night; and its sound, which is prodigiously loud and strong, has a most awful effect in the night-time, by reverberating round the walls and the echo of the surrounding country. There are several others likewise of a vast size in the same city; one of which deserves greatly to be admired on account of the beautiful characters with which it is covered: and which are as neat and perfect as if traced out by the hand of the finest writer, or formed by means of a stamp upon wax. F. le Comte tells us, that in all the cities of China there are bells for marking the hours and watches of the night. They generally divide the night into five watches, beginning at seven or eight in the evening. On the commencement of the first they give one stroke, which is repeated a moment after; and thus they continue for two hours till the beginning of the second; they then give two strokes, which are repeated at equal intervals till the beginning of the third watch; and thus they proceed to the fourth and fifth, always increasing the number of the strokes. For the same purpose also they use enormous drums, which they beat in a similar manner. F. Magailans mentions one at Peking upwards of 40 feet in circumference.

The instrument called *huien*, which is made of baked earth is highly esteemed by the Chinese on account of its antiquity. It is distinguished into two kinds, the great and small; the former being of the size of a goose's egg; the latter of that of a hen's. It has six holes, and a seventh for the mouth.

The *kin* and *tebe* have been known from the remotest antiquity. The *kin* has seven strings made of silk, and is distinguished into three kinds, differing only in size. The body is formed of a kind of wood varnished black, and its whole length about five feet five inches. The *tebe* is about nine feet in length, has 25 strings, and is divided into 25 kinds. F. Amiot assure us, that we have no instrument in Europe which deserves to be preferred to it.

The instruments which emit the sound of wood are the *tebon*, the *yu*, and the *tebon-tou*. The first is shaped like a bell-flute, and is beat on the inside with a hammer; the second, which represents a tyger squatting, is made to sound by scraping its back gently with a rod; the third is a collection of twelve pieces of boards tied together, which are used for beating time, by holding them in the right hand, and knocking them gently against the palm of the left.

Many instruments are constructed of the bamboo. These consist of pipes joined together, or separate, and pierced with more or fewer holes. The principal of these wind instruments is the *chung*, which emits the sound of a gourd. This is formed by cutting off the neck of a gourd, and referring only the lower part. To this a cover is fitted, having as many holes as are equal to the number of sounds required. In each of these holes a pipe made of bamboo is fixed, and shorter or longer according to the tone intended. The mouth of the instrument is formed of another pipe shaped like the neck of a goose; which is fixed to the gourd on the outside, and serves to convey the air into the pipes it contains. The ancient *chung* varied in the number of their pipes; those used at present have only 13.

The painting of the Chinese is undoubtedly inferior to that of the Europeans, though we are not by any means to judge of the abilities of the painters of this empire by the performances which are brought to Europe. M. Grolier remarks, that the works of the eminent Chinese painters are never brought to Canton, because they cannot find purchasers among the European merchants. The latter delight only in obscene pictures, which are not permitted by government, nor indeed will any artist of character execute them, though they prevail upon some of the inferior daubers to gratify them in this respect. It seems, however, to be universally agreed, that the Chinese have a great deal of correctness or perspective, and little knowledge of the proportions of the human body, though it cannot be denied that they excel in painting flowers and animals. In these they pride themselves in a scrupulously exact imitation of nature, inasmuch that it is no uncommon thing to hear a painter ask his pupil how many seals are between the head and tail of a carp.

Painting in fresco was known in China long before the Christian era; and, like the Greeks, the Chinese boast much of their celebrated painters of antiquity. Thus we are told of a door painted by *Pan-hien*, which was so perfect an imitation, that the people who entered the temple where it was attempted to go out by it, unless prevented by those who had seen it before.
The present emperor has in his park an European village painted in fresco, which produces the most agreeable deception. The remaining part of the wall represents a landscape and little hills, which are so happily blended with the distant mountains, that nothing can be conceived more agreeable. This was the production of Chinesse painters, and executed from designs sketched out for them.

Engraving. Engraving in three, four, or five colours, is very ancient among the Chineses, and was known in this empire long before its discovery in Europe. A multiplicity of bridges are rendered necessary in Chine by the vast number of canals and rivers which intersect the empire. Anciently, however, the Chineses made bridges were much more ingenuous as well as magnificent than we are at present. Some of them were so contrived that they could be erected in one day to supply the place of others which might happen to be broken down, or for other purposes. At that time they had bridges which derived their name from their figure: as refreshing the rainbow; draw-bridges, bridges to move with pulleys, compass-bridges, &c. with many others entirely unknown at present. The building of bridges indeed was once a luxurious folly of the emperors; so that they were multiplied from whim or caprice, without any necessity, and without use. Still, however, many of them are extremely beautiful and magnificent. The arches of some are very lofty and acute, with easy stairs on each side, the steps of which are not quite three inches in thickness, for the greater facility of ascending and descending; others have no arches, but are composed of large stones, sometimes 18 feet in length, placed transversely upon piles like planks. Some of these bridges are constructed of stone, marble, or brick; others of wood; and some are formed of a certain number of balks joined together by very strong iron chains. These are known by the name of floating bridges, and several of them are to be seen on the large rivers Kiang and Hoang-ho.

For several centuries the Chinese have made no progress in ship-building. Their vessels have neither masts, nor rigging. They have none housetops, nor fore-mast, to which is sometimes added a fore-lant-mast. The main-mast is placed aloft in the same part of the deck as ours; but the fore-mast stands much farther forward. The latter is to the former in the proportion of two to three; and the main-mast is generally two-thirds of the length of the vessel. They use mats for sails, strengthening them with whole bamboos equal in length to the breadth of the sail, and extended across it at the distance of a foot from one another. Two pieces of wood are fixed to the top and bottom of the sail; the upper serves as a sail-yard; and the lower, which is about five or six inches in thickness, keeps the sail fletched when it is necessary to hoist or lower it. This kind of sail may be folded or unfolded like a screen. For caulking their vessels they do not use pitch, but a particular kind of gum mixed with lime, which forms a composition of such excellent quality, that one or two wells in the hold are sufficient to keep the vessel dry. They have not yet adopted the use of pumps, and therefore draw up the water with buckets. Their anchors are made of the hard wood called iron-wood, which they say is much superior.
superior to the metal, because the latter sometimes bend, but the former never do.

The Chinese pretend to have been the first inventors of the mariner's compass, but seem to have little inclination to improve such an important machine: however, they are well acquainted with the art of maneuvering a vessel, and make excellent coasting pilots, though they are bad sailors in open sea.

Chlo.-Root, in the materia medica, the root of a species of Smilax, brought both from the East and West Indies; and thence distingukshed into oriental and occidental. Both roots are longish, full of joints, of a pale-redish colour, with no smell, and very little taste. The oriental, which is the most esteemed, is considerably harder and paler-coloured than the other. Such should be chosen as is fresh, close, heavy, and upon being chewed appears full of a fat unctuous juice. It is generally supposed to promote insensible perspiration and the urinary discharge, and by its unctuous quality to obtund arrimonious juices. China-root was first brought into Europe in the year 1555, and used as a specific against venereal and cutaneous disorders. With this view it was made use of for some time; but has long since given place to more powerful medicines.

China-Ware. See Porcelain.

Chinca, a sea-port town of Peru in South America, situated in an extensive valley of the same name, in W. Long. 76. 0. S. Lat. 13. 0.

Chincough, a convulsive kind of cough to which children are generally subject. See Medicine-Index.

Chinese, in general denotes any thing belonging to China, or its inhabitants.

Chinese Swanpan. See Swanpan.

Chinkapin. See Fagus.

Chinnor, a musical instrument among the Hebrews, consisting of 32 chords. Kircher has given a figure of it, which is copied on Plate CXXXV.

Chinon, an ancient town of Touraine in France, remarkable for the death of Henry II. king of England, and for the birth of the famous Rabelais. It is seated on the river Vienne, in a fertile and pleasant country, in E. Long. 0. 18. N. Lat. 47. 2.

Chio, or Chios, an Aryan island lying near the coast of Natolia, opposite to the peninsula of Ionia. It was known to the ancients by the name of Æthalia, Macris, Pithynia, &c. as well as that of Chios. According to Herodotus, the island of Chios was peopled originally from Ionia. It was at first governed by kings; but afterwards the government assumed a republican form, which by the direction of Iocrates was modelled after that of Athens. They were, however, soon enlaved by tyrants, and afterwards conquered by Cyrus king of Persia. They joined the other Grecians in the Ionian revolt; but were shamefully abandoned by the Samians, Lesbians, and others of their allies; so that they were again reduced under the yoke of the Persians, who treated them with the utmost severity. They continued subject to them till the battle of Mycale, when they were restored to their ancient liberty: this they enjoyed till the downfall of the Persian empire, when they became subject to the Macedonian princes. In the time of the emperor Vespasian the island was reduced to the form of a Roman province; but the inhabitants were Chioceca allowed to live according to their own laws under the suzerainty of a praetor. It is now subjuct to the Turks, and is called Siza. See that article.

Chioceca, in botany: A genus of the monogynia order, belonging to the pantandria class of plants; and in the natural method ranking under the 48th order, Sipariaceae. It is common in Virginia and South Carolina, where it grows by the sides of rivulets. It rises to the height of ten feet; the leaves are small as those of the laurel, but much thinner. They are propagated in May, and are of a pure white; from whence it has the name of the snow-drop tree. They hang down in large branches, and are cut into narrow segments; from which it has got its other name of the fringe-tree. After the flowers are fallen off, the fruit appears, which grows to the size of a floe, having a floe in the middle. The plants are propagated, in Britain, from seeds sown on a hot-bed, and kept in a floe. Some have been raised from layers; but this method is very precarious, and therefore the other is to be preferred. The seeds are procured from America, for they never come to perfection in Britain.

Chione, in fabulous history, was daughter of Daedalion, of whom Apollo and Mercury became enamoured. To enjoy her company, Mercury inflamed her to sleep with his caduceus; and Apollo, in the night, under the form of an old woman, obtained the same favours as Mercury. From this embrace Chione became mother of Philammon and Autolyclus; the former of whom, as being son of Apollo, became an excellent musician; and the latter was equally notorious for his robberies, of which his father Mercury was the patron. Chione grew so proud of her commerce with the gods, that she even preferred her beauty to that of Juno; for which impiety she was killed by the gods, and changed into a hawk. Another of the same name was daughter of Boreas and Ori­ thyia, who had Eumolphus by Neptune. She threw her son into the sea; but he was preferred by his father.

Chios. See Chio and Scio.

Chiourlie, an ancient town of Turkey in Europe, and in Romani, with a see of a Greek bishop. It is seated on a river of the same name, in E. Long. 7. 47. N. Lat. 41. 18.

Chiozzo, an ancient and handsonie town of Italy, in the territory of Venice, and in a small Island, near the Lagunes, with a pontefit, a bishop's see, and a harbour defended by a fort. E. Long. 12. 23. N. Lat. 45. 17.

Chippenham, a town of Wilshire, seated on the river Avon. It is a good thoroughfare town; has a handsome stone-bridge over the river, consisting of 16 arches; and sends two members to parliament.

There
CHIPPING, a phrase used by the potters and china-men to express that common accident both of our own stone and earthen ware, and the porcelain of China, the flying off of small pieces, or breaking at the edges. Our earthen wares are particularly subject to this, and are always finished by it before any crack of the flaw appears in them. Our stone-wares escape it better than these; but not so well as the porcelain of China, which is less subject to it than any other manufacture in the world. The method by which the Chineses defend their ware from this accident, is this: They carefully burn some small bamboo canes to a sort of charcoal, which is very light, and very black; this they reduce to a fine powder, and then mix it into a thin paste, with some of the varnish which they use for their ware: they next take the vessels when dried, and not yet baked, to the wheel; and turning them softly round, they, with a pencil dip in this paste, cover the whole circumference with a thin coat of it; after this, the vessel is again dried; and the border made with this paste appears of a pale greyish colour when it is thoroughly dry. They work on it afterwards in the common way, covering both this edge and the rest of the vessel with the common varnish. When the whole is baked on, the colour given by the ashes disappears, and the edges are as white as any other part; only when the baking has not been sufficient, or the edges have not been covered with the second varnishing, we sometimes find a dusky edge, as in some of the ordinary thick tea-cups. It may be a great advantage to the English manufacturers to attempt something of this kind. The willow is known to make a very light and black charcoal; but the elder, though a thing seldom used, greatly exceeds it. The young green shoots of this shrub, which are almost all pith, make the lightest and the blackest of all charcoal; this readily mixes with any liquid, and might be used in the same way that the Chineses use the charcoal of the bamboo cane, which is a light hollow vegetable, more resembling the elder shoots than any other English plant. It is no wonder that the fixed salt and oil contained in this charcoal should be able to penetrate the yet raw edges of the ware, and to give them in the subsequeint baking a somewhat different degree of vitrification from the other parts of the vessel; which, though, if given to the whole, it might take off from the true semivitrified state of that ware, yet at the edges is not to be regarded, and only serves to defend them from common accidents, and keep them entire. The Chinese use two cautions in this application: the first in the preparation; the second in the laying it on. They prepare the bamboo canes for burning into charcoal, by peeling off the rind. This might easily be done with the elder shoots, which are so succulent, that the bark strips off with a touch. The Chineses say, that if this is not done with their bamboo, the edges touched with the paste will burst in the baking; this does not seem indeed very probable; but the charcoal will certainly be lighter made from the peeled sticks, and this is a known advantage. The other caution is, never to touch the vessel with hands that have any greasy or fatty sub-

CHIROGRAPH, was anciently a deed which, requiring a counterpart, was engrossed twice on the same piece of parchment, counterpart; leaving a space between, wherein was written CHIROGRAPH through the middle whereof the parchment was cut, sometimes straight, sometimes indented; and a moity given to each of the parties. This was afterwards called dividenda, and charta divisa; and was the same with what we now call charter-party. See Charter-Party. The first use of these chirographs, in Britain, was in the time of Henry III.

CHIROGRAPH was also anciently used for a fine; and the manner of engrossing the fines, and cutting the parchment in two pieces, is still retained in England, in the office called the chirographer's office.

CHIROGRAPHER OF FINES, an officer in the common pleas, in England, who engraves FINES acknowledged in that court into a perpetual record (after they have been examined, and passed by other officers), and writes and delivers the indentures thereof to the party. He makes two indentures; one for the buyer, the other for the seller; and a third indented piece, containing the effect of the fine, and called the face of the fine; and delivers it to the esquire breviam. The same officer also, or his deputy, proclaims all fines in court every term, and indorses the proclamations on the backside of the foot; keeping, withal, the writ of covenant, and the note of the fine.

CHIROMANCY, a species of divination drawn from the lines and lineaments of a person's hand; by which means, it is pretended, the dispositions may be discovered. See DIVINATION, no. 9.

CHIRON, a famous peripatetic of antiquity; styled by Plutarch, in his dialogue on music, 'The wife Centaur.' Sir Isaac Newton places his birth in the first age after Deucalion's deluge, commonly called the Golden Age; and adds, that he formed the constellations for the use of the Argonauts, when he was 88 years old; for he was a practical astronomer, as well as his daughter Hippo: he may, therefore, be said to have flourished in the earliest ages of Greece, as he preceded the conquest of the Golden Fleece, and the Trojan war. He is generally called the son of Saturn and Phyllis; and is said to have been born in Thessaly among the Centaurs, who were the first Greeks that had acquired the art of breaking and riding horses: whence the poets, painters, and sculptors, have represented them as a compound of man and horse; and perhaps it was at first imagined by the Greeks, as well as the Americans, when they first saw cavalry, that the horse and the rider constituted the same animal.

Chiron was represented by the ancients as one of Bacco's first inventors of medicine, botany, and chirur. Hyst. of gery; a word which some etymologists have derived from his name. He inhabited a grotto or cave in the foot of Mount Pelion, which, from his wisdom and great knowledge of all kinds, became the most famous and frequented school throughout Greece. Almost all the heroes of his time were fond of receiving his instructions; and Xenophon, who enumerates them, names the following illustrious personages among his disciples: Cephalus, Æsculapius, Melanion, Neor, and Chiron.
CHIRONIA, in antiquity, the art of representing any past transaction by the gestures of the body, more especially by the motions of the hands: this made a part of liberal education; it had the approbation of Socrates, and was ranked by Plato among the political virtues.

CHIROTONY, among ecclesiastical writers, denotes the imposition of hands used in conferring priestly orders. However, it is proper to remark, that chirotony was a method of electing magistrates by holding up the hands.

CHIRURGEON, or SURGEON. See SURGERY.

CHIRURGERY. See SURGERY.

CHISLEY-LAND, in agriculture, a foil of a middle nature between sandy and clayey land, with a large admixture of pebbles.

CHISON, KISON, or KISSON, (Judges iv. and v.), a river of Galilee; said to rise in mount Tabor, to run by the town of Naim, and to fall into the Mediterranean between mount Carmel and Ptolemais, 1 Kings xviii. 40.

CHISSEL, or CHISEL, an instrument much used in sculpture, masonry, joinery, carpentry, &c.

There are chisels of different kinds; though their chief difference lies in their different size and strength, as being all made of steel well sharpened and tempered; but they have different names, according to the different uses to which they are applied.—The chisels used in carpentry and joinery are, 1. The former; which is used first of all before the paring-chisel, and just after the work is finished. 2. The paring-chisel, which has a fine smooth edge, and is used to pare off or smooth the irregularities which the former makes. This is not stuck with a mallet as the former is, but is pressed with the shoulder of the workman. 3. Skew-former: this is used for cleaning acute angles with the point or corner of its narrow edge. 4. The morifice-chisel, which is narrow, but very thick and strong, to endure hard blows, and it is cut to a very broad bevel. Its use is to cut deep square holes in the wood for mortises. 5. The gouge, which is a chisel with a round edge; one side whereof serves to prepare the way for an angle, and the other to cut such wood as is to be rounded, hollowed, &c. 6. Socket-chisels, which are chiefly used by carpenters, &c. have their...
CHITTON, in zoology, a genus of the order of vermes tellaceae. The name chiton is from χίτων, Lorica, a coat of mail. The shell is plated, and consists of many parts lying upon each other transfereably; the inhabitant is a species of the Doris. They are common on the shores of Scarborough, Aberdeen, and Lochbroom. See several species represented of their natural size on Plate CXXXVIII.

CHITTRICK'S MEDICINE FOR THE STONE. This medicine was some years ago kept as a secret, and has great reputation as a lithontriptic, which indeed in medicine is more remarkable events, throw a faint light on the origin of chivalry, as had yielded not only to the arms of the Romans, but also to the influence of their laws, arts, and manners; and the barbarians, who proceeding from the northern regions of Asia and Europe, the wilds of Scythia and Germany, dislocated the fabric of the Roman empire, and made themselves lords of Europe. Amid this confusion of nations, institutions and customs, it becomes almost impossible to trace any regular series of causes and effects.

Yet as the history of that period is not entirely unknown to us, and the obscure and imperfect records in which it is preserved, while they commemorate the more remarkable events, throw a faint light on the customs, manners, and ordinary transactions of the age; we can at least collect some circumstances, which, if they did not of themselves give rise to the institution of chivalry, must certainly have co-operated with others to that end. We may even be allowed, if we proceed with due diffidence and caution, to deduce, from a consideration of the effect, some inferences concerning the cause; from those particulars of its history which are known to us, we may venture to carry imagination backwards, under a proper restraint, to those, which are hid under the darkness of a rude and illiterate age.

Distinction of ranks appear to be essentially necessary to the existence of civil order. Even in the simplest and rudest social establishments, we find not merely the natural distinctions of weak and strong, young and old, parent and child, husband and wife, but these are always accompanied with others which owe their institution to the invention of man, and the consent, either tacit or formal, of the society among whom they prevail. In peace and in war, such distinctions are equally necessary: they constitute an essential and important part of the mechanism of society.

One of the earliest artificial distinctions introduced among mankind, is that which separates the bold and skilful warrior from those whose feebleness of body and mind renders them unable to excel in dexterity, strength, or valour. Among rude nations, who are but imperfectly acquainted with the advantages of civil order, this distinction is more remarkably eminent than in any other state of society. The ferocity of the human character in such a period produces almost continual hostilities among neighbouring tribes: the elements of nature, and the brute inhabitants of the forest, are not yet reduced to be subservient to the will of man; and these, with other concomitant circumstances, render the warrior, who is equally distinguished by cunning and valour, more useful and respectable than any other character.

On the same principles, as the boundaries of society are enlarged, and its form becomes more complex, the classes into which it is already distinguished are again subdivided. The invention of arts, and the acquisition of property, are the chief causes of these new distinctions which now arise among the orders of society; and...
and they extend their influence equally through the whole system. Difference of armour, and different modes of military discipline, produce distinction of orders among those who practice the arts of war; while other circumstances, originating from the same general causes, occasion similar changes to take place amid the scenes of peace.

None of the new distinctions which are introduced among men, with respect to the discipline and conduct of war, in consequence of the acquisition of property and the invention of arts, is more remarkable than that occasioned by the use of horses in military expeditions, and the training of them to the evolutions of the military art. Fire-arms, it is true, give to those who are acquainted with them a greater superiority over those to whom their use is unknown than what the horsemanship over him who fights on foot. But the use of fire-arms is of such importance in war, and the expense attending it is inconceivable, that wherever these have been introduced, they have seldom been confined to one particular order in an army; and therefore they produce indeed a remarkable, though transient, distinction among different nations; but establish no permanent distinctions in the armies of any one nation. But to maintain a horse, to equip him with costly furniture, to manage him with dexterity and vigour, are circumstances which have invariably produced a standing and conspicuous distinction among the military orders, whenever bodies of cavalry have been formed. The Roman equites, who, though they became at length a body of sufferers and farmers-general, were originally the only body of cavalry employed by the state, occupied a respectable rank between the senators and the plebeians; and the elegance and humanity of their manners were suitable to their station. In ancient Greece, and in the celebrated monarchies of Asia, the same distinction prevailed at a similar period.

Since the circumstances and principles on which this distinction depends are not such as must be confined in their influence to one particular nation, or one region of the globe, we may hope to trace their effects among the savage warriors of Scythia and Germany, as well as among the Greeks or Romans. From the valuable treatise of Tacitus de moribus Germanorum, we learn, that among the German warriors a distinction somewhat of this nature did actually subsist; not so much indeed a distinction between the warrior who fought on horseback and those who fought on foot, as between those whom vigour of body and energy of mind enabled to brave all the dangers of war, and such as, from the imbecility of youth, the infirmities of age, or the natural inferiority of their mental and bodily powers, were unequal to scenes of hardship and deeds of valour. The youth was not permitted to take arms and join his warlike countrymen in their expeditions; whereas he himself thought proper. There was a certain age before which he could not be invested with armour. When he had attained that period, if not found deficient in strength, activity, or courage, he was formally honoured with the shield and the lance, called to the duties, and admitted to all the privileges, of a warrior.

Another fact worthy of notice respecting the manners of the barbarians of Germany before they established themselves in the cultivated provinces of the Roman empire is, that their women, contrary to what we find among many other rude nations, were treated with a high degree of respect. They did not generally vie with the men in deeds of valour, but they were admired by them for their orations, with prophetic powers, capable to foresee events hid in the womb of futurity, and even to influence the will of the deities. Hence, though domestic duties were their peculiar province, yet they were not hardly treated nor confined to a state of slavery. There appears indeed a striking analogy between the condition of the women among the rude soldiers of Sparta and the rank which they occupied among the warlike cantons of Germany. Perhaps, indeed, the German were still more honourable than the Spartan women, as they were taught to wield the magic weapons of superstition, which in Greece were appropriated to the priests.

It appears, therefore, that, in the forests of Germany at least, if not in the more northern regions of Asia and Europe, the conquerors of the Roman empire, before they penetrated into its provinces, treated their women with a degree of respect unknown to most of the nations of antiquity; that the character of the warrior was likewise highly honourable, being unfrocked to unite all those qualities which were in the higher estimation; and that it was only at a particular age, and with certain forms, that the youth were admitted to bear arms.

When these nations fell from their defects and changes in the manners of the barbarians, they took place on their circumstances was remarkable; and by a natural influence, it could not but produce an equally settled in remarkable change on their habits, customs, and manners. The great outlines might still remain: but empire, they could not now fail to be filled up in a different manner. Here, however, the records of history are peculiarly imperfect. We have no Caesar or Tacitus to supply facts or direct our reasonings; the Gothic and Roman historians had not yet learned the art of letters, and the Romans were so depressed under the yoke of their own miseries, as to be negligent of the changes which happened around them. But as soon as the light of history begins again to dawn, we find that the leading features of the barbarian character were not effaced, but only modifie in a particular manner, in consequence of their mixing among a more polished people, becoming acquainted with the luxuries of life, and acquiring extensive power and property.

Those who fought on horseback now began to be distinguished with peculiar honours. The manners of the warrior too were become more cultivated, and his spirit more humane. Leisure and opulence, with the influence of a polished people, even though in a state of slavery, taught those barbarians to aspire after more refined pleasures and more splendid amusements than those which they had been before satisfied with. The influence of Christianity too, which, though grossly corrupted, was still favourable to the social happiness of mankind, concurred to polish their manners and exalt their character. Hence, in the end of the tenth and in the beginning of the eleventh century, we fee
Chivalry, knight-errantry, with that romantic gallantry, piety, and humanity, by which it was principally distinguished, made its appearance. At the court of every prince, count, or baron, jousts and tournaments became the favourite amusements. At those entertainments, skill in arms, devotion to the fair, and generosity, were all at once cultivated. About this period began the crusades; and these, to which alone some have referred the origin of chivalry, though they could not give rise to what was already in existence, yet moulded the form and directed the spirit of the institution in such a manner, as to raise it, by a rapid progression from infancy, as it were, to full vigour and maturity. Its character, as it appeared when fully formed, is well described by an eloquent historian in the following manner:

"Between the age of Charlemagne and that of the crusades, a revolution had taken place among the Spaniards, the Normans, and the French, which was gradually extended to the rest of Europe. The service of the infantry was degraded to the plebeians; the cavalry formed the strength of the armies, and the honourable name of knight, or soldier, was confined to the gentlemen who served on horseback, and were invested with the character of knighthood. The dukes and counts, who had usurped the rights of sovereignty, divided the provinces among their faithful barons: the barons distributed among their vassals the fees or benefits of their jurisdiction; and these military tenants, the peers of each other and of their lord, composed the noble or equestrian order, which disdained to conceive the peafant or burgher as of the same species with themselves. The dignity of their birth was preferred by pure and equal alliances; their sons alone who could produce four quarters or lines of ancestry, without spot or reproach, might legally pretend to the honour of knighthood; but a valiant plebeian was sometimes enriched and ennobled by the sword, and became the father of a new race. A single knight could impart, according to his judgment, the character which he received; and the warlike sovereigns of Europe derived more glory from this personal distinction than from the luster of their diadem. This ceremony was in its origin simple and profane; the candidate, after some previous trial, was invested with his sword and spurs; and his cheek and shoulder were touched with a flight blow as the emblem of the left affront which it was lawful for him to endure. But superiority mingled in every public and private action of life: In the holy wars, it sanctified the profession of arms; and the order of chivalry was assimilated in its rights and privileges to the sacred orders of priesthood. The bath and white garment of the novice, were an inexact copy of the regeneration of baptism: his sword, which he offered on the altar, was blessed by the ministers of religion; his solemn reception was preceded by fasts and vigils; and he was created a knight in the name of God, of St George, and of St Michael the archangel. He swore to accomplish the duties of his profession; and education, example, and the public opinion, were the inviolable guardians of his oath. As the champion of God and the ladies, he devoted himself to speak the truth; to maintain the right; to protect the distressed; to practice courtesy, virtue less familiar to the ancients; to pursue the infidels; to subdue the allurements of ease and safety; and to vindicate in every perilous adventure the honour of his character. The abuse of the same spirit provoked the illiterate knight to disdain the arts of industry and peace; to esteem himself the sole judge and avenger of his own injuries; and proudly to neglect the laws of civil society and military discipline. Yet the benefits of this institution, to refine the temper of barbarians, and to exalt some principles of faith, justice, and humanity, were strongly felt, and have been often observed. The superiority of national prejudice was softened; and the community of religion and arms spread a similar colour and generous emulation over the face of Christendom. Abroad, in enterprise and pilgrimage; at home, in martial exercise, the warriors of every country were perpetually associated; and impartial warfare must prefer a Gothic tournament to the Olympic games of classic antiquity. Instead of the naked spears which corrupted the manners of the Greeks, and banished from the stadium the virgins and matrons, the pomposous decoration of the lists was crowned with the presence of chaste and high-born beauty, from whose hands the conqueror received the prize of his dexterity and courage. The skill and strength that were exercised in wrestling and boxing, bear a distant and doubtful relation to the merits of a soldier; but the tournaments, as they were invented in France, and eagerly adopted both in the east and west, presented a lively image of the business of the field. The single combats, the general skirmish, the defence of a pass or castle, were rehearsed as in actual service; and the contest, both in real and mimic war, was decided by the superior management of the horse and lance. The lance was the proper and peculiar weapon of the knight; his horse was of a large and heavy breed; but his charger, till he was routed by the approaching danger, was usually led by an attendant, and he quietly rode a pad or palfrey of a more easy pace. His helmet and sword, his greaves and buckler, it would be superfluous to describe; but I may remark, that at the period of the crusades, the armour was less ponderous than in latter times; and that, instead of a massive cuirass, his breast was defended by an hauberk or coat of mail. When their long lances were fixed in the rest, the warriors furiously spurred their horses against the foe; and the light cavalry of the Turks and Arabs could fold them stand against the direct and impetuous weight of their charge. Each knight was attended to the field by his faithful squire, a youth of equal birth and similar hopes; he was followed by his archers and men at arms; and four, or five, or six soldiers, were computed as the furniture of a complete lance. In the expeditions to the neighbouring kingdoms or the Holy Land, the duties of the feudal tenure no longer subsisted; the voluntary service of the knights and their followers was either prompted by zeal or attachment, or purchased with rewards and promises; and the numbers of each squadron were measured by the power, the wealth, and the fame of each independent chieftain. They were distinguished by his banner, his armament, and his cry of war; and the most ancient families of Europe must seek in these achievements the origin and proof of their nobility."
Chivalry, traces, with great ingenuity and erudition, a strong resemblance between the manners of the age of chivalry and those of the old heroic ages delineated by Homer. There is, says he, a remarkable correspondence between the manners of two of Chivalry.

There is, says he, a remarkable correspondence between the manners of the old heroic ages, as painted by their great romancer Homer, and those which are represented to us in the modern books of knight-errantry. A fact of which no good account can be given, but by another not less certain; that the political states of Greece, in the earliest periods of its story, was similar in many respects to that of Europe, as broken by the feudal system into an infinite number of petty independent governments.

Some obvious circumstances of agreement between the heroic and Gothic manners may be worth putting down.

1. The military enthusiasm of the barons is but a piece with the fanaticism of the heroes. Hence the same particularity of description in the accounts of battles, wounds, deaths, in the Greek poet as in the Gothic romancers. Hence that minute curiosity in the display of their dresses, arms, accompaniments. The minds of all men being occupied with warlike images and ideas, were much gratified by those details, which appear cold and uninteresting to modern readers.

We hear much of knights-errant encountering giants and quelling savages in books of chivalry. These giants were opprobrious feudal lords; and every lord was to be met with, like the giant, in his strong-hold or castle. Their dependents of a lower form, who resided in the deferts, a savage for his brutality. The greater lord was called a giant for his power; the less, a savage for his brutality.

2. Another terror of the Gothic ages was monsters, dragons, and serpents. Their stories were received in those days for several reasons: 1. From the vulgar belief of enchantments: 2. From being reported on the faith of Eastern tradition, by adventurers from the Holy Land: 3. In still later times from the strange things told and believed on the discovery of the new world.

In all these respects, Greek antiquity resembles the Gothic. For what are Homer's Laërtrius and Cypresses, but bands of lawless savages, with each of them a giant of enormous size at their head? And what are the Grecian Bacchus, Hercules, and Theseus, but knights-errant, the exact counterparts of Sir兰ce-lot and Amadis de Gaul?

3. The oppression with which it was the glory of the knights to avenge, were frequently carried on, as we are told, by the charms and enchantments of women. These charms, we may suppose, are often metaphorical; as expounding only the blandishments of the sex. Sometimes they are taken to be real, the ignorance of those ages accounting in such conceits. And are not these stories matched by those of Calypso and Circe, the enchantresses of the Greek poet?

4. Robbery and piracy were honourable in both; so far were they from reflecting any discredit on the ancient and modern redressers of wrongs. What account can be given of this, but that, in the feudal times, and in the early days of Greece, when government was weak, and unable to redress the injuries of petty sovereigns, it would be glorious for private adventurers to undertake this work; and, if they could accomplish it in no other way, to pay them in kind by downright plunder and rapine?

5. Balladry was in credit with both. They were extremely watchful over the chastity of their own women; but such as they could seize upon in the enemies quarter, were lawful prize. Or, if, at any time, they transgressed in this fort at home, the fault was covered by an ingenious fiction. The offspring was reputed divine. Their greatest heroes were the fruit of goddeses approached by mortals; just as we hear of the doughnutkings being born of fairies.

6. With the greatest fierceness and savageness of character, the utmost generosity, hospitality, and courtesy, were imputed to the heroic ages. Achilles was at once the most relentless, vindictive, and generous, and the friendliest of men. We have the very same representation in the Gothic romances. As in those lawless times, dangers and difficulties of all kinds abounded, there would be the same demand for compassion, gentleness, and generous attachment to the unfortunate, those especially of their own clan, as of resentment, rage, and animosity against their enemies.

7. Again, the martial games celebrated in ancient Greece, on great and solemn occasions, had the same origin and the same purpose as the tournaments of the Gothic warriors.

8. Lastly, the passions for adventures so natural in their situation, would be as naturally attended with the love of praise and glory. Hence the same encouragement, in the old Greek and Gothic times, to pugnacity and poets. In the affairs of religion and gallantry, indeed, the resemblance between the hero and the knight is not so striking. But the religious character of the knight was an accident of the times and no proper effect of his civil condition. And that his devotion for the fair sex should so far surpass that of the hero, is a confirmation of the futility here advanced. For the consideration had of the females in the feudal constitution, will of itself account for this deference. It made them capable of succeeding to seats, as well as the men. And does not one see, on the instant, what respect and dependence this privilege would draw upon them?

It was of mighty consequence who should obtain the favour of a rich heiress. And though, in the strict feudal times, she was supposed to be in the power and at the disposal of her superior lord, yet this rigid state of things did not last long. Hence we find some distressed damsel was the spring and mover of every knight's adventure. She was to be rescued by his arms, or won by the fame and admiration of his prowess. The plain meaning of all which was this: That as, in these turbulent times, a protector was necessary to the weakness of the sex, so the courteous and valorous knight was to approve himself qualified for that purpose.

It may be observed, that the two poems of Homer were intended to expoze the mischiefs and inconveniences arising from the political state of Old Greece: the Iliad, the dispositions that naturally spring up among independent chiefs; and the Odyssey, the infolence of their greater subjects, more especially when unrestrained by the presence of their sovereign. And can any thing more exactly resemble the condition of the
CHIVALRY, in law, is used for a tenure of lands by knight's service; whereby the knight was bound to perform service in war unto the king, or the mean lord of whom he held by that tenure. And chivalry was either general or special: general, when it was only in the efferitance that the tenant held per servitium militare, without any specification of serjeantry, ecussonage; &c.; special, when it was declared particularly by what kind of knight service the land was held.

For the better understanding of this tenure it hath been observed, that there is no land but is held mediately or immediately of the crown by some service; and therefore all freeholds that are to us and our heirs, are called feuda or foeda, "fees;" as proceeding from the king for some small yearly rent, and the performance of such services as were originally laid upon the land at the donation thereof. For as the king gave to the great nobles his immediate tenants, large possessions for ever, to hold of him for this or that service or rent; so they in time parcelled out to such others as they liked the same lands for rents and services as they thought good: and these services were by Littleton divided into two kinds, chivalry and serjeantry; the first whereof was martial and military, the other rustic.

Chivalry, therefore, was a tenure of service, whereby the tenant was obliged to perform some noble or military office unto his lord: and it was of two kinds, either regal, that is, held only by the king; or common, where held of a common person. That which might be held only of the king was called servitium, or serjeantry; and was again divided into grand and petit serjeantry. The grand serjeantry was where one held lands of the king by service, which he ought to do in his own person; as to bear the king's banner or spear, to lead his host, to find men at arms to fight, &c. Petit serjeantry was when a man held lands of the king, to yield him annually some small thing towards his wars, as a sword, dagger, bow, &c. Chivalry that might be held of a common person was termed featagium, "ecussonage;" that is, service of the shield; which was either uncertain or certain.

Ecnage uncertain, was likewise two-fold: first, where the tenant was bound to follow his lord, going in person to the king's wars, either himself, or lending a sufficient man in his place, there to be maintained at his expense, so long as was agreed upon between the lord and his first tenant at the granting of the fee; and the days of such service seem to have been rated by the quantity of land so held: as if it extended to a whole knight's fee, then the tenant was to follow his lord 40 days: and if but to half a knight's fee, then 20 days; if a fourth part, then 10 days, &c. The other kind of this ecussonage was called cattle-ward, where the tenant was obliged, by himself or some other, to defend a castle as often as it should come to his turn. And these were called ecussonage uncertain; because it was uncertain how often a Chivalry man should be called to follow his lord to the wars, or to defend a castle, and what his charge would be therein.

Ecnage certain, was where the tenure was set at a certain sum of money to be paid in lieu of such services, as that a man should pay yearly for every knight's fee, half for a knight's fee 10s., or some like rate; and this service, because it is drawn to a certain rent, growtheth to be of a mixed nature, not merely socage, and yet socage in effect, being now neither personal service nor uncertain. The tenure called chivalry had other conditions annexed to it: but there is a great alteration made in these things by the Stat. 12. Car. 2. c. 24, whereby tenures by knight's service of the king, or any other person in capite, &c. and the fruits and consequences thereof, are taken away and discharged; and all tenures are to be confirmed and adjudged to be free and common socage, &c.

Court of Chivalry, a court formerly held before the lord high constable and earl marshal of England jointly, and having both civil and criminal jurisdiction: but since the attainder of Stafford Duke of Buckingham under Henry VIII. and the consequent extinction of the office of lord high constable, it hath usually, with respect to civil matters, been heard before the earl marshal only. This court, by Stat. 13. Rich. II. c. 2. hath cognizance of contracts and other matters touching deeds of arms and war, as well out of the realm as in. And from its sentences lies an immediate appeal to the king in person. This court was in great reputation in the times of pure chivalry; and afterwards during the English connections with the continent, by the territories which their princes held in France: but it is now grown almost entirely out of use, on account of the feebleness of its jurisdiction, and want of power to enforce its judgments; as it can neither fine nor imprison, not being a court of record.

1. The civil jurisdiction of this court of chivalry is principally in two points; the redressing injuries of honour, and correcting encroachments in matters of coat armour, precedence, and other distinctions, of families. As a court of honour, it is to give satisfaction to all such as are aggrieved in that point; a point of a nature so nice and delicate, that its wrongs and injuries escape the notice of the common law, and yet are fit to be redressed somewhere. Such, for instance, as calling a man a coward, or giving him the lie; for which, as they are productive of no immediate damage to his person or property, no action will lie in the courts at Westminster; and yet they are such injuries as will prompt every man of spirit to demand some honourable amends; which by the ancient law of the land, was given in the court of chivalry. But modern resolutions have determined, that how much soever a jurisdiction may be expedient, yet no action for words will at present lie therein. And it hath always been most clearly held, that as this court cannot meddle with any thing determinable by common law, it therefore can give no pecuniary satisfaction or damages; in as much as the quantity and determination thereof is ever of common law cognizance. And therefore this court of chivalry can at most order reparation in point of honour; as, to compel
CHIUM

CHIUM, or CHEVAN, in Hebrew antiquity. We meet with this word in the prophet Amos, cited in the Acts of the Apostles. St. Luke reads the passage thus: “Ye took up the tabernacle of Moloch, and the star of your god Remphan, figures which ye made to worship them.” The import of the Hebrew is as follows: “Ye have borne the tabernacle of your king, and the pekefuf (the chiun) of your images, the star of your gods, which ye made to yourselves.” The Septuagint in all probability read Rephan or Revan, instead of Chiu or Chevan, and took the pekefuf for a god.

Some say that the Septuagint, who made their translation in Egypt, changed the word Chiu into that of Remphan because they had the same signification. M. Balfage, in his book Intitulé Jewish Antiquities, after having discredited a good deal upon Chiu or Remphan, concludes that Moloch was the sun, and Chiu, Chion, or Remphan, the moon.

CHLAMYDS, in antiquity, a military habit worn by the ancients over the tunica. It belonged to the patricians, and was the same in the time of war that the toga was in the time of peace. This sort of gown was called palla, from the rich embroidery with figures in Phrygian work; and purpurea, because the ground-work was purple. The chlamydes of the emperors were all purple, adorned with a golden and embroidered border.

CHLOEIA, in antiquity, a festival celebrated at Athens in honour of Ceres, to whom, under the name Xaoi, i.e. Carii, they sacrificed a ram.

CHLORA, in botany, a genus of the monogynia order, belonging to the oenandria class of plants. The calyx is ochrophyllous, the corolla monopetalous and oenoid; the capsule unilocular, bivalved, and polyispermous.

CHLOROSIS, in medicine, a disease, commonly called the green-sickness, incident to young girls. See (The Index subjoined to) MEDICINE.

CHOCOLATE, in commerce, a kind of paste or cake prepared of certain ingredients, the basis of which is cacao. See CACAO.

The Indians, in their first making of chocolate, used to roast the cacao in earthen pots; and having afterwards cleared it of the husks, and bruised it between two flones, they made it into cakes with their hands. The Spaniards improved this method: when the cacao is properly roasted and well cleared, they pound it in
Cholera. a mortar, to reduce it into a coarse mass, which they afterwards grind on a stone till it be of the utmost fineness; the paste being sufficiently ground, is put quite hot into tin moulds, in which it congeals in a very little time. The form of these moulds is arbitrary: the cylindrical ones, holding two or three pounds, are the most proper; because the bigger the cake is, the longer they will keep. Observe, that these cakes are very liable to take any good or bad scent, and therefore they must be carefully wrapped up in paper, and kept in a dry place. Complaints are made, that the Spaniards mix with the cacao nuts too great a quantity of cloves and cinnamon, besides other drugs without number, as muilk, ambergraife, &c. The grocers of Paris use few or none of these ingredients; they only choose the best nuts, which are called caracas, from the place from whence they are brought; and with these they mix a very small quantity of cinnamon, the fresh sweet vanilla, and the finest sugar, but very seldom any cloves. In England, the chocolate is made of the simple cacao, excepting that sometimes sugar and sometimes vanilla is added.

Chocolate ready made, and cacao paste, are prohibited to be imported into Britain from beyond the seas. It made and sold in Great Britain, it pays inland duty 1s. 6d. per lb. avoidupoise; it must be inclosed in papers containing one pound each, and produced at the excise office to be stamped. Upon three days notice given to the officer of excise, private families may make chocolate for their own use, provided no less than half an hundred weight of nuts be made at one time.

The chocolate made in Portugal and Spain is not near so well prepared as the English, depending perhaps on the machine employed there. viz. the double cylinder, which seems very well calculated for exact trituration. If perfectly prepared, no oil appears on the solution. London chocolate gives up no oil like the foreign; and it also may, in some measure, depend on the thickness of the preparation. The solution requires more care than is commonly imagined. It is proper to break it down, and diffuse it thoroughly in cold water by milling it with the chocolate stick. If heat is applied, it should be done slowly: for, if suddenly, the heat will not only coagulate it, but separate the oil; and therefore much boiling after it is dissolved, is hurtful. Chocolate is commonly required by people of weak stomachs; but often rejected for want of proper preparation. When properly prepared, it is easily digested; is an excellent food where a liquid nutritious vegetable one is required, and is less flainty than any of the farinacea.

Mr. Henry, an ingenious electrician, has lately discovered that chocolate, fresh from the mill, as it cools in the tin-pans into which it is received, becomes strongly electrical; and that it retains this property for some time after it has been turned out of the pans, but soon loses it by handling. The power may be once or twice renewed by melting it again in an iron ladle, and pouring it into the tin pans as at first; but when it becomes dry and powdery, the power is not capable of being revived by simple melting; but if a small quantity of olive oil be added, and well mixed with the chocolate in the ladle, its electricity will be completely restored by cooling it in the tin-pan as before. From this experiment he conjectures, that there is a great affinity between phlogiston and the electric fluid, if indeed they be not the same thing.

Chocolate-Nut Tree. See Cacao.

Chohinix, χοϊίξ, an ancient dry measure, containing the 48th part of a medimnus, or six bushels.

Choir, that part of the church or cathedral where choirmasters sing divine service; it is separated from the chancel where the communion is celebrated, and also from the nave of the church where the people are placed: the patron is said to be obliged to repair to the choir of the church. It was in the time of Constan- tinople that the choir was separated from the nave. In the twelfth century they began to include it with walls; but the ancient basilicas have since been restored, out of a view to the beauty of architecture.

Choir in nunneries, is a large hall adjoining to the body of the church, separated by a grate, where the nuns sing the office.

Chosi (Francis Timoleon de), dean of the cathedral of Bayeux, and one of the forty of the French academy, was born at Paris in 1644. In 1685, he was sent with the chevalier de Chamont to the King of Siam, and was ordained priest in the Indies by the a-potolic vicar. He wrote a great number of works, in a polite, florid, and easy style, the principal of which are, 1. Four dialogues on the Immortality of the Soul, &c. 2. Account of a voyage to Siam. 3. An Ecclesiastical History, in 4 Vols. 4. A Life of David, with an interpretation of the Psalms. 5. Life of Solomon, &c. He died at Paris, in 1724.

Cholechochus, in anatomy, a term applied to a canal or duct, called also ductus communis; formed of the union of the porus bilarius and ductus clycosus. The word comes from χοίλη, cholera; and δυσμὸς, I receive, or contain. The cholechochus ductus passing obliquely to the lower-end of the duodenum, serves to convey the bile from the liver to the intestines. See Anat. n° 97.

Choler. See Bile.

Cholera morbus, a sudden eruption or over-flowing of the bile or bilious matters both upwards and downwards. See (the Index subjoined) to Medicine.

Chomer, or Omer. See CORUS.

Chondrilla, in botany, a genus of the polygama equals order, belonging to the fyngeesia class of plants; and in the natural method ranking under the 40th order, Compositae. The receptacle is naked; the calyx calculated; the pappus simple and flaked; the florets in a unifoliate series.

Chondropterygi, in ichthology, a term for
Chop-church, or Church-chopper, a name, or rather nick-name, given to parsons who make a practice of exchanging benefices. See Permutation.

Chop-church, occupying an ancient stature as a lawful trade or occupation; and some of the judges say it was a good addition. Both holds that it was no occupation, but a thing permissible by law.

Chopin, or Chopine, a liquid measure used both in Scotland and France, and equal to half their pint.

See Pint and Measure.

Chopin (Rene), a famous civilian born at Baileuil in Anjou in 1537. He was advocate in the parliament of Paris, where he pleaded for a long time with great reputation. He at last shut himself up in his closet; and composed many works, which have been collected together, and printed in 6 vols. folio. He died at Paris in 1606.

Choral, signifies any person that, by virtue of any of the orders of the clergy, was in ancient times admitted to fit and serve God in the choir.

Dugdale, in his history of St Paul's Church, says, that there were with the choros formerly six vicars choral belonging to that church.

Chorassan, or Khorassan, a province of Persia adjoining to Ubec Tartary. This was the ancient Baetria, and the birth-place of Kouli Khan.

Chorax, or Charax. See Characene.

Chorazin, or Charax. See Characene.

Choral, or Cord, primarily denotes a lusher or cordage *. The word is formed of the Latin, chorda, and that from the Greek, χορδα, a gut, whereof strings may be made.

Chord, in geometry, a right line drawn from one part of an arch of a circle to another. Hence, Chord of an Arch, is a right line joining the extremities of that arch.

Chord, in music, the union of two or more sounds uttered at the same time, and forming together an entire harmony.

The natural harmony produced by the resonance of a sound-body, is composed of three different sounds, without reckoning their octaves; which form among themselves the most agreeable and perfect chord that can possibly be heard: for which reason they are called, on account of their excellence, perfect chords. Hence, in order to render this harmony complete, it is necessary that each chord should at least consist of three sounds. The trio is likewise found by musicians to include the perfection of harmony; whether because in this all the cords, and each in its full perfection, are used; or, because upon such occasions as render it improper to use them all, and each in its integrity, arts have been successfully practised to deceive the ear, and to give it contrary persuasion, by deluding it with the principal sounds of each chord, in such a manner as to render it forgetful of the other sounds necessary to their completion. Yet the octave of the principal sound produces new relations, and new consonances, by the completion of the intervals: they commonly add this octave, to have the embellishment of all the consonances in one and the same chord; (See Consonance.) Moreover, the addition of the diapason (see Discord), producing a fourth sound superadded to the perfect chord, it becomes indispensably necessary, if we would render the chord full, that we should include a fourth part to express this diapason. Thus the series of chords can neither be complete nor connected but by means of four parts.

Chords are divided into perfect and imperfect. The perfect chord is that which we have lately described: which is composed of the fundamental sound below, of its third, is fifth, and its octave: they are likewise subdivided into major and minor, according as the thirds which enter into their composition are flat or sharp: (See Interval.) Some authors likewise give the name of perfect to all chords, even to dissonances, whose fundamental sounds are below. Imperfect chords are those in which the sixth, instead of the fifth, prevails, and in general all those whose lowest are not their fundamental sounds. These denominations, which had been given before the fundamental bass was known, are now most unaptly applied: those of chords direct and reversed, are much more suitable in the same sense.

Chords are once more divided into consonances and dissonances. The chords denominated consonances, are the perfect chord, and its derivatives; every other chord is a dissonance.

A table of both, according to the system of M. Rameau, may be seen in Rouleau's Musical Dictionary, vol. 1. p. 27.

After the table to which our readers have been referred, Rouleau adds the following observations, which are at the same time so just and so important, that we should be very sorry if they escape the reader's attention.

At the words harmony, fundamental bass, composition, &c. he promises to treat concerning the manner of using all the chords to form regular harmony; and only adds, in this place, the subjequent reflections.

1. It is a capital error to imagine, that the methods of inverting the same chord are in all cases equally eligible for the harmony and for the expression. There is not one of these different arrangements but had its proper character. Every one feels the contrast between the softness of the flat fifth, and the grating found of the tritone, though the one of these intervals is produced by a method of inverting the other. With the seventh diminished, and the second redundant, the caes are the same with the interval of the second in general use, and the seventh. Who does not feel how much more vocal and sonorous the fifth appears when compared with the fourth? The chord of the great sixth, and that of the lesser sixth minor, are two forms of the same fundamental chord: but how much less is the one harmonious than the other? On the contrary, the chord of the lesser sixth major is mucius more pleasing and agreeable than that of the flat fifth. And only to mention the most simple of all chords, reflect on the majesty of the perfect chord, the sweetness of that which is called the chord of the sixth, and the insipidity of that which is composed of...
CHORDS. [ 706 ]

CHO

a sixth and a fourth; all of them, however, composed of the same sounds. In general, the redundant intervals, the sharps in the higher part, are proper by their severity to express violent emotions of mind, such as anger and the rougher passions. On the contrary, flats in the higher parts, and diminished intervals, form a plaintive harmony, which melts the heart. There are a multitude of similar observations, of which when a musician knows how to avail himself, he can command at will the affections of those who hear him.

2. The choice of simple intervals is scarcely of less importance than that of the chords, with regard to the stations in which they ought to be placed. It is, for instance, in the lower parts that the fifth and octave should be used in preference; in the upper parts, the third and sixth are more proper. If you transpose this order, the harmony will be ruined even though the same chords are preferred.

3. In a word, the chords are rendered still more harmonious, by being approximated and only divided by the smallest practicable intervals, which are more suitable to the capacity of the ear than such as are remote. This is what we call contrasting the harmony, an art which few composers have skill and abilities enough to put in practice. The limits in the natural compass of voices, afford an additional reason for lessening the distance of the intervals, which compose the harmony of the chorus, as much as possible. We may affirm, that a chorus is improperly composed when the distance between the chords increases; when those who perform the different parts are obliged to scream; when the voices rise above their natural extent, and are so remotely distant from one another, that the perception of harmonical relations between them is lost.

We say likewise, that an instrument is in concord when the intervals between its fixed sounds are what they ought to be; we say in this sense, that the chords of an instrument are true or false, that it preserves or does not preserve its chords. The same term of speaking is used for two voices which sing together, or for two winds which are heard at the same time, whether in unison or in parts.

CHORDS, or CHORDS, of Musical instruments, are strings, by the vibration of which the tension of sound is excited, and by the divisions of which the several degrees of tone are determined.

CHORDEE, in medicine and surgery, a symptom attending a gonorrhoea, consisting in a violent pain under the fricrum, and along the duct of the urethra during the erection of the penis, which is incurvated downwards. These erections are frequent and involuntary.

CHOREA SACRIP II. See VIRUS'S DANCE.

CHOREPISCOPI, an officer in the ancient church, about whose function the learned are extremely divided. The word comes from CHOREUS, a chorus, little country, and episcopus, a bishop, or overseer.

The choreepisci were suffragan or local bishops, holding a middle rank between bishops and presbyters, and delegated to exercise episcopal jurisdiction within certain districts, when the boundaries of particular churches, over with separate bishops presided, were considerably enlarged. It is not certain when this office was first introduced: some trace it to the close of the first century; others tell us, that choreeposci were not known in the east till the beginning of the fourth century; and in the west about the year 459. They ceased both in the east and west in the tenth century.

CHOREPISCOPI is also the name of a dignity still subsisting in some cathedrals, particularly in Germany; signifying the same with CHOREUS, or bishop of the choir. The word, in this sense, does not come from CHOREAUS, place, but CHOREAUS guor, &c. In the church of Cologne, &c. the first chanter is called choreepiscopus.

CHOREUS, XOBUO, a foot in the ancient poetry, more commonly called trocheus. See TROCHEE.

CHORIAMBUS, in ancient poetry, a foot consisting of four syllables, whereof the first and last are long, and the two middle ones are short; or, which is the same thing, it is made up of a trocheus and lambus; such is the word nöbaus.

CHORIOIDES, or CHOROEIDES, in anatomy, the exterior membrane which invests the focus in the uterus. See FEETUS.

CHOROBATA, or CHOROBATES, a kind of water level among the ancients, of the figure of the letter T, according to Vitruvius's description.

CHOROGRAPHY, the art of making a map of some country or province.

Chorography differs from geography, as the description of a particular country is different from that of the whole earth; and from topography, as the description of a country is different from that of a town or district. See the articles GEOGRAPHY, TOPOGRAPHY, and MAP.

CHOROIDES, or CHOROEIDES, in anatomy, a term applied to several parts of the body; bearing some resemblance to the chorion. The word is formed from CHOREUS, chorion, and OIDE, likeness.

CHOROEIDES is particularly used for the inner membrane which immediately invests the brain; so called as being intermingled with a great number of blood-vessels, like the chorion; but more usually denominated the pia mater, or meninx tenus.

PLEXUS or Lucii CHOROEIDES, is a knot of veins and arteries in the anterior ventricle of the brain, woven out of the branches of the carotid.

CHOROEIDES is also applied to the inner and posterior tunics of the eye; immediately under the sclerotica. It is soft, thin, and black; and its inner or concave surface is very smooth and polished. It has its name from its being intermixed with vessels.

CHORUS, in dramatic poetry, one or more persons present on the stage during the representation, and supposed to be by-standers without any share in the action.

Tragedy in its origin was no more than a single chorus, who trod the stage alone, and without any actors, singing dithyrambs or hymns in honour of Bacchus. Thebpis, to relieve the chorus, added an actor, who rehearsed the adventures of some of their heroes; and Aeschyus, finding a single person too dry an entertainment, added a second, at the same time reducing the singing of the chorus, to make more room...
CHOUSCH, in ornithology, the trivial name of a species of Corvus.

CHOUS, in the eastern military orders, the title of the messengers of the divan of Janisaries. There are several degrees of honour in this post. When a person is first advanced to it, he is called a cucuk, or little choos; after this he is advanced to be the alloy choos; that is, the messenger of ceremonies; and from this, having passed through the office of perelma, or procurator of the effects of the body, he is advanced to be the bat choos.

CHOWDER-BEER, a provincial phrase of Devonshire, in England, denoting a cheap and easily prepared drink, highly commended for preventing the scurvy in long voyages, or for the cure of it where it may have been contracted. It is prepared in the following manner: Take twelve gallons of water, in which put three pounds and a half of black spruce; boil it for three hours, and having taken out the fir or spruce, mix with the liquor seven pounds of melasses, and juice boil it up; strain it through a sieve, and when milk warm put it to about four spoonfuls of yeaf to work it. In two or three days flop the bung of the cafe, and in five or six days, when fine, bottle it for drinking. Two gallons of melasses are sufficient for an hoghead of liquor; but if melasses cannot be procured, treacle or coarse sugar will answer the purpose.

CHREMENITZ, the principal of the nine-towns in Upper Hungary, situated about 68 miles north-east of Pressburg, and subject to the house of Austria. E. Long. 10. N. Lat. 48. 45.

CHREMENCRUDA, a term occurring in writers of the middle age, and expressing a custom of those times; but its signification is doubtful. It is mentioned in Leges Salicae, Tit. 61. which says, he who kills a man, and hath not wherewithal to satisfy the law or pay the fine, makes oath that he has delivered up every thing he was possessed of; the truth of which must be confirmed by the oaths of 12 other persons. Then he invites his next relations by the father's side to pay off the remainder of the fine, having first made over to them all his effects by the following ceremony. He goes into his house, and taking in his hand a small quantity of dust from each of the four corners, he returns to the door, and with his face towards the door dust with his left hand over his shoulders, and his nearest of kin. Which done, he xips to his shirt, and coming out with a pole in his hand, jumps over the hedge. His relations, whether one or several, are

CHOUS. [707] CHR

Das in prison, and the son upon the throne of Persia. He used his father tenderly at first; but afterwards called him to be put to death. This, together with his killing some of the nobility, obliged him to fly: he gave his horse the bride, which carried him into a town of the Romans, where Maurice, the emperor, received him kindly, and sent an army under Narses, which set him again upon the throne. He took Jerusalem; after this he made himself master of Libya and Egypt, and carried Carthage. Heraclius sued for peace; which was offered him on condition, That he and his subjects should deny Jesus Christ; hereupon Heraclius attacked him with success, and put him to flight. His own son purified him, and he was starved in prison in 627.

CHOUCH, in music, is when, at certain periods of a song, the whole company are to join the finger in repeating certain couplets or verses.

CHOSE, (Fr.) "a thing:" used in the common law with divers epithets: as chose local, chose translatory, and choes in action. Chose local is such a thing as is annexed to a place, as a mill and the like; chose translatory, is that thing which is moveable, and may be taken away, or carried from place to place; and chose in action is a thing incorporeal, and only a right, as an obligation for debt, annuity, &c. And generally all causes of suit for any debt, duty, or wrong, are to be accounted choses in action: and it seems, chose in action may be also called chose in sequence; because it hath no real existence, or being, nor can properly be said to be in our possession.

CHOSROES I. the Great, king of Persia, after his father Cabades, A. D. 532. He made peace with the Romans; but broke it the third year, and forced Jusfinian to a disadvantageous peace. Afterward, he was so swelled with his victories, as to bid the emperor's ambassador follow him for audience to Caucasus: but Tibereus sent an army under Jusfinian, who made himself master of the country, and put Chosroes to death in 586.

CHOSROES II. His subjects put his father Hormif-
CHR [708]  CHR

Chelsea upon this obliged to pay off the composition for the
murder. And if these (or any one of them) are not
able to pay, iterum super ilium chronencia, qui pauper
est, jadat, et ille totam legem componat. Whence it ap-
ppears, that chronencia, is the same with throwing
the duft, gathered from the four corners of the
hoafe. Goldastus and Spelman translate it viridem
herbam, "green grafts," from the German, gruen, kraut,
or from the Dutch, groen, "green," and gnrad, "grafts."
Wendelinus is of a contrary opinion, who thinks that
by this word denstar purifications approbationem, from
cherem, "pure, chaste, clean," and keuren, "to prove;"
so that it must refer to the oaths of the twelve juors.
Be this as it will, king Childebert reformed this law
by a decree, chap. 15, both because it favoured of
pagan ceremonies, and because several persons were
thereby obliged to make over all their
revenue, chrein, ofes, white frankincenfe, and fcveral other drugs
formed by a decree, chap. 15, of the adminiftration of baptifm,
confirmation, and extreme
unction, by Albert bishop of Riga.

CHRIST is also the name of a military order in Li-
bonia, instituted in 1205 by Alexander bishop of Riga.
The end of this institution was to defend the new
Christians, who were converted every day in Lisbonia,
but were perfecuted by the heathens. They wore on
their cloaks a sword with a crofs over it, whence they
were also denominated brothers of the sword.

Chri$t-Burgh, a town of Poland, near the lake
Draufen, and about three Polish miles from Marien-
burgh.

Chri$t-Church, a borough-town of Hampshire, in
England, 30 miles south-west of Winchester, near the
sea-coast. W. Long. 2. N. Lat. 50. 40. It sends two
members to parliament.

Chri$t-Tree, in botany. See Rhamnus.

Chri*stan. See Christianity and Chri*tians.

Mfi Christian King, one of the titles of the king
of France.

The French antiquariest race the origin of this ap-
pellation up to Gregory the Great, who, writing a
letter to Charles Martel, occasionally gave him that
title, which his successors have since retained.

Christian Religion, that instituted by Jesus Christ.
See Christianity.

CHRISTIANITY, the religion of Christians. The Origin of
word is analogically derived, as other abstractions from
their concretes, from the adjective Christian. This
again is derived from the name Christ, from the
word χριστός, ἵνα πνεύμα, I anoint. Christ is called the
annoned, from a custom which extensively prevailed in anj-
curity, and was originally paid to be of divine infli-
ton, of anointing persons in the facerdotal or regal
character, as a public signal of their conferation to
their important offices, and as a testimony that heav-
in itself was the guarantee of that relation which
then commenced between the persons thus conferat-
ced and their subordinates.

The disciples of Jesus, after the death of their teach-
er, had for some time been called Nazarens, from the name
Nazaréth in Galilee where he dwelt; which after-
wards became the designation of a particular sect.

They, who adopted the principles and profess the
guiled
religion which he taught, were first distinguished by
the name of Christians at Antioch. That profession,
and those doctrines, we now proceed to delineate with
as much perfisquity as the limits of our plan will ad-
mite, yet with the conciseness which a work so fo-
form and extensive requires.

the materials of which it is compos’d, be extracted or deduced. Other formulæs, or confessions of faith, may, according to the Christian, deserve more or less attention, as they are more or less immediately contained or implied in the scriptures. But whatever is not actually exprefled in, or deduced by fair and necessary conjequence from, these writings, must be regarded as merely human; and can have no other title to our affent and observation than what they derive from their conformity with the scriptures, with the dictates and feelings of a reformed and cultivated mind, or with those measures which are found expedient and useful in human life. But as those books, from whence the Christian investigates his principles of belief and rules of conduct, have been variously interpreted by different professors and commentators, these diversities have given birth to a multiplicity of different facts. It cannot, therefore, be expected, that any one who undertakes to give an account of Christianity, should comprehend all the writings and opinions which have been propagated and exhibited by historical, systematical, or polemical authors. These, if at all contained in such a work as this, should be ranged under their properarticles, whether scientifical, controversial, or biographical. It is our present business, if possible, to confine ourselves to a detail of such facts and doctrines as in the strict and primitive sense of the word, are catholic, or in other exprefions, to such as uniformly have been, and still are, recognized and admitted by the whole body of Christians.

We have already faid that these, or at leaft the greatest number of them, appeal to the scriptures of the Old and New Testament as the ultimate standard, the only infallible rule of faith and manners. If you ask them, by what authority these books claim an absolute right to determine the confidences and understandings of men with regard to what they should believe and what they should do? they will answer you, that all scripture, whether for doctrine, correction, or reproof, was given by immediate inspiration from God.

If again you interrogate them how these books, which they call Scripture, are authenticated? they reply, that the evidences by which the Old and New Testament are proved to be the Word of God, are either external or internal. The external may again be divided into direct or collateral. The direct evidences are such as arise from the nature, confciency, and probability, of the facts; and from the simplicitly, uniformity, compenance, and fidelity, of the testimonies by which they are supported. The collateral evidences, are either the same occurrences supported by Hea-then testimonies, or others which concur with and corroborate the history of Christianity. Its internal evidences arise either from its exact conformity with the character of God, from its aptitude to the frame and circumstances of man, or from those supernatural convictions and affinities which are impressed on the mind by the immediate operation of the divine Spirit. These can only be mentioned in a cursory manner in a detail too concise as the present.

Such facts as are related in the history of his religion, the Christian afferts to be not only consistent each with itself, but likewise one with another. Hence it is, that, by a series of antecedents and conjequences, they corroborate each other, and form a chain which cannot be broken but by an absolute subversion of all historical authenticity. Nor is this all; for, according to him, the facts on which Christianity is founded, not only constitute a series of themselves, but are likewise in several periods the best resources for supplying the chafms in the history of our nature, and preferring the tenor of its annals entire. The facts themselves are either natural or supernatural. By natural facts we mean such occurrences as happen or may happen from the various operations of mechanical powers, or from the interposition of natural agents without higher affi.iations. Such are all the common occurrences of history, whether natural, biographical, or civil. By supernatural facts, we mean such as could not have been produced without the interposition of Deity, or at leaft of powers superior to the laws of mechanism or the agency of embodied spirits. Among these may be reckoned the immediate change of water into wine, the instantaneous cure of diseases without the intervention of medicine, the refolution of the dead, and others of the same kind. In this order of occurrences may likewise be numbered the extraordinary talents and performances of prophetic power, where the persons by whom these extraordinary talents were displayed, could neither by penetration nor conjecture unravel the mazes of futurity, and trace the events of which they spoke from their primary causes to their remote completions. So that they must have been the passive organs of some superior Being, to whom the whole concatenation of causes and effects which operate from the origin to the consummation of nature, was obvious at a glance of thought.

It has already been hinted, that the facts which we Natural have called natural, not only agree with the analogy of human events, and corroborate each other, but in a great many emergencies nobly illustrate the history of nature in general. For this a Christian might offer the illustration of one instance, of which philosophy will not perhaps be history, able to produce any tolerable solution, without having recourse to the facts upon which Christianity is founded. For if mankind were originally descended from one pair alone, how should it have happened that long before the date of authentic history every nation had its own distinct language? Or if it be supposed, as some late philosophers have maintained, that man is an indigenous animal in every country; or, that he was originally produced in, and created for, each particular soil and climate which he inhabits; still it may be demanded, whence the prodigious multiplicity, the immense diversity of languages? Is the language of every nation intuitive, or were they dictated by exigencies, and establihed by convention? If the last of these suppositions be true, what an immense period of time must have passed? How many revolutions of material and intellectual nature must have happened? What accessions of knowledge, refinement, civilization, must human intercourse have gained before the formation and establishment even of the most simple, imperfect, and barbarous language? Why is a period so vast, obliterated so entirely as to escape the retrospect of history, of tradition, and even of fable itself; Why was the acquisition and improvement of other
arts are so infinitely distant from that of language, that 
the aera of the latter is entirely lost, whilst we can 
trace the former from their origin through the vari-
ous gradations of their progress.

These difficulties, inextricable by all the lights of 
history or philosophy, this more than Cimmerian dark-
ness, is immediately disipated by the Mofaic ac-
count of the confusion of tongues: wisely intended to 
separate the tribes of men one from another, to replen-
ish the surface of the globe, and to give its multiplied 
habitants those opportunities of improvement which 
might be derived from experiment and industry, var-
iously exerted, according to the different situations in 
in which they were placed, and the different employ-
ments which those situations dictated. Thus the time 
of nature's existence is limited to a period within the 
ken of human intellect. Thus whatever has happen-
ded might have happened during the present mode of 
things; whereas, if we deduce the origin and diversity 
of language from a period so remotely di
distant as to be 
abolutely lost, and entirely detached from all the 
known occurences and vicissitudes of time, we must 
admire the present forms and arrangements of things 
to have fulfilled perhaps for a much longer duration 
than any mechanical philosopher will allow to be pos-
ible. Other infancies equally pregnant with convic-
tion might be multiplied; but, precluded by the limits 
of our plan, we proceed to a single observation upon 
the facts which have been termed supernatural.

Of those changes which happen in sensible objects, 
fatination alone can be judge. Reason has nothing to 
do in the matter. She may draw conclusions from 
the testimonies of sense, but can never refute them.
If, therefore, our senses inform us that snow is white, 
in vain would the most learned and subtle philosopher 
endeavour to convince us that it was of a contrary 
colour. He might confound us, but never could per-
suade us. Such changes, therefore, as appear to hap-
pen in sensible objects, must either be real or fallac-
ious. If real, the miracle is admitted, if falacious, 
there must be a case of deception equally unaccount-
able from the powers of nature, and therefore equally 
miraculous. If the veracity or competency of the 
witneces be questioned, the Christian answers, that 
they must be competent, because the facts which they 
relate are not beyond their capacity to determine. 
They must likewise be faithful, because they had no 
peculiar motives for maintaining, but many for sup-
prefing or disbelieving, what they testified. Now the Chri-
Stian appeals to the whole series of history and expe-
rience, whether such a man is or can be found, as will 
offer a voluntary, solemn, and deliberate facrifice of 
truth at the shrine of caprice. But such facts as after 
a long continuance of time have been found exactly 
agreable to predictions formerly emitted, must su-
forder the fidelity of testimony, and infallibly prove 
that the event was known to the Being by whom it 
was foretold. In vain has it been urged, that proph-
ecies are ambiguous and equivocal. For though they 
may prefigure inordinate events, yet if the grand oc-
currences to which they ultimately relate, can alone 
fulfil them in their various circumstances, and in their 
utofit extent, it is plain, that the Being by whom 
they were revealed must have been actually present 
of those events, and must have had them in view when 
the predictions were uttered. For this see a learned 
and ingenious Dissertation on the Credibility of Gop-
history, by Dr M'Knight; where the evidences 
urged by the Christian in defence of his tenets, which 
appear detached and scattered through innumerable 
Volumes, are assembled and arranged in such a manner 
as to derive strength and luftre from the method in 
which they are disposed, without diminishing the 
force of each in particular. See also the works of Dr 
Hurd; confult likewise those of Newton, Sherlock 
Chandler, &c. For the evidences of those preternatu-
ral facts which have been termed miracles, the reader 
may consult a short but elegant and conclusive defence 
of these astonishing phenomena, in answer to Mr Hume, 
by the Rev. George Campbell, D. D.

It must be obvious to every reflecting mind, that Properties 
whether we attempt to form the idea of any religion common 
apriori, or contemplate those which have been already 
exhibited, certain facts, principles, or data, must be 
pre-established, from whence will result a particular 
frame of mind and course of action suitable to the 
character and dignity of that Being by whom the 
religion is enjoined, and adapted to the nature and situ-
ation of those agents who are commanded to observe it. Hence Christianit 
may be divided into creeds or doctrines, and agendas or precepts.

As the great foundation of his religion, therefore, Christian 
the Christian believes the existence and government theology. 
of one eternal and infinite God, who, for ever re-
tains in himself the cause of his own existence, and 
inhernently posses all those perfections which are com-
patible with his nature: such are, his almighty power, 
omnicient wisdom, infinite justice, benevolence good-
ness, perfect holiness, and universal presence. That Jefus Chrift is the Son of God, in whom the fulnes-
se of the Godhead dwells, by whom he created and 
governs the univerfe, exercising in his universal govern-
ment the energy of the Holy Spirit, and conducing 
all his dispensations to accomplish the designs of infi-
nite wisdom and benevolence.

The Supreme Being, though absolutely independent 
and for ever sufficient for his own beatitude, was gra-
ciously pleased to create an univerfe replete with in-
ferior intelligences, who might for ever contemplate and 
and enjoy his glory, participate his happiness, and imita-
tate his perfections. But as freedom of will is essen-
tial to the nature of moral agents, that they may co-
operate with God in their own improvement and hap-
piness, to their natures and powers are necessarily li-
imited, and by that constitution rendered peccable. 
This degeneracy first took place in a rank of intelli-
gence superior to man. But guilt is never stationary. 
Impatient of itself, and cursed with its own feelings, it 
proceeds from bad to worse, whilst the poignancy of 
it torment is increafes with the number of its perpe-
trations. Such was the situation of Satan, and his apo-

defate angels. They attempted to transfer their tur-
pitude and misery to man; and were, alas! but too 
foeful. Hence the heterogeneous and irreconcilable 
principles which operate in his nature. Hence 
that inexplicable medley of wisdom and folly, of re-
titude and error, of benevolence and malignity, of fin-
cerity and fraud, exhibited through his whole con-
duct.
The Christian is convinced, that there is and shall continue to be a society upon earth, who worship God as revealed in Jesus Christ; who believe his doctrines; who observe his precepts; and who shall be saved by his death, and by the use of these external means of salvation which he hath appointed.

These are few and simple. The sacraments of the extern-baptism and the eucharist, the interpretation and application of scripture, the habitual exercise of public and private devotion, are obviously calculated to diffuse and promote the interests of truth and virtue, by superinducing the salutary habits of faith, love, and repentance.

The Christian is firmly persuaded, that at the period which God hath appointed, and to which the purposes of providence in the various revolutions of progressive nature tend, the whole human race shall once more be free from their graves; some to supreme felicity, in the actual perception and enjoyment of their Creator’s presence; others to that consummate flame and misery, which are the native confusions of their wickedness.

The two grand principles of action, according to Christian the Christian, are, The love of God, which is the sovereign passion in every perfect mind; and the love of man, which regulates our actions according to the various relations in which we stand, whether to communities or individuals. This sacred connection can never be totally extinguished by any temporary injury. It ought to subsist in some degree even amongst enemies. It requires that we should pardon the offences of others, as we expect pardon for our own; and that we should no farther refill evil than is necessary for the preservation of personal rights and social happiness. It dictates every relative and reciprocal duty between parents and children, masters and servants, governors and subjects, friends and friends, men and men. Nor does it merely enjoin the observation of equity, but enforces it with the motive of benevolence and extensive charity, a boundless and disinterested effusion of tender affections for the whole species, which feeds their diftresses and operates for their relief and improvement. These celestial dispositions, and the different duties which are their natural exertions, are the various gradations by which the Christian hopes to attain the perfection of his nature; and the most exquisite happiness of which it is susceptible.

Such are the speculative, and such the practical principles of Christianity. From the former, its vortaries contend, that the origin, economy, and revolutions of intelligent nature alone can be rationally explained. From the latter, they assert, that the nature of man, whether considered in his individual or social capacity, can alone be conducted to its highest perfection and happiness. With the determined Atheists they fearlessly design to expostulate. For, according to them, philosophers who can deduce the origin and constitution of things from casual encounters or mechanical necessity, are capable of deducing any conclusion from any premises. Nor can a more glaring instance of absurdity be produced, than the idea of a contingent or self-originated universe. When Deists
Decorts and other sceptics upbraid them with mysterious or incompatible principles, they without hesitation deny the charge. They demand of any reasoner who admits that a being may be omnipresent without extension; or that he can impute motion upon other things whilst he himself is necessarily immovable upon what ground he charges Christianity with incompatible principles. They ask the fage, why it should be thought more extraordinary, that the Son of God should be sent to this world, that he should be a man of like passions with other men, that he should suffer and die for the relief of his degenerate creatures, than that an existence whose felicity is eternal, inherent, and infinite, should have any motive for creating beings exterior to himself? Is it not, says the Christian, equally worthy of the divine interposition to restore order and happiness where they are lost, as to communicate them where they never have been? Is not infinite goodness equally confounding in relieving misery as in diffusing health? Is not the existence of wise beings, who call evil in the world, under the tuition of an infinitely perfect Being, as inferterable as the mean exhibited by Christianity for its abolition? The death and resurrection of the Son of God, and pardon and life through him, are certainly not less reconcilable to human reason, a priori, than the existence of vice and punishment in the productions of infinite wisdom, power, and goodness; particularly when it is considered, that the virtues exerted and displayed by a perfect Being in a state of humiliation and suffering, shall ultimately be productive of the restored felicity of inferior creatures, in proportion to their glory and excellence; and that such goodness may apply the blessings which it has obtained, in whatever manner, in whatever degree, and to whomsoever it pleases, without being under any necessity to violate the freedom of moral agents, by recalling them to the paths of virtue and happiness by a mechanical and irresistible force.

It will be granted to philosophy by the Christian, that no theory of mechanical nature can be formed without presupposing sacred and established laws from which the ought rarely or never to deviate, so in fact the tenaciously pursues these general institutions, and from their constant observance refult the order and regularity of things. But he cannot admit, that the important ends of moral and intellectual improvement may be uniformly obtained by the same means. He affirms, that if the hand of God should either remain always entirely invisible, or at least only perceptible in the operation of second causes, intelligent beings would be apt in the course of time to resolve the interpositions of Deity into the general laws of mechanism, to forget their connection with nature, and consequently their dependence upon him. Hence, according to the dictates of common sense, and to the unanimous voice of every religion in every age or clime, for the purposes of wisdom and benevolence, God may not only control, but has actually controlled, the common course and general operations of nature. So that, as in the material world the law of cause and effect is generally and supremely observed for the purposes of natural subsistence and accommodation; thus dispensations and changes of that universal law are equally necessary for the advancement of moral and intellectual perfection.

But the disciple of Jesus not only contends, that no system of religion has ever yet been exhibited so conformable with itself, so congruous to philosophy and the common sense of mankind, as Christianity; he likewise avers, that it is infinitely more productive of real and sensible consolation than any other religious opinion or philosophical tenet, which has ever entered into the soul, or been applied to the heart of man. For what is death to that mind which considers eternity as the career of its existence? What are the frowns of fortune to him who claims an eternal world as his inheritance? What is the loss of friends to that heart which feels, with more than natural conviction, that it shall quickly rejoin them in a more tender, intimate, and permanent intercourse than any of which the present life is susceptible? What are the fluctuations and vicissitudes of external things to a mind which strongly and uniformly anticipates a state of ends and immovable felicity? What are misfortunes, disappointments, and insults, to a spirit which is conscious of being the original offspring and adopted child of God; which knows that its omnipotent Father will, in proper time, effectually avert the dignity and privileges of its nature? In a word, as earth is but a specé of creation, as time is not an instant in proportion to eternity, such are the hopes and prospects of the Christian in comparison of every fublime misfortune or difficulty. It is therefore, in his judgment, the eternal wonder of angels, and indelible opprobrium of man, that a religion so worthy of God, so favorable to the frame and circumstances of our nature, so conformable to all the dictates of reason, so friendly to the dignity and improvement of intelligent beings, pregnant with genuine comfort and delight, should be rejected and despised. Were there a possibility of falshood or hesitation between this and any other religion extant, he could freely trust the determination of a question so important to the candid decision of real virtue and impartial philosophy.

Mr. Gibbon, in his History of the Decline and Fall of the Roman Empire, mentions five secondary causes to which he thinks the propagation of Christianity, and all the remarkable circumstances which attended it, may be with good reason ascribed. He seeks to intimate, that Divine Providence did not act in a regular or extraordinary manner in disseminating the religion of Jesus through the world; and that, if every other argument which has been adduced to prove the sacred authority of this religion can be repaired or refuted, nothing can be deduced from this source to prevent it from sharing the same fate with other systems of superstition. The causes of its propagation were in his opinion founded on the principles of human nature and the circumstances of society. If we ascribe not the propagation of Mahometanism, or of the doctrines of Zerdust, to an extraordinary interposition of divine providence, operating by an unperceived influence on the dispositions of the human heart, and controlling and confounding the ordinary laws of nature; neither can we, upon any reasonable grounds, refer the promulgation of Christianity to such an interposition.

The
The secondary causes to which he ascribes these effects are, 1. The indolent and intolerant zeal of the Christians; derived from the Jewish religion, but purified from the narrow and unocial spirit which, instead of inviting, deterred the Gentiles from embracing the law of Moses. 2. The doctrine of a future life, improved by every additional circumstance which could give weight and efficacy to that important truth. 3. The miraculous powers ascribed to the primitive church. 4. The pure and abstract morals of the Christians. 5. The union and discipline of the Christian republic, which gradually formed an independent and increasing state in the heart of the Roman empire.

In pointing out the connection between the first of these causes and the effects which he represents as arising from it, this learned and ingenious writer observes, that the religion of the Jews does not seem to have been intended to be propagated among the Heathens, and that the conversion of profelytes was rather accidental than consistent with the purport and the general spirit of the institutions of Judaism. The Jews were, of consequence, induced to preserve themselves a peculiar people. Their zeal for their own religion was intolerant, narrow, and unocial.

In Christianity, when it made its appearance in the world, all the better part of the predominant spirit of Judaism was retained; but whatever might have a tendency to confine its influence within narrow limits was laid aside. Christians were to maintain the doctrines and adhere to the institutions of their religion with sacred fidelity. They were not to violate their allegiance to Jesus by entertaining or professing any reverence for Jupiter or any other of the Heathen deities; it was not even necessary for them to comply with the positive and ceremonial institutions of the law of Moses,—although these were acknowledged to have been of divine origin. The zeal, therefore, which their religion inculcated, was inflexible. It was even intolerant: for they were not to content themselves with professing Christianity and conforming to its laws; they were to labour with unremitting avidity, and to expose themselves to every difficulty and danger, in converting others to the same faith.

But the same circumstances which rendered it thus intolerant, communicated to it a more liberal and a less unocial spirit than that of Judaism. The religion of the Jews was intended only for a few tribes: Christianity was to become a catholic religion; its advantages were to be offered to all mankind.

All the different sects which arose among the primitive Christians uniformly maintained the same zeal for the propagation of their own religion, and the same abhorrence for every other. The Orthodox, the Ebionites, the Gnostics, were all equally animated with the same exclusive zeal, and the same abhorrence of idolatry, which had distinguished the Jews from other nations.

Such is the general purport of what Mr. Gibbon advances concerning the influence of the first of these secondary causes in the propagation of Christianity. It would be unaccountable to deny, that his statement of facts appears to be, in this instance, almost fair, and his deductions tolerably logical. The first Christians were remarkable for their detestation of idolatry, and for the generous disinterested zeal with which they laboured to convert others to the same faith. The first of these principles, no doubt, contributed to maintain the dignity and Christlike purity of Christianity; and the second to diffuse it through the world. But the facts which he relates are far less consistent throughout. He seems to represent the zeal of the first Christians as so hot and intolerant, that they could have no social intercourse with those who still adhered to the worship of Heathen deities. In this case, how could they propagate their religion? Nay, we may even ask, How could they live? If they could not mingle with the Heathens in the transactions either of peace or war, nor mingle in the marriage or the funeral of the nearest friend, if a Heathen; nor practice the elegant arts of music, painting, eloquence, or poetry; nor venture to use freely in conversation the language of Greece or Rome:—it is not easy to see what opportunities they could have of disseminating their religious sentiments. If, in such circumstances, and observing rigidly such a tenor of conduct, they were yet able to propagate their religion with such amazing success as they are said to have done; they must surely either have practiced some wondrous arts unknown to us, or have been assisted by the supernatural operation of divine power.

But all the historical records of that period, whether placed or profane, concur in testifying that the primitive Christians in general did not retire with such religious horror from all intercourse with the Heathens. They refused not to serve in the armies of the Roman empire: They appealed to Heathen magistrates, and submitted respectfully to their decisions: The Husband was often a Heathen, and, the wife a Christian; or, again, the husband a Christian, and the wife a Heathen. These are facts so universally known and believed, that we need not quote authorities in proof of them.

This respectable writer appears therefore not to have stated the facts which he produces under this head with sufficient ingenuity; and he has taken care to exaggerate and improve those which he thinks useful to his purpose with all the dazzling, delusive colours of eloquence. But had the zeal of the first Christians been so intolerant as he represents it, it must have been highly unfavourable to the propagation of their religion: all their wishes to make converts would, in that case, have been counteracted by their unwillingness to mix, in the ordinary intercourse of life, with those who were to be converted. Their zeal, and the liberal spirit of their religion, were indeed secondary causes which contributed to its propagation: but their zeal was by no means so ridiculously intolerant as this writer would have us believe; if it had, it must have produced effects directly opposite to those which he ascribes to it.

In illustrating the influence of the second of these secondary causes to which he ascribes the propagation of Christianity, Mr. Gibbon displays no less ingenuity than in tracing the nature and the effects of the first. The doctrine of a future life, improved by every additional circumstance which can give weight and efficacy to that important truth, makes a conspicuous figure in the Christian system; and it is a doctrine highly flattering to the natural hopes and wishes of the human heart.

Though the Heathen philosophers were not acquainted with this doctrine, yet to them the spirituality of the human soul, its capacity of existence in a separate state from the body, its immortality, and its
Christianity. prospect of lasting happiness in a future life, rather appeared things possible and desirable, than truths fully established upon solid grounds. These doctrines, Mr. Gibbon would persuade us, had no influence on the moral sentiments and general conduct of the Heathens. Even the philosophers, who amused themselves with displaying their eloquence and ingenuity on those splendid themes, did not allow them to influence the tenor of their lives. The great body of the people, who were occupied in pursuits very different from the speculations of philosophy, and were unacquainted with the questions discussed in the schools, were scarce ever at pains to reflect whether they consisted of material and a spiritual part, or whether their existence was to be prolonged beyond the term of the present life; and they could not regulate their lives by principles which they did not know.

In the popular superstition of the Greeks and Romans, the doctrine of a future state was not omitted. Mankind were not only flattered with the hopes of continuing to exist beyond the term of the present life; but different conditions of existence were promised or threatened, in which retributions for their conduct in human life were to be enjoyed or suffered. Some were exalted to heaven, and associated with the gods; others were rewarded with less illustrious honours, and a more moderate state of happiness, in Elysium; and those, again, who by their conduct in life had not merited rewards, but punishments, were configned to Tartarus. Such were the ideas of a future state which made a part of the popular superstition of the Greeks and Romans. But they produced only a very faint impression on the minds of those among whom they prevailed. They were not truths supported by evidence; they were not even plausible; they were a tinsel of absurdities. They had not therefore a more powerful influence on the morals, than the more refined speculations of the philosophers.

Even the Jews, whose religion and legislature were communicated from heaven, were in general, till within a very short time before the propagation of the gospel, as imperfectly acquainted with the doctrine of a future state as the Greeks and Romans. This doctrine made no part of the law of Moses. It is but darkly and doubtfully intimated through the other parts of the Old Testament. Those among the Jews who treated the sacred scriptures with the highest reverence, always denied that such a doctrine could be deduced from any thing which they taught; and maintained that death is the final dissolution of man.

The rude tribes who inhabited ancient Gaul, and some other nations not more civilized than they, entertained ideas of a future life, much clearer than those of the Greeks, the Romans, or the Jews.

Christianity, however, explained and inculcated the truth of this doctrine in all its splendour and all its dignity. It exhibited an alluring, yet not absurd, view of the happiness of a future life. It conferred new horrors on the place of punishment, and added new severity to the tortures to be inflicted, in another world. The authority on which it taught these doctrines, and displayed these views, was such as to silence inquiry and doubt, and to command implicit belief. What added to the influence of the doctrine of a future state of existence, thus explained and inculcated, was that the first Christians confidently prophesied and sincerely believed that the end of the world, the consummation of all things, was fast approaching, and that the generation then present should live to witness that awful event. Another circumstance which contributed to render the same doctrine so favourable to the propagation of Christianity was, that the first Christians dealt censure without remorse, and almost without making any exceptions, on all who died in the belief of the absurdities of Heathen superstition. Thus taught and improved with these additional and heightening circumstances, this doctrine, partly by presenting alluring prospects and exciting pleasing hopes, partly by working upon the fears of the human heart with representations of terror, operated in the most powerful manner in extending the influence of the Christian faith.

Here, too, facts are rather exaggerated, and the observations scarce fairly deduced. It must be confessed, that the speculations of the Heathen philosophers did not fully and undeniable establish the doctrine of the immortality of the human soul; nor can we presume to assert, in contradiction to Mr. Gibbon, that their arguments could impress such a conviction of this truth as might influence in a very strong degree the moral sentiments and conduct. They must, however, have produced some influence on those. Some of the most illustrious among the Heathen philosophers appear to have been so strongly impressed with the belief of the soul's immortality, and of a future state of retribution, that their general conduct was confantly and in a high degree influenced by that belief. Plato and Socrates are eminent and well known instances. And if, in such instances as these, the belief of these truths produced such conspicuous effects; it might be fairly inferred, though we had no further evidence, that those characters were far from being singular in this respect. It is a truth acknowledged as unquestionable in the history of the arts and sciences, that wherever any one person has cultivated these with extraordinary success, some among his contemporaries will always be found to have rivalled his excellence, and a number of them to have been engaged in the same pursuits. On this occasion we may venture, without hesitation, to reason upon the same principles. When the belief of the immortality of the human soul produced such illustrious patterns of virtue as a Plato and a Socrates; it must certainly have influenced the moral sentiments and conduct of many others, although in an inferior degree. We speculate, we doubt, concerning the truth of many doctrines of Christianity; many who profess that they believe them, make this profession only because they have never considered seriously whether they be true or false. But, notwithstanding this, these truths still exert a powerful influence on the sentiments and manners of society in general. Thus, also, it appears, that the doctrines of ancient philosophy concerning a future life, and even the notions concerning Olympus, Elysium, and Tartarus, which made a part of the popular superstition, did produce a certain influence on the sentiments and manners of the heathens in general. That influence was often indeed inconsiderable, and not always happy; but still it was somewhat greater than Mr. Gibbon seems willing to allow. Christians have been sometimes at pains to exaggerate the absurdities of Pagan superstition, in order that the advantages.
The advantages of Christianity might acquire new value from being contrasted with it. Here we find one who is rather disposed to be the enemy of Christianity, displaying, and even exaggerating, those absurdities for a very different purpose. But the truth may be fairly admitted: it is only when exaggerated that it can serve any purpose improper to the sacred authority of our holy religion. Mr Gibbon certainly represents the religious doctrine of the ancient Gauls, in respect to the immortality of the human soul and a future state, in too favourable a light. It is only because the whole system of superition which prevailed among those barbarians is so imperfectly known, that it has been imagined to conflict of more sublime doctrines than those of the popular superstition of the Greeks and Romans. The evidence which Mr Gibbon adduces in proof of what he affers concerning these opinions of the ancient Gauls, is partial, and far from satisfactory. They did indeed affect and believe the soul to be immortal; but this doctrine was blended among a number of absurdities much greater than those which characterize the popular religion of the Greeks and Romans. The latter was the superstition of a civilized people, among whom reason was unfolded and improved by cultivation, and whose manners were polished and liberal; the former was that of barbarians, among whom reason was, as it were, in its infancy, and who were strangers to the improvements of civilization. When hasty observers found that those barbarians were not absolutely strangers to the idea of immortality, they were moved to undue admiration; their surprife at finding what they had not expected, confused their understanding, and led them to misconceive and misrepresented. What we ought to ascribe to the savage ferocity of the character of those rude tribes, has been atributed by mistake to the influence of their belief of a future state.

In the law of Moses, it must be allowed, that this doctrine is not particularly explained nor earnestly inculcated. The author of the Divine Legation of Moses, &c. has founded upon this fact an ingenious theory, which we shall elsewhere have occasion to examine. The reasons why this doctrine was not more fully explained to the Jews, we cannot pretend to assign, at least in this place: yet we cannot help thinking, that it was more generally known among the Jews than Mr Gibbon and the author of the Divine Legation are willing to allow. Though it be not strongly inculcated in their code of laws, yet there is some reason to think that it was known and generally prevalent among them long before the Babylonish captivity; even in different passages in the writings of Moses, it is mentioned or alluded to in an unequivocal manner. In the history of the patriarchs, it appears that this doctrine was known to them; it appears to have had a strong influence on the mind of Moses himself. Was David, was Solomon, a stranger to this doctrine? We cannot here defend to very minute particulars; but surely all the efforts of ingenuity must be insufficient to torture the sacred scriptures of the Old Testament, so as to prove that they contain nothing concerning the doctrine of a future state anywhere but in the writings of the latter prophets, and that even in these it is only darkly intimated. Were the Jews, in the earlier part of their history, so totally secluded from all intercourse with other nations, that a doctrine of so much importance, more or less known Christianity to all around, could not be communicated to them? The Pharisees did admit traditions, and set upon them an undue value; yet they appear to have been confedered as the most orthodox of the different sects which prevailed among the Jews: the Sadducees were rather regarded as innovators.

But though we are of opinion, that this ingenious writer allows to the doctrine of the Greek and Roman philosophers, concerning the immortality of the human soul, as well as to the notions concerning a future state which made a part of the popular superstitions of those nations, less influence on the moral sentiments and conduct of mankind than what they really exerted; though we cannot agree with him in allowing the ideas of the immortality of the soul and of a future state, which were entertained by the Gauls and some other rude nations, to have been much superior in their nature, or much happier in their influence, than those of the Greeks and Romans; and though, in consequence of reading the Old testament, we are disposed to think that the Jews knew somewhat more concerning the immortality of the human soul, and concerning the future state in which human beings are destined to exist, than Mr Gibbon represents them to have known; yet still we are very sensible, and very well pleased to admit, that "life and immortality were brought to light through the gospel."

The doctrine of a future life, as it was preached by the first Christians, was established on a more solid basis than that on which it had been before maintained; was freed from every absurdity; and was, in short, so much improved, that its influence, which, as it was explained by Heathen poets and philosophers, must be confessed to have been in many instances doubtful, now became favourable only to the interests of piety and virtue, and to them in a very high degree. It undoubtedly contributed to the successful propagation of Christianity; for it was calculated to attract and please both the speculating philosopher and the simple unenlightened votary of the vulgar superstition. The views which it exhibited were distinc; and all was plausible and rational, and demonstrated by the fullest evidence. But the happiness which it promised was of a less sensual nature than the enjoyments which the Heathens expected on Olympus or in Elysium; and would therefore appear less alluring to those who were not very capable of refined ideas, or preferred the gratification of the senses in the present life to every other species of good. If the first Christians rejoiced in the hope of beholding all the votaries of Pagan idolatry afflicted with the torments of hell in a future state, and boasted of these hopes with inhuman exultation, they would in all probability rather irritate than alarm those whom they sought to convert from that superstition: the Heathens would be moved to regard with indignant scorn the preacher who pretended, that those whom they venerated as gods, heroes, and wise men, were condemned to a state of unpeachable and laffing torment. Would not every feeling of the heart revolt against the idea, that a parent, a child, a husband, a wife, a friend, a lover, or a mistress, but lately left, and still lamented, was consigned to eternal torments for affions and opinions which they had deemed highly agreeable to superior powers? We
We may conclude, then, with respect to the influence of this secondary cause in promoting the propagation of Christianity, that the circumstances of the Hebraic world was less favourable to that influence than Mr. Gibbon pretended; that the means by which he represents the primitive Christians, as improving its efficacy, were of some them not employed, and others rather likely to weaken than to strengthen it; and that therefore more is attributed to the operation of this cause than it could possibly produce.

The third cause, the miraculous powers of the primitive church, is with good reason represented as having conducted very often to the conviction of infidels. Mr. Gibbon's reasonings under this head are, That numerous miraculous works of the most extraordinary kind were ostentatiously performed by the first Christians: that, however, from the difficulty of fixing the period at which miraculous powers ceased to be communicated to the Christian church, and from some other circumstances, there is reason to suspect them to have been merely the pretences of imposture; but this (to use a phrase of his own) is only darkly intimated: and, lastly, that the Heathens having been happily prepared to receive them as real by the many wondrous nearly of a similar nature to which they were accustomed in their former superstition, the miracles which the first Christians employed to give a sanction to their doctrines, contributed in the most effectual manner to the propagation of Christianity.

In reply to what is here advanced, it may be suggested, that the miracles recorded in the New Testament, as having been performed by the first Christians when engaged in propagating their religion, as well as a number of others recorded by the Fathers, are established as true, upon the most indubitable evidence which human testimony can afford for any fact. An ingenious Scotch writer *, who was fond of employing his ingenuity in undermining truths generally received, has endeavoured to prove that no human testimony, however strong and unexceptionable, can afford sufficient evidence of the reality of a miracle. But his reasonings on this head, which once excited doubt and wonder, have been since completely refuted; and mankind still continue to acknowledge, that though we are all liable to mistakes and capable of deceit, yet human testimony may afford the most convincing evidence of the most extraordinary and even supernatural facts. The reader will not expect us to enter, in this place, into a particular examination of the miracles of our Saviour, and his apostles, and the primitive church. An enquiry into these will be a capital object in another part of this work (Theology). We may here consider it as an undeniable and a generally acknowledged fact, that a certain part of those miracles were real. Such as were real, undoubtedly contributed, in a very eminent manner, to the propagation of Christianity; but they are not to be ranked among the natural and secondary causes.

It is difficult to distinguish at what period miraculous gifts ceased to be conferred on the members of the primitive church; yet we may distinguish, if we take pains to inquire with minute attention, at what period the evidence ceases to be satisfactory. We can also by considering the circumstances of the church through the several stages of its history, form some judgment concerning the period during which the gifts of prophecy, and speaking with tongues, and working miracles, were most necessary to Christians to enable them to avert the truth and dignity of their religion. The Heathens were strangers to pretended miracles and prophecies, and other seeming interpositions of superior beings, disturbing the ordinary course of nature and of human affairs: but the miracles to which they were familiarised had been so often detected to be tricks of imposture or pretences of mad enthusiasm, that, instead of being prepared to witness or to receive accounts of new miracles with easy credulity, they must have been in general disposed to view them with jealousy and suspicion. Besides, the miracles to which they had been accustomed, and those performed by the apostles and the first preachers of Christianity, were directly contradictory; and therefore the one could receive no assistance from the other.

Yet we must acknowledge, notwithstanding what we have above advanced, that as disagreements with respect to the principles and institutions of their religion very early arose among Christians; so they, likewise sought to extend its influence, at a very early period, by the use of pious frauds. Pious frauds, too, appear to have sometimes served the immediate purposes for which they were employed, though eventually they have been highly injurious to the cause of Christianity.

We conclude, then, that Christianity was indebted to the influence of miracles in a considerable degree for its propagation: but that the real miracles of our Saviour and his apostles, &c. were not among the secondary causes of its success: that the Heathens who were to be converted were not very happily prepared for receiving the miracles of the gospel with blind credulity: that, as it is possible to discern between sufficient and insufficient evidence, so it is not more difficult to distinguish between true and false miracles: and, lastly, that false miracles were soon employed by Christians as engines to support and propagate their religion, and perhaps not unsuccessfully; but were, upon the whole, more injurious than serviceable to the cause which they were called in to maintain.

The fourth of this series of secondary causes, which this author thinks to have been adequate to the propagation of Christianity, is the virtues of the primitive Christians. These he is willing to attribute to other and less generous motives, rather than to the pure influence of the doctrines and precepts of their religion.

The first converts to Christianity were most of them from among the lowest and most worthless characters. The wife, the mighty, and those who were distinguished by generous virtues, were in general perfectly satisfied with their present circumstances and future prospects. People whose minds were naturally weak, unenlightened, or oppressed with the sense of atrocious guilt, and who were infamous or outcasts from society, were eager to grasp at the hopes which the gospel held out to them.

When, after enlisting under the banner of Christ, they began to consider themselves as "born again to newness of life; remorse and fear, which evenly prevail over weak minds; selfish hopes of regaining their reputation, and attainting to the honours and happiness of those mansions which Jesus was said to have gone to prepare;
The principles, too, from which the virtues of the first Christians originated, were not peculiarly mean and filthy; nay, they seem to have been uncommonly sublime and disinterested. Remove in the guilty mind is a natural and reasonable sentiment; the desire of happiness in every human breast is equally so. It is uncandid to cavil against the first Christians for being, like the rest of mankind, influenced by these sentiments. And when we behold them overlooking temporary poffessions and enjoyments, extending their views to futurity, and "living by faith;" when we observe them "doing good to those who hated them, blefling those who cursed them, and praying for those by whom they were defpised," the reader will not deny their virtues to have been of the most generous and disinterested kind.

We allow, then, that the virtues of the first Christians must have contributed to the propagation of their religion: but it is with pain that we observe this respectable writer studiously labouring to misrepresent the principles from which those virtues arose; and not only the principles from which they arose, but also their importance in society.

The fifth cause was the mode of church government. The Church adopted by the first Christians, by which they were knit together in one society; who preferred the church and its interests to their county and civil concerns. We wish to deny, that the mutual attachment of the primitive Christians contributed to spread the influence of their religion; and the order which they maintained, in conformance of being animated with this spirit of brotherly love, and with such ardent zeal for the glory of God, must have doubt have produced no less happy effects among them than order and regularity produce on every other occasion on which they are strictly observed. But whether the form of church-government, which was gradually established in the Church, was actually the happiest that could possibly have been adopted; or whether, by establishing a distinct society, with separate interests, within the Roman empire; it contributed to the dissolution of that mighty fabric, we cannot here pretend to decide. These are subjects of diffision, with respect to which we may with more propriety endeavour to satisfy our readers elsewhere.

From the whole of this review of what Mr. Gibbon generally has so speciously advanced concerning the influence of conclusion the five secondary causes in the propagation of the gospel, we think ourselves warranted to conclude that the zeal of the first Christians was not, as he represents it, intolerant: that the doctrine of the immortality of the human soul was somewhat better understood in the heathen world, particularly among the Greeks and Romans and the Jews, than he represents it to have been; and that an influence more happily than what he ascribes to it: That the additional circumstances by which, he tells us, the first preachers of Christianity improved the effects of this doctrine, were far from being calculated to allure converts: That the heathens, therefore, were not quite so well prepared for an eager reception of this doctrine as he would persuade us they were; and, of consequence, could not be influenced by it in so considerable a degree, in their conversion: That real, unquestionable miracles, performed by our Saviour, by his apostles, and
CHRISTIANS, those who profess the religion of Christ. See Christianitv and Messiah.—The name Christian was first given at Antioch in the year 42 to such as believed in Christ, as we read in the Acts: till that time they were called disciples.

The first Christians distinguished themselves in the most remarkable manner by their conduct and their virtues. The faithful, whom the preaching of St Peter had converted, hearkened attentively to the exhortations of the Apostles, who failed not carefully to instruct them, as persons who were entering upon an entirely new life. They went every day to the temple with one heart and one mind, and continued in prayers; doing nothing different from the other Jews, because it was yet not time to separate from them. But they made a still greater progress in virtue: for they fold all that they possessed, and distributed their goods in proportion to the wants of their brethren. They set their meat with gladness and singleness of heart, praising God, and having favour with all the people. St Chrysostom, examining from what source the eminent virtue of the first Christians flowed, ascribes it principally to their devoting themselves of their possessions; For "(says that father) persons from whom all that they have is taken away, are not subject to sin: whereas, whoever has large possessions, wants not a devil or a tempter to draw him into hell by a thousand ways."

The Jews were the first and the most inveterate enemies of the Christians had. They put them to death as often as they had it in their power: and when they revolted against the Romans in the time of the emperor Adrian, Barchochbas, the head of that revolt, employed against the Christians the most rigorous punishments to compel them to blaspheme and renounce Jesus Christ. And we find that, even in the third century, they endeavoured to get into their hands Christian women, in order to torture and stone them in their synagogues. They forced the Christians solemnly three times a-day in their synagogues, and their rabbins would not suffer them to converse with Christians upon any occasion. Nor were they contented to hate and detest them, but they dispatched emissaries all over the world to defame the Christians, and spread all sorts of calumnies against them. They accused them, among other things, of worshipping the sun and the head of an ass. They reproached them with idleness, and being an useless race of people. They charged them with treason, and endeavouring to erect a new monarchy against that of the Romans. They affirmed, that, in celebrating their mysteries, they used to kill a child and eat its flesh. They accused them of the most shocking iniquities, and of intemperance in their feasts of charity. But the lives and behaviour of the first Christians were sufficient to refute all that was said against them, and evidently demonstrated that these accusations were mere calumnies and the effect of inveterate malice.

Pliny the younger, who was governor of Pontus and Bithynia between the years 103 and 105, gives a very particular account of the Christians in that province, in a letter which he wrote to the emperor Trajan, of which the following is an extract: "I take the liberty, Sir, to give you an account of every difficulty which arises to me. I have never been prefect at the examination of the Christians; for which reason I know not what questions have been put to them, nor in what manner they have been punished. My behaviour towards those who have been accused to me has been this: I have interrogated them, in order to know whether they were really Christians. When they have confessed it, I have repeated the same question two or three times, threatening them with death if they did not renounce this religion. Those who have persisted in their confession, have been, by my order, led to punishment. I have even met with some Roman citizens guilty of this perversity, whom, in regard to their quality, I have set apart from the rest, in order to send them to Rome. These persons declare, that their whole crime, if they are guilty, consists in this; that, on certain days, they assemble before sun-rise, to sing alternately the praises of Christ, as of a God, and to oblige themselves, by the performance of their religious rites, not to be guilty of theft, or adultery, to observe inviolably their word, and to be true to their truth. This deposition has obliged me to endeavour to inform myself still farther of this matter, by putting to the torture two of their women-servants, whom they call despenfieres; but I could learn nothing more from them, than that the superstitious of these people is as ridiculous as their attachment to it is astonishing."

There is extant a justification, or rather panegyric, of the Christians, pronounced by the mouth of a Pagan prince. It is a letter of the emperor Antoninus, written in the year 152, in answer to the States of Asia, who had accused the Christians of being the cause of some earthquakes which had happened in that part of the world. The emperor advises them to take care, left, in torturing and punishing those whom they accused of Atheism (meaning the Christians,
Chriilians), they should render them more obdurate, instead of prevailing upon them to change their opinion; since their religion taught them to suffer with pleasure for the sake of God." As to the earthquakes which had happened, he puts them in mind, "that they themselves are always discouraged, and link under such misfortunes; whereas the Christians never discovered more cheerfulness and confidence in God than upon such occasions." He tells them, "that they pay no regard to that religion, neither to the sacrifices of the Eternals, and, because the Christians honour and adore Him, therefore they are jealous of them, and persecute them even to death." He concludes: "Many of the governors of provinces have formerly written to my father concerning them; and his answer always was, that they should not be molested or disturbed, provided they quietly submitted to the authority of the government. Many persons have likewise consulted me upon this affair, and I have returned the same answer to them all; namely, that if any one accuses a Christian merely on account of his religion, the accused person shall be acquitted, and the accuser himself punished." This ordinance, according to Eusebius, was publicly fixed up at Ephesus in an assembly of the states. It is no difficult matter to discover the causes of the many persecutions, to which the Christians were exposed during the three first centuries. The purity of the Christian morality, directly opposite to the corruption of the Pagans, was double to one of the most powerful motives of the public averion. To this may be added, the many calumnies unjustly spread about concerning them by their enemies, particularly the Jews. And this occasioned so strong a prejudice against them, that the Pagans condemned them without inquiring into their doctrine, or permitting them to defend themselves. Besides, their worshipping Jesus Christ, as God, was contrary to one of the most ancient laws of the Roman empire, which expressly forbade the acknowledging of any God which had not been approved by the senate.

But notwithstanding the violent opposition made to the establishment of the Christian religion, it gained ground daily, and very soon made a surprizing progress in the Roman empire. In the third century, there were Christians in the camp, in the senate, in the palace; in short, everywhere, both in the temples and the theatres: they filled the towns, the country, the islands. Men and women, of all ages and conditions, and even those of the first dignities, embraced the faith; insomuch that the Pagans complained that the revenues of their temples were ruined. They were in such great numbers in the empire, that (as Tertullian expresses it,) were they to have retired into another country, they would have left the Romans only a frightful solitude.

The primitive Christians were not only remarkable for the practice of every virtue; they were also very eminently distinguished by the many miracles, gifts and graces bestowed by God upon them. "Some of the Christians (says Irenæus) drive out devils, not in appearance only, but so as that they never return; whence it often happens, that those who are possessed of evil spirits embrace the faith and are received into the church. Others know what is to come, feer visions, and deliver oracles as prophets. Others heal the sick by laying their hands on them, and restore them to perfect health: and we find some who even raise the dead.—It is impossible to reckon up the gifts and graces which the church has received from God—what they have freely received they as freely bestow. They offer these gifts by prayer alone, and invocation, of the name of Jesus Christ, without any mixture of enchantment or superstition."

We shall here subjoin the remarkable story, attested by pagan authors themselves, concerning the Christian legion in the army of the emperor Marcus Aurelius. That prince having led his forces against the Quadi, a people on the other side of the Danube, was surprised and hemmed in by the enemy in a disadvantageous place, and where they could find no water. The Romans were greatly embarrassed, and, being pressed by the enemy, were obliged to continue under arms, exposed to the violent heat of the sun, and almost dead with thirst; when, on a sudden, the clouds gathered, and the rain fell in great abundance. The soldiers received the water in their bucklers and helmets, and satisfied both their own thirst and that of their horses. The enemy, presently after, attacked them; and so great was the advantage they had over them, that the Romans must have been destroyed, but had not heaven again interposed by a violent storm of hail, mixed with lightning, which fell on the enemy, and obliged them to retreat. It was found afterwards, that one of the legions, which consisted of Christians, had by their prayers, which they offered up on their knees before the battle, obtained this favour from heaven: and from this event that legion was firnamed the Thundering Legion. See, however, the criticism of Mr. Moyle on this story in his Works, vol. ii. p. 31—390. See also Mofheim’s Church History, vol. i. p. 124.

Such were the primitive Christians, whose religion has by degrees spread itself over all parts of the world, though not with equal purity in all. And though, by the providence of God, Mahometans and Idolaters have been suffered to possess themselves of those places in Greece, Asia, and Africa, where the Christian religion formerly most flourished; yet there are still such remains of the Christian religion among them as to give them opportunity sufficient to be converted. For, in the dominions of the Turk in Europe, the Christians make two thirds parts at least of the inhabitants; and in Constantinople itself there are above twenty Christian churches, and above thirty in Thessalonica. Philadelphia, now called Alus-Shahir, has no fewer than twelve Christian churches. The whole island of Chio is governed by Christians; and some islands of the Archipelago are inhabited by Christians only. In Africa, besides the Christians living in Egypt, and in the kingdom of Congo and Angola, the islands upon the western coasts are inhabited by Christians; and the vast kingdom of Abyssinia, supposed to be as big as Germany, France, Spain, and Italy, put together, is possessed by Christians. In Asia, most part of the empire of Russia, the countries of Circassia and Mingrelia, Georgia, and Mount Libanus, are inhabited only by Christians. In America, it is notorious that the Christians are very numerous, and spread over most parts of that vast continent.

 Chr. of St. John, a seat of Christians very numerous in Baffara and the neighbouring towns: they formerly
CHRISTIANA, a town of Norway, in the province of Agderhusa, situated on a bay of the sea. E. Long. 10° 15'. N. Lat. 59° 30'.

CHRISTIANOPLE, a port-town of Sweden, situated on the Baltic Sea, in the territory of Blecking, and province of South Gothland. E. Long. 15° 40'. N. Lat. 57°.

CHRISTIANSTAD, a strong fortified town of Sweden; situated in the territory of Blecking and province of South Gothland. It was built in 1614 by Christian IV. king of Denmark, when this province belonged to the Danes; and finally ceded to the Swedes by the peace of Roskild in 1658. The town is small but neatly built, and is esteemed the strongest fortres in Sweden. The houses are all of brick, and mosty flueced white. It stands in a marshy plain close to the river Helge-a, which flows into the Baltic at Ahus about the distance of 20 miles, and is navigable only for small craft of seven tons burden. English vessels annually resort to this port for alum, pitch, and tar. The inhabitants have manufactures of cloth and flake stuffs, and carry on a small degree of commerce. E. Long. 14° 40'. N. Lat. 56° 30'.

CHRISTINA, daughter of Gustavus Adolphus king of Sweden, born in 1626; and succeeded to the crown in 1632, when only seven years of age. This princess discovered even in her infancy, what afterwards expressed in her memoirs, an invincible antipathy for the employments and conversation of women; and she had the natural awkwardness of a man with respect to all the little works which generally fall to their share. She was on the contrary, fond of violent exercises, and such amusements as consist in feats of strength and activity. She had also both ability and taste for abstracted speculations; and amused herself with language and the sciences, particularly that of legislature and government. She derived her knowledge of ancient history from its source: and Polybius and Thucydides were her favourite authors. As she was the sovereign of a powerful kingdom, it is not strange that almost all the princes in Europe aspired to her bed. Among others, were the Prince of Denmark, the Elector Palatine, the Elector of Brandenburg, the king of Spain, the king of the Romans, Don John of Austria; Sigismund of Rockocci, count and general of Cauffia; Stanislaus king of Poland; John Callimur his brother; and Charles Gustavus duke of Deux Ponts, of the Bavarian Palatinate family, son of her father the great Gustavus's sister, and consequently her first cousin. To this nobleman, as well as to all his competitors, she faintly refused her hand; but she caused him to be appointed her successor by the slates. Political interests, differences of religion, and contrariety of manners, furnished Christina with pretences for rejecting all her suitors; but her true motives were the love of independence, and a strong aversion she had conceived, even in her infancy, from the marriage yoke. "Do not force me to marry (said she to the slates); for if I should have a son, it is not more probable that he should be an Augustus than a Nero."

An accident happened in the beginning of her reign which gave her a remarkable opportunity of displaying the strength and equanimity of her mind. As she was at the chapel of the castle of Stockholm, sitting at divine service with the principal lords of her court, a poor wretch, who was disordered in his mind, came to the place with a design to assassinate her. This man, who was preceptor of the college, and in the full vigour of his age, chose, for the execution of his design, the moment in which the assembly was performing what in the Swedish church is called an act of recollection; a silent and separate act of devotion, performed by each individual kneeling and hiding the face with the hands. Taking this opportunity, he rushed through the crowd, and mounted a balloontrade within which the queen was upon her knees. The Baron Braki, chief justice of Sweden, was alarmed, and cried out; and the guards crost their partisans, to prevent his coming further: but he struck them furiously on one side; leaped over the barrier; and, being then close to the queen, made a blow at her with a knife which he had concealed without a sheath in his sleeve. The queen avoided the blow, and pulled the captain of her guards, who instantly threw himself upon the assassin, and feized him by the hair. All this happened in less than a moment of time. The man was known to be mad, and therefore nobody supposed he had any accomplices; they therefore contented themselves with locking him up, and the queen returned to her devotion without the least emotion that could be perceived by the people, who were much more frightened than herself.

One of the great affairs that employed Christina while she was upon the throne, was the peace of Westphalia, in which many clashing interests were to be reconciled, and many claims to be ascertained. It was concluded in the month of October 1648. The success of the Swedish arms rendered Christina the arbitrers of this treaty; at least as to the affairs of Sweden, to which this peace confirmed the possession of many important countries. No public event of importance took place during the rest of Christina's reign; for there were neither wars abroad, nor troubles at home. This quiet might be the effect of chance; but it might also be the effect of a good administration,
during this accident, her recollection was such, that the moment her lips were above water, she cried, out, "Take care of the Admiral." When she was got out of the water, she discovered no emotion either by her gesture or countenance; and she disdained the same day in public, where she gave a humorous account of her adventure.

But, though at first she was fond of the power and splendor of royalty, yet she began at length to feel that it embarrassed her; and the same love of independence and liberty which had determined her against marriage, at last made her weary of her crown. As, after her first disgust, it grew more and more intolerable to her, she resolved to abdicate; and, in 1652, communicated her resolution to the senate. The senate zealously remonstrated against it; and was joined by the people; and even by Charles Gustavus himself, who was to succeed her: she yielded to their importunities, and continued to sacrifice her own pleasure to the will of the public till the year 1654, and then she carried her design into execution. It appears by one of her letters to M. Canut, in whom she put great confidence, that she had meditated this project for more than eight years; and that she had communicated it to him five years before it took place.

The ceremony of her abdication was a mournful solemnity, a mixture of pomp and sadness, in which scarce any eyes but her own were dry. She continued firm and composed through the whole; and, as soon as it was over, prepared to remove into a country more favourable to science than Sweden was. Concerning the merit of this action, the world has always been divided in opinion; it has been condemned alike both by the ignorant and the learned, the trifler and the sage. It was admired, however, by the great Condé: "How great was the magnanimity of this prince (said he), who could so easily give up that for which the rest of mankind are continually destroying each other, and which so many throughout their whole lives, pursue without attaining!" It appears by the works of St. Evermond, that the abdication of Christina was at that time the universal topic of speculation and debate in France. Christina, besides abdicating her crown, abjured her religion: but this act was universally approved by one party and condemned by another; the Papists triumphed, and the Protestants were offended. No prince, after a long imprisonment, ever showed so much joy upon being restored to his kingdom, as Christina did in quitting hers. When she came to a little brook, which separates Sweden from Denmark, she got out of her carriage; and leaping to the other side, cried out in a transport of joy, "At last I am free, and out of Sweden, whither I hope I shall never return." She disinherited her women, and laid by the habit of her sex: "I would become a man (said she); yet I do not love men because they are men, but because they are not women." She made her abjuration at Brussels; where she saw the great Condé, who, after his defection, made that city his asylum. "Cousin (said she), who would have thought ten years ago, that we should have met at this distance from our countries!

The inconstancy of Christina's temper appeared in her going continually from place to place: from Brus-
Bayle was also threatened for having said that the Christina letter which Chriflina wrote, upon the revocation of the edict of Nantes, was "a remain of Proteftantism;" but he made his peace by apologies and submission. See the article Bayle.

Upon the whole, it appears to have been an uncommon mixture of faults and great qualities; which, however it might excite fear and reftlefs, was by no means amiable. She had wit, taste, parts, and learning; she was indefatigable upon the throne; great in private life; firm in misfortunes; impatient of contradiction; and, except in her love of letters, infconftant in her inclinations. The moft remarkable infance of this ficklenefs is, That after she had abdicated the crown of Sweden, she intrigued for that of Poland. She was, in every action and purpofe, violent and ardent in the higheft degree; impetuous in her defires, dreadful in her relentment, and fickle in her conduct. She fays of herfelf, "that she was minutrafh, ambitious, pafiionate, haughty, impatient, contemptuous, fafyrical, incredulous, undevout, of an ardent and violent temper, and extremely amorous;" a disposition, however, to which, if she may be believed, her pride and her virtufe were always fuperior. In general, her failings were thofe of her fex, and her virtues the virtues of ours.

Santa-CHRISTINA, one of the M Arquesas Islands.

CHRISTMAS-DAY, a festival of the Chrifiian church; obferved on the 25th of December, in memory of the nativity or birth of Jesus Christ. As to the antiquity of this festival, the ftirt footsteps we find of it are in the fecond century, about the time of the emperor Commodus. The decretal epifoles indeed carry it up a little higher; and fay that Telephorus, who lived in the reign of Antoninus Pius, ordered divine service to be celebrated, and an angelfcal hymn to be ftung, the night before the nativity of our Saviour. However, that it was kept before the times of Conflantine we have a melancholy proof: for while the perfecutions raged under Dioclefas, who then kept his courft at Nicomedia, that prince, among other acts of cruelty, finding multitudes of Chrifilians assembled together to celebrate Chrift's nativity, commanded the church-doors where they were met to be ftung, and fire to be put to it, which, in a short time, reduced them and it to ashes.

CHRISTOPHER'S, St. one of the Caribbea Islands, in America, lying to the north-weft of Nevis, and about 60 miles weft of Antigua. It was formerly inhabited by the French and Engliſh; but, in 1712, it was ceded entirely to the latter. In 1782, it was taken by the French, but refcued by Britain at the peace. It is about 20 miles in breadth and feven in length; and has high mountains in the middle, whence rivulets run down. Between the mountains are dreadful rocks, horrid precipices, and thick woods; and in the south-weft part of the island, hot sulphurous springs at the foot of them. The air is good; the falt, light, fandy, and fruitful; but the island is fubjeft to hurricanes. The produce is chiefly fugar, cotton, gin­ger, indigo, and the tropical fruits. W. Lon. 62. 52. N. Lat. 17. 20.

CHRIOASTACES, in natural history, a genus of pellicud gems, comprehending all thofe of variable colours, as viewed in different lights; of which kinds are
CHROMATIC, a kind of music which proceeds by several semitones in succession. The word is derived from the Greek χρωματικ, which signifies colour. For this denomination several causes are assigned, of which none appear certain, and all equally unsatisfactory. Instead, therefore, of fixing upon any, we shall offer a conjecture of our own; which, however, we do not impose upon the reader as more worthy of his attention than any of the former. χρωματικ may perhaps not only signify a colour, but that shade of a colour by which it melts into another, or what the French call nuance. If this interpretation be admitted, it will be highly applicable to semitones; which being the smallest interval allowed in the diatonic scale, will most easily run one into another. To find the reasons assigned by the ancients for this denomination, and their various divisions of the chromatic species, the reader may have recourse to the same article in Rolfeau’s Musical Dictionary. At present, that species consists in giving such a procedure to the fundamental bass, that the parts in the harmony, or at least some of them may proceed by semitones, as well in rising as descending; which is most frequently found in the minor mode, from the alterations to which the sixth and seventh note are subjected, by the nature of the mode itself.

The successive semitones used in the chromatic species are rarely of the same kind; but alternately major and minor, that is to say, chromatic and diatonic: for the interval of a minor tone contains a major or chromatic semitone, and another which is major or diatonic; a measure which temperament renders common to all tones: so that we cannot proceed by two minor semitones which are conjunctive in succession, without entering into the enharmonic species: but two major semitones twice follow each other in the chromatic order of the scale.

CHROMATICS;

That part of optics which explains the several properties of the colours of light, and of natural bodies.

Before the time of Sir Isaac Newton, we find no hypothesis concerning colours of any consequence. The opinions of the old philosophers, however, we shall briefly mention, in order to gratify the curiosity of our readers. The Pythagoreans called colour the superficies of body. Plato said that it was a flame flowing from them. According to Zeno, it is the first configuration of matter; and Aristotle said it was that which moved bodies actually transparent. Defartes asserted, that colour is a modification of light; but he imagined, that the difference of colour proceeds from the prevalence of the direct or rotary motion of the particles of light. Father Grimaldi, Dechales, and many others, thought the differences of colour depended upon the quick or slow vibrations of a certain elastic medium filling the whole universe. Rohault imagined, that the different colours were made by the rays of light entering the eye at different angles with respect to the optic axis; and from the phenomenon of the rainbow, he pretended to calculate the precise quantity of the angle that constituted each particular colour. Lastly, Dr. Hook, the rival of Newton, imagined that colour is caused by the refraction of the oblique or uneven pulse of light; and this being capable of no more than two varieties, he concluded there could be no more than two primary colours.

In the year 1666, Sir Isaac Newton began to investigate this subject; and finding the coloured image of the sun, formed by a glass prism, to be of an oblong and not of a circular form, as, according to the laws of refraction, it ought to be, he began to conjecture that light is not homogeneal; but that it consists of rays, some of which are much more refrangible than others. See this discovery fully explained and ascertained under the article Optics.

This method of accounting for the different colours of bodies, from their reflecting this or that kind of rays most copiously, is so easy and natural, that Sir Isaac's system quickly overcame all objections, and to

CHR [ 723 ]
CHROMATICS.

this day continues to be almost universally believed. It is now acknowledged, that the light of the sun, which to us seems perfectly homogeneal and white, is composed of no fewer than seven different colours, viz. red, orange, yellow, green, blue, purple, and violet or indigo. A body which appears of a red colour, has the property of reflecting the red rays more powerfully than any of the others; so of the orange, yellow, green, &c. A body which is of a black colour, instead of reflecting, absorbs all or the greatest part of the rays that fall upon it; and, on the contrary, a body which appears white, reflects the greatest part of the rays indiscriminately, without separating the one from the other.

The foundation of a rational theory of colours being thus laid, it next became natural to inquire, by what peculiar mechanism in the structure of each particular body it was fitted to reflect one kind of rays more than another? This Sir Isaac Newton attributes to the density of these bodies. Dr Hooke had remarked, that thin transparent substances, particularly water and soap blown into bubbles, exhibited various colours according to their thiness, though, when they have a considerable degree of thiness, they appear colourless; and Sir Isaac himself had observed, that as he was compressing two prisms hard together, in order to make their sides (which happened to be a little convex) to touch one another, in the place of contact they were both perfectly transparent, as if they had been but one continued piece of glass. Round the point of contact, where the glasses were a little separate from each other, rings of different colours appeared. To observe more nicely the order of the colours produced in this manner, he took two object-glasses; one of them a plano-convex one belonging to a 14 feet reflecting telescope, and the other a large double convex one for a telecope of about 50 feet; and laying the former of them upon the latter, with its plain side downwards, he pressed them slowly together; by which means the colours very soon emerged, and appeared distinct to a considerable distance. Next to the pellucid central spot, made by the contact of the glasses, succeeded blue, white, yellow, and red. The blue was very little in quantity, nor could he discern any violet in it; but the yellow and red were very copious, extending about as far as the white, and four or five times as far as the blue. The next circuit immediately surrounding these, consisted of violet, blue, green, yellow, and red: all these were copious and vivid, except the green, which was very little in quantity, and seemed more faint and dilute than the other colours. Of the other four, the violet was the least in extent; and the blue less than the yellow or red. The third circle of colours was purple, blue, green, yellow, and red. In this the purple seemed more red-diff than the violet in the former circuit and the green was more conspicuous; being as brisk and copious as any of the other colours, except the yellow; but the red began to be a little faded, inclining much to purple. The fourth circle consisted of green and red; and of these the green was very copious and lively, inclining on the one side to blue, and on the other to yellow; but in this fourth circle there was neither violet, blue, nor yellow, and the red was very imperfect and dirty.

All the succeeding colours grew more and more imperfect and dilute, till after three or four revolutions they ended in perfect whiteness.

As the colours were thus found to vary according to the different distances of the glass-plates from each other, our author thought that they proceeded from the different thinesses of the plate of air intercepted between the glasses; this plate of air being, by the mere circumstance of thiness or thiness, dispensed to reflect or transmit this or that particular colour. From this he concluded, as already observed, that the supposed colours of all natural bodies depended on their density, or the bigness of their component particles. He also constructed a table, wherein the thickness of a plate necessary to reflect any particular colour was expressed in parts of an inch divided into 1,000,000 parts.

Sir Isaac Newton pursuing his discoveries concerning colours by reflecting the colours of thin substances, found that the same reflection were also produced by plates of a considerable thickness. There is no glass or speculum, he observes, how well polished soever, but, besides the light which it refracts or reflects regularly, scatters every irregularly a faint light; by means of which the polished surface, when illuminated in a dark room by a beam of the sun's light, may easily be seen in all portions of the eye. It was with this scattered light that the colours in the following experiments were produced.

The fun shining into his darkened chamber through a hole in the shutter one inch wide, he let the beam of light fall perpendicularly upon a glass speculum, concave on one side and convex on the other, ground to a sphere of five feet eleven inches radius, and quicksilvered over on the convex side. Then, holding a quire of white paper at the centre of the sphere, to which the speculums were ground, in such a manner that the beam of light might pass through a little hole made in the middle of the paper, to the speculum, and thence be reflected back to the same hole, he observed on the paper four or five concentric rings of colours, like rainbows surrounding the spot, very much like those which appeared in the thin plates abovementioned, but larger and fainter. These rings, as they grew larger and larger, became more dilute, so that the fifth was hardly visible; and yet sometimes, when the sun shone very clear, there appeared faint traces of a sixth and sevenths.

We have already taken notice, that the thin plates colours by made use of in the former experiments reflected some refracted kinds of rays in particular parts, and transmitted and reflection coloured others in the same parts. Hence the coloured rings appeared variously dispensed, according as they were viewed by transmitted or reflected light; that is, according as the plates were held up between the light and the eye, or not. For the better understanding of which we subjoin the following table, wherein on one side are mentioned the colours appearing on the plates by reflected light, and on the other those which were opposite to them, and which became visible when the glasses were held up between the eye and the window.

We have already observed, that the centre, when the glasses were in full contact, was perfectly transparent. This spot, therefore, when viewed by reflected light,
appeared black, because it transmitted all the rays: and for the same reason it appeared white when viewed by transmitted light.

The colours of the rings produced from reflection by the thick plates, followed the order of those produced by transmission through the thin ones: and by the analogy of their phenomena with those produced from the thin plates, Sir Isaac Newton concluded that they were produced in a similar manner. For he found, that if the quicksilver was rubbed off from the back of the speculum, the glafs alone would produce the same rings, but much more faint than before; so that the phenomenon did not depend upon the quicksilver, except as far as, by increasing the reflection at the back of the glafs, it increased the light of the coloured rings. He also found that a speculum of metal only, produced none of those rings; which made him conclude, that they did not arise from one surface only, but depended on the two surfaces of the plate of glafs of which the speculum was made, and upon the thickness of the glafs between them.

From these experiments and observations, it will be easy to understand the Newtonian theory of colours. Every substance in nature seems to be transparent, provided it is made sufficiently thin. Gold, the most dense substance we know, when reduced into thin leaves, transmits a bluish-green light through it. If, therefore, we suppose any body, gold, for instance, to be divided into a vast number of plates so thin as to be almost perfectly transparent, it is evident that all or greatest part of the rays will pass through the upper plates, and when they lose their force will be reflected from the under ones. They will then have the same number of plates to pass through which they had penetrated before; and thus, according to the number of those plates through which they are obliged to pass, the object appears of this or that colour, just as the rings of colours appeared different in the experiment of the two plates, according to their distance from one another, or the thickness of the plate of air between them.

This theory is adopted by Edward Hicsey Delaval, in his Experimental Inquiry into the cause of the changes of colours in opaque and coloured bodies. He endeavours to confirm it by a number of experiments on the infusions of flowers of different colours, which his strongest arguments seem to be those derived from the different tinges given to glafs by metallic substances. Here he observes, that each metal gives a tinge according to its specific density: the more dense metals producing the less refrangible colours, and the lighter ones those colours which are more easily refrangible. Gold, which is the densest of all metals, imparts a red colour to glafs, whenever it can be divided into particles so minute, that it is capable of being mixed with the materials of which glafs is made. It seems indifferent by what means it is reduced to this state, nor can it by any means be made to produce another colour. If it is mixed in large masses without being minutely divided, it imparts no colour to the glafs, but remains in its metallic form. Lead, the metal whose density is next in order to that of gold, affords a glafs of the colour of the hyacinth; a gem whose distinguishing characteristic is, that it is red with an admixture of yellow, the same colour which is usually called orange. Glafs of lead is mentioned by several authors as a composition proper, without the addition of any other ingredient, for imitating the hyacinth. Silver, next in density to lead, can only be made to communicate a yellow colour to glafs. If the metal is calcined with sulphur, it readily communicates this colour. Lead-silver laid upon red-hot glafs-like tinges it yellow. When we meet with authors who mention a blue or greenish colour communicated by silver, the cause, most have been, that the silver used in such processes was mixed with copper. Mr Delaval assures us, from his own experience, that silver purified by the tefl retains so much copper, that, when melted several times with nitre and borax, it always imparted a green colour at the first and second melting; though afterwards no such colour was obtainable from it. The only colour produced by copper is green. It is indifferent in what manner the copper is prepared in order to tinge the glafs, provided it is exposed without any other ingredient to a sufficient degree of heat. If a quantity of salts are added in the preparation, they will, by attenuating the mixture, make the glafs incline to blue, the colour next in order; but this happens only when the fire is moderate; for, in a greater degree of heat, the redundant salts, even those of the most fixed nature, are expelled. It is true, that copper is mentioned by some writers as an ingredient in red glafs and enamel: but the red, which is the colour of the metal not divided or mixed with the glafs, remains only while the composition is exposed to such a degree of heat as is too small to melt and incorporate it; for, if it be suffered to remain in the furnace a few minutes after the copper is added, the mass will turn green instead of red. Iron, the metal next in density to copper, is apt to be calcined, or reduced to a ruddy crocus, similar to that rust which it contracts spontaneously in the air. In this state, it requires a considerable degree of heat to dissolve and incorporate it with glafs: till that heat is applied, it retains its ruddy colour: by increasing the heat, it passes through the intermediate colours, till it arrives at its permanent one, which is blue; this being effected in the greatest degree of heat.
the glass will bear, without losing all colour whatever. Iron vitrified per se is converted into a blue glass. In short, it is indubitable, that iron is the only metal which will, without any addition, impart to the glass a blue colour: for copper will not communicate that colour without the addition of a considerable quantity of salts; or some other matter that alleviates it; and the other metals cannot by any means be made to produce it at all.

These are the principal of Mr Delaval's arguments in favour of Sir Isaac Newton's theory of colours being formed by density. Dr Priestley too hath mentioned some which deserve attention. "It was a discovery of Sir Isaac Newton (says he), that the colours of bodies depend upon the thickness of the fine plates which compose their surfaces. He hath shown, that a change of the thickness of these plates occasions a change in the colours of the body; rays of a different colour being thereby disposed to be transmitted through it; and consequently rays of a different colour reflected at the same place, so as to present an image of a different colour to the eye. A variation in the density occasions a variation in the colour; but still a medium of any density will exhibit all the colours, according to the thickness of it. These observations he confirmed by experiments on plates of air, water, and glass. He likewise mentions the colours which arise on polished steel by beating it, as likewise on bell-metal, and some other metaline substances, when melted and poured on the ground, where they may cool in the open air; and he attributes them to the scoriæ or vitrified parts of the metal, which, he says, most metals, when heated or melted, do continually protrude and f entend out to their surfaces, covering them in the form of a thin glassy skin. This great discovery concerning the colours of bodies depending on the thickness of the fine plates which compose their surfaces, of whatever density these plates may be, I have been so happy as to hit upon a method of illustrating and confirming by means of electrical experiments. A number of these being received on the surface of any piece of metal, change the colour of it to a considerable distance from the spot on which they were discharged; so that the whole circular space is divided into a number of concentric rings, each of which consists of all the prismatic colours, and perhaps as vivid as they can be produced in any method whatever. Upon showing these coloured rings to Mr Canton, I was agreeably surprized to find, that he had likewise produced all the prismatic colours from all the metals, but by a different operation. He extended fine wires of all the different metals along the surfaces of pieces of glass, ivory, wood, &c.; and when the wire was exploded, he always found them tinged with all the colours. They are not disposed in so regular and beautiful a manner as in the rings I produced, but they equally demonstrate that none of the metals thus exploded discovers the least preference to one colour more than to another. In what manner these colours are formed it may not be easy to conjecture. In Mr Canton's method of producing them, the metal, or the calcined and vitrified parts of it, seem to be dispersed, in all directions from the plate of explosion, in the form of spheres of a very great variety of sizes, tinged with all the variety of colours, and some of them smaller than can be distinctly seen by any magnifier. In my method of making these colours, they seem to be produced in a manner similar to the production of noise in a drum by the concussion of a small metal ball by heat; i. e., the surface is affected without the parts of it being removed from their places, certain plates or laminae being formed of a thickness proper to exhibit the respective colours."

But, however well supported this doctrine of the Newtonian formation of colours by density may be, we find the theory infamous author (Dr Priestley), whom we have just now seen arguing for it in his history of electricity, arguing against it in his history of vision. "There are (says he) no optical experiments with which Sir Isaac Newton seems to have taken more pains than those relating to the rings of colours which appear in thin plates; and in all his observations and investigations concerning them, he discovers the greatest sagacity both as a philosopher and mathematician; and yet in no subject to which he gave his attention, does he seem to have overlooked more important circumstances in the appearances he observed, or to have been more mistaken with regard to their causes. The former will be evident from the observations of those who succeeded him in these inquiries, particularly those of the Abbé Mazes. This gentleman, endeavouring to give a very high polish to the flat side of an object-glass, happened to be rubbing it against another piece of flat and smooth glass; when he was surprized to find, that after this friction, they adhered very firmly together, till at last he could not move the one upon the other. But he was much more surprized to observe the same colours between these plane glasses that Newton observed between the convex object-glasses of a telescope and another that was plane. These colours between the plane glasses, the Abbé observes, were in proportion to their adhesion. The resemblance between them and the colours produced by Newton, induced him to give a very particular attention to them; and his observations and experiments are as follows:

"If the surfaces of the pieces of glass are transparent, and well polished, such are used for mirrors, and the pressure be as equal as possible on every part of the two surfaces, a resistance, he says, will soon be perceived when one of them is made to slide over the other; sometimes towards the middle, and sometimes towards the edges; but wherever the resistance is felt, two or three very fine curve lines will be perceived, some of a pale red, and others of a faint green. Continuing the friction, the red and green lines increase in number at the place of contact, the colours being sometimes mixed without any order, and sometimes disposed in a regular manner. In the latter case, the colored lines are generally concentric circles, or ellipses, or rather ovals, more or less elongated as the surfaces are more or less united. These figures will not fail to appear, if the glasses are well wiped and warmed before the friction."

"When the colours are formed, the glasses adhere with considerable force, and would always continue so without any change in the colours. In the centre of all these ovals, the longer diameter of which generally exceeds ten lines, there appears a small plate of the same figure, exactly like a plate of gold interpolated between the glasses; and in the centre of it there is often..."

When these coloured glases were suspended over the flame of a candle, the colours disappeared suddenly, though the glases still continued to adhere to one another when they were parallel to the horizon. When they were heated to near the flame, the colours returned by degrees to their former places, in the order of the preceding table.

After this the Abbe took two plates much thicker than the former, in order to observe at his leisure the action of fire upon the matter which he supposed to produce the colours and observed, that as they grew warm, the colours retired to the edges of the glases, and there became narrower and narrower till they were reduced to imperceptible lines. Withdrawing the flame, they returned to their place. This experiment he continued till the glases were bent by the violence of the heat. It was pleasant, he says, to observe these colours slide over the surface of the glases as they were purfued by the flame.

At the first, our author had no doubt but that these colours were owing to a thin plate of air between the glases, to which Newt. has ascribed them; but the remarkable difference in the circumstances attending these produced by the flat plates, and those produced by the object-glasses of Newton, convinced him that the air was not the cause of this appearance. The colours of the flat plates vanished at the approach of flame, but those of the object-glasses did not. He even heated the latter till that which was next the flame was cracked by the heat, before he could observe the least dilatation of the coloured rings. This difference was not owing to the plane glases being lens compressed than the convex ones; for though the former were compressed ever so much by a pair of forces it did not in the least hinder the effect of the flame.

Afterwards he put both the plane glases and the convex ones into the receiver of an air-pump, suspending the former by a thread, and keeping the latter compressed by two string; but he observed no change in the colours of either of them in the most perfect vacuum he could make.

Notwithstanding these experiments seemed to be conclusive against the hypothesis of these colours being formed by a plate of air, the Abbe frankly acknowledges, that the air may adhere so obstinately to the surface of the glases as not to be separated from them by the force of the pump; which, indeed, is agreeable to other appearances; but the following experiments of our author make it still more improbable that the air should be the cause of these colours.
CHROMATICS.

"To try the utmost effect of heat upon these coloured plates, after warming them gradually, he laid them upon burning coals; but though they were nearly red, yet when he rubbed them together by means of an iron rod, he observed the same coloured circles and oval as before. When he ceased to press upon them, the colours seemed to vanish; but when he repeated the friction, they returned, and continued till the pieces of glass began to be red-hot, and their surfaces to be united by fusion.

"When the outward surface of one of his plates of glass was quicksilvered, none of those colours were visible, though the glasses continued to adhere with the same force. This he ascribed to the stronger impression made on the eye by the greater quantity of light reflected from the quicksilver.

"Judging from the resemblance between his experiments and those of Sir Isaac Newton, that the colours were owing to the thickness of some matter, whatever that was, interpolated between the glasses, the Abbe, in order to verify his hypothesis, tried the experiment on thicker substances. He put between his glasses a little ball of wax, about a fourth of a line in diameter, and prefixed it between the two surfaces, warming them at the same time, in order to disperse the wax; but, though he rubbed them together as before, and used other soft substances besides wax, his endeavours to produce the colours had no effect. But, rubbing them with more violence in a circular manner, he was surprised, on looking at a candle through them, to see it surrounded with two or three concentric rings, very broad, and with very lively delicate colours; namely, a red inclining to a yellow, and a green inclining to that of an emerald. At that time he observed only these two colours; but continuing the friction, the rings assumed the colours of blue, yellow, and violet, especially when he looked through the glasses on bodies directly opposed to the sun. If, after having rubbed the glasses, the thickness was considerably diminished, the colours grew weaker by transmitted light, but they seemed to be more stronger by reflection, and to gain on one side what they lost on the other.

"Our author was confirmed in his opinion, that there must be some error in Newton's hypothesis, by considering, that, according to his measures, the colours of the plates varied with the difference of a millionth part of an inch; whereas he was satisfied that there must have been much greater differences in the distance between his glasses, when the colours remained unaltered.

"If the colour depended upon the thickness only, he thought that the matter interpolated between the glasses ought to have given the same colour when it was reduced to a thin plate by simple fusion as well as by friction, and that, in rubbing two plates together, warming them at different times, and compressing them with a considerable force, other colours would have appeared besides those above mentioned.

"These circumstances made him suspect, that the different thicknesses of the substance interpolated between the glasses served only to make them more or less transparent, which was an essential condition in the experiment; and he imagined that the friction diffused over the surface of the thin substance a kind of matter on which the colours are formed by reflection.

"To try the effect of vapour, he breathed upon one of his plates of glass, and observed that the vapours which adhered to the glasses sometimes formed, before they were entirely dispersed, a surprising variety of colours. This experiment, he observes, does not always succeed at the first trial. The glass must be breathed upon several times, and care must be taken to wipe it every time with one's hand, both to take off the moisture, and also to make upon the glass a kind of furrows, which contribute very much to the variety of colours, by making inequalities in the thicknesses of the vapours. It is necessary, also, that the glasses
**CHROMATICS.**

When the particles of water which formed this vapour were too thick to exhibit their colours, he struck them several times with his pencil, in order to attenuate them; and then he saw an infinity of small coloured threads which succeeded one another with great rapidity.

"Putting a drop of water between two pieces of common glass, he observed that the compression of them produced no colour; but if, while they were compressed, the water was made to pass from one place to another, it left behind it large spots, red, yellow, green, purple, &c. and the spots allured different colours with a surprising rapidity, and presented to the eye a most beautiful variety of shades.

"In order to determine with greater certainty whether they were vapours that caused the colours in his first observations, he first breathed upon one of his plates of glass, and then rubbed them against one another, when the colours appeared in the same order as before, but darker, and dispersed in confusion in the places occupied by the vapours; but when he made use of fire to diffuse the watery particles, the colours refumed their lustre.

"Newton, having introduced a drop of water between his two object-glasses, observed, that in proportion as the water imbibed itself between the glasses, the colours grew fainter, and the rings were contracted; and ascribing these colours to the thickness of the plate of water, as he ascribed the former to that of the plate of air, he measured the diameters of the coloured rings made by the plate of water, and concluded that the intervals between the glasses at the similar rings of these two mediums were nearly as three to four; and thence he inferred, that, in all cases, these intervals would be as the sines of the refractions of these mediums.

"The Abbé Mazeas, in order to abuse himself whether, agreeable to this rule, the coloured rings of his glases depended upon the thickness of the water only, dipped one of the edges of his coloured glases in a vellcel of water, having taken care to wipe and warm them, and before he produced his colours by friction. The water was a considerable time in rising as high as the glases; and in proportion as it ascended, he perceived a very thin plate of water, which seemed to pass over the matter which he thought produced the colours, without mixing with it; for beyond this plate of water, he still perceived the colours in the same place and order, but deeper and darker; and holding the glases above the flame of a candle, he saw the colours go and come several times as he moved them nearer to or farther from the flame. He then moistened both the glasses more than before; and rubbing them with oil, he always saw the same appearance; and feeling the moment when the colours had disappeared to separate the glasses, he always found that they were wet. On this account, he thought that it could not be the water on which the colour depended, but some substance much more volatile than heat. He also thought that these coloured rings could not be owing to the compression of the glases; or that, if this circumstance did contribute any thing to them, it served rather to modify than to generate them.

"M. du Tour gave particular attention to the preceding observations of the Abbé Mazeas. He repeated the experiments with some variation of circumstances, particularly comparing them with those of Sir Isaac Newton. He is so far from supposing a plate of air to be necessary to the formation of these coloured rings, that he thinks the reason of their not appearing between the flat plates of glass is the adhering of the air to their surfaces; and that mere pressure is not sufficient to expel it; except, as the Abbé Mazeas observed, the rings had before been made in the same place; in which case, simple apposition without friction is sufficient; the air, probably, not having had time to apply itself closely to the surface of the glass. The contact of some other substances, M. du Tour observes, is not prejudicial in this experiment as that of air; for he found, that, if he only gave the plates a light coating of any kind of grease, the rings would appear without friction. Also dipping them lightly in water, or wiping them with his finger, would answer the same purpose. He verified his conjectures by means of the air-pump: for, dipping two pieces of glass in water, one of which had been wiped, and the other not, the former appeared to have no bubbles adhering to it when the air was exhausted, whereas the other had.

"When one of the glases is convex, our author observes, that the particles of air may more easily make their escape by pressure only; whereas their retreat is in a manner cut off when they are compressed between two flat surfaces. The air-pump, he found, was not able to detach these particles of air from the surfaces to which they adhere; leaving these flat plates for a considerable time in an exhausted receiver, was not sufficient to prepare them so well for the experiment, as wiping them.

"Besides the observations on the colours of thin plates, it has been seen that Sir Isaac Newton imagined he could account for the colours exhibited by thick ones in some cases in a similar manner; particularly in those curious experiments in which he admitted a beam of light through a hole in a piece of pasteboard, and observed the rings of colours reflected back upon it by a concave glass mirror of equal thickness in all places. These experiments were resumed, and happily pursued, by the Duke de Chaullins, who ascribed these colours to the refraction of light. Chance, as B. O. led the duke to observe, that when the nearer surface of the glases mirror was clouded by breathing upon it, so as lightly to tarnish it, a white diffused and vivid light was seen upon the pasteboard, and all the colours of the rings became much stronger, and more distinct. This appearance he made contiguous by moistening the surface of the mirror with a little milk and water, and suffered it to dry upon it.

"In all his experiments upon this subject, he found, when the rays fell converging on the surface of the mirror, the rings were hardly visible; when they fell parallel upon it, as they must have done in all the experiments of Newton, they appeared sufficiently distinct; but when, by means of a convex lens placed in the hole of the window, they were made to diverge from
from the centre of the sphere to which the mirror was ground, so that they fell perpendicularly on the surface of the mirror, the colours were as vivid as he could make them. In this case he could remove the reflected image to a great distance from the hole, without making the rings disappear; and he could plainly perceive them to arise from their central spot, which changed their colours several times.

"The effect of tarnishing the mirror convinced him, that these coloured rings depended on the first surface of the mirror, and that the second surface, or that which reflected them after they had passed the first, only served to collect and throw them upon the pasteboard in a quantity sufficient to make them visible, and he was confirmed in his supposition by the following experiments.

"He took a plano-convex object-glass, of six feet focus, and placed it six feet from the pasteboard with its convex side towards it. By this means the rays which fell upon that surface, after being refracted there, were transmitted through the thickness of the glass, parallel to one another, and fell perpendicularly on the plane surface that reflected them, and, in their return, would be collected upon the pasteboard. In these circumstances the rings appeared very distinct after he had tarnished the convex surface, which in this position was next to the light.

"Turning the same glass the contrary way, so that the plane surface was towards the pasteboard, he could perceive none of the rings at the distance of six feet; but they were visible at the distance of three feet: because at that distance the second surface reflected the rays by its convexity directly towards the pasteboard.

"These two experiments demonstrate the use of the second surface of the mirror, and show the manner of placing it to most advantage. Tho' that follow show the use of the first surface with respect to these rings; and he was led to make them by the casual observation aforesaid.

"Newton, he observes, had remarked, that when he made use of a mirror of the same focus with the first he had used, but of twice the thickness, he found the diameter of the rings much smaller than before. This observation the duke thought favourable to his own conclusion; for if these rings depend upon the first surface, the nearer it is to the second, which only reflects the ray transmitted from it, the larger they ought to appear upon the pasteboard.

"To ascertain this fact, he thought of making use of two moveable surfaces; and to make use of a micrometer to measure the distance between them with exactness. For this purpose he took a metallic mirror belonging to a reflecting telescope, being part of a sphere of ten feet radius; and he fixed it firm upon a foot in which was a groove that carried a light frame, to which was fastened a thin piece of tallow tarnished with milk and water. The frame that supported the piece of tallow could neither be brought into contact with the mirror, or be removed to the distance of eight or nine inches from it, and the micrometer showed to the utmost exactness the least motion of the frame.

"Having placed this mirror ten feet from the pasteboard, that is, at the distance of the radius of its own sphere, he observed the rings to appear very distinct: the form of his mirror being very true; but the diameter of the rings upon the pasteboard varied with the distance of the tallow from the mirror; so that they were very large when the tallow was near the mirror, and very small when it was placed at the distance of seven or eight inches.

"These experiments proved, that the rings were formed by the first surface, and reflected by the second; but it still remained to be determined in what manner they were formed. He imagined, that the small pencils of rays that were transmitted through the pores of the glass, or any other transparent substance, might suffer a kind of refraction, which might change the cylinder which they formed into a truncated cone, either by means of their different degrees of inflexibility, or by the different distances at which they pass by the edges of the small hole through which they are transmitted. Pursuing this idea, he thought of making use of some body, the pores of which were of a known and determined shape. Instead, therefore, of the piece of tallow, he placed a piece of fine linen in the above-mentioned frame, stretching it as even as possible, to make the pores formed by the threads more exact and more permeable by the light; and he soon found, with great pleasure, that his conjecture was verified: for, instead of the circular rings which he had before, they were now manifestly square, though their angles were a little rounded; and they were coloured as the others, though the light was not very vivid, on account of the quantity that was stopped by the muslin.

"When, instead of the muslin, he stretched across his frame fine silver wires exactly parallel, at the distance of about three quarters of a line, or a whole line from one another, without any other wires across them; instead of the rings which he had seen before, there was nothing upon the pasteboard but a gleam of white light divided by many small streaks, coloured in a very vivid manner, and in the same manner as the rings."

Thus we have another hypothesis of the formation of colours, namely, by the refraction of light in its passage out from between the solid and impenetrable particles of which bodies are composed. It is, however, very difficult, upon the hypothesis either of Sir Isaac Newton, or that of the Duke de Chauny, to give a reason why bodies that are not entirely white, should not appear variously coloured. For, it appears from Sir Isaac Newton's experiments, that plates of different density are capable of exhibiting the same colours; and that where a plate is continually varying in density, it will produce all the colours. Now it is evident, that the plates of which we suppose all natural bodies to be composed, must be similar to one that is perpetually varying in its thickness; for supposing the plates of which any substance is composed to be of any determinate thickness, 9 millionth parts of an inch for instance; such of the rays that are reflected from this plate will be red. But if any of them penetrate to the depth of 1/10 of these parts, they will be reflected of a violet colour, &c. and thus must alloy and obscure the red, and so of others. If we suppose the colours to be produced by reflection, it will be equally difficult to account for some particular rays being infected and others not; seeing we observe:
serve that all of them are capable of being infected by every substance whatever, when they pass very near it. In some cases too, colours are produced when the light is neither refracted nor infected, as far as we can judge; and this seems to obscure the theory of chromatics more than any thing we have yet mentioned.

As the experiments we are now about to mention are of the greatest importance, and in direct terms contradict one of Sir Isaac Newton's, we shall give a full account of them, from Prieley's history of Vision, &c. with his remarks thereon.

The experiment in question is the eight of Newton's second book of Optics: "He (Sir Isaac Newton) found, that when light goes out of air through several contiguous refracting mediums, as through water and glafs, and thence goes out again into air, whether the refracting surfaces be parallel or inclined to one another, that light, as often as, by contrary refractions, it is so corrected, that it emerges in lines parallel to those in which it was incident, continues ever after to be white: but if the emergent rays be inclined to the incident, the whiteness of the emerging light will, by degrees, in passing on from the place of emergence, become tinged, at its edges with colours. This he tried by refracting light with prisms of glafs, placed within a prismatic vessel of water.

"By theorems deduced from this experiment, he infers, that the refraction of the rays of every fort, made out of any medium into air, are known by having the refraction of the rays of any one fort; and also, that the refraction out of one medium into another is found as often as we have the refractions of them both into any third medium.

"On the contrary, a Swedish philosopher (M. Klingentierna) observes*, that, in this experiment, the rays of light, after passing through the water and the glafs, though they come out parallel to the incident rays, will be coloured; but that the smaller the glafs prism is, the nearer will the refult of it approach to Newton's description.

"This paper of M. Klingentierna, being commu­nicated to Mr Dollond by M. Mallet, made him entertain doubts concerning Newton's report of the refult of his experiment; and determined him to have recourse to experiments of his own.

"He therefore cemented together two plates of parallel glafs, at their edges, so as to form a prismatic vessel when flopped at the ends or bafes; and the edge being turned downwards, he placed in it a glafs prism with one of its edges upwards, and filled up the vacan­cy with clear water: so that the refraction of the prism was contrived to be contrary to that of the water, in order that a ray of light, transmitted through both these refracting mediums, might be affected by the difference only between the two refractions. As he found the water to refract more or less than the glafs prism, he diminished or increased the angle between the glafs plates, till he found the two contrary refractions to be equal, which he discovered by viewing an object through this double prism. For when it appeared neither raised nor depressed, he was satisfied that the refractions were equal, and that the emergent rays were parallel to the incident.

"Now, according to the prevailing opinion, he observes, that the object should have appeared through this double prism in its natural colour; for if the difference of refrangibility had been in all respects equal, in the two equal refractions, they would have rectified each other. But this experiment fully proved the fallacy of the received opinion, by showing the divergency of the light by the glafs prism to be almost double of that by the water; for the image of the object, though not at all refracted, was yet as much infected with prismatic colours, as though it had been seen through a glafs wedge only, while the angle was near 30 degrees.

"This experiment is the very same with that of Sir Isaac Newton abovementioned, notwithstanding the refult was so remarkably different; but Mr Doll­ond affures us, that he used all possible precaution and care in his process; and he kept his apparatus by him, that he might evince the truth of what he wrote, whenever he should be properly required to do it.

"He plainly saw, however, that if the refra­acting angle of the water-vessel could have admitted of a sufficient increafe, the divergency of the coloured rays would have been greatly diminished, or entirely rectified; and that there would have been a very great refraction without colour, as he had already produced a great difcolouring without refraction: but the inconvenient of fo large an angle as that of the prismatic vessel must have been, to bring the light to an equal divergency with that of the glafs prism, whose angle was about 60°, made it necessary to try some experiments of the same kind with smaller angles.

"Accordingly he got a wedge of plate-glafs, the angle of which was only nine degrees; and, using it in the same circumstances, he increafed the angle of the water-vessel, in which it was placed, till the divergency of the light by the water was equal to that by the glafs; that is, till the image of the object, though considerably refracted by the excess of the refraction of the water, appeared nevertheless quite free from any colour proceeding from the different refrangibility of the light.

"Notwithstanding it evidently appeared, I may defy almost all philosophers, that Mr Dollond had made a real discovery of something not comprehended in the optical principles of Sir Isaac Newton, it did not appear to fo sensible a man, and fo good a mathematician, as Mr Murdoch is universally acknowledged to be. Upon this occasion he interposed in the defence, as he imagined, of Sir Isaac Newton; maintaining, that Mr Dollond's positions, which he says, he knows not by what mishap have been deemed paradoxes in Sir Isaac's theory of light, are really the necessary con­sequences of it. He also endeavours to shew, that Sir Isaac might not be mistaken in his account of the experiment abovementioned. But admitting all that he advances in this part of his defence, Newton must have made use of a prism with a much smaller refracting angle than, from his own account of his experiments, we have any reason to believe he ever did make use of.

"The faét probably was, that Sir Isaac deceived himself in this case, by attending to what he imagined to be the clear con­sequences of his other experiments; and though the light he saw was certainly tinged with
CHROMATICS.

The changes of colour in permanently coloured bodies, our author observes, are produced by the same laws which take place in transparent colourless substances; and the experiments by which they can be investigated chiefly of various methods of uniting the colouring particles into larger, or dividing them into smaller masses. Sir Isaac Newton made his experiments chiefly on transparent substances; and in the few places where he treats of others, acknowledges his deficiency of experiments. He makes the following remark, however, on those bodies which reflect one kind of light and transmit another, viz. that if these glases or liquors were so thick and mally that no light could get through them, he questioned whether they would not, like other opaque bodies, appear of one and the same colour in all positions of the eye; though he could not yet affirm it from experience.

It was the opinion of this great philosopher, that all coloured matter reflects the rays of light, some reflecting the more refrangible and others the less refrangible rays more copiously; and that this is not only a true reason of these colours, but likewise the only reason. He was likewise of opinion that opaque bodies reflect the light from their anterior surface by some power of the body evenly diffused over and external to it. With regard to transparent coloured liquids, he expresses himself in the following manner: "A transparent body which looks of any colour by transmitted light, may also look of the same colour by reflected light; the light of that colour being reflected by the farther surface of that body, or by the air beyond it; and then the reflected light will be diminished, and perhaps cease, by making the body very thick, and pitching it on the back-side to diminish the reflection of its farther surface, so that the light reflected from the tinging particles may predominate. In such cases the colour of the reflected light will be apt to vary from that of the light transmitted."

To investigate the truth of these opinions Mr Delaval entered upon a course of experiments with transparent coloured liquids and glases, as well as with opaque and semitransparent bodies. From these he discovered several remarkable properties of the colouring matter; particularly, that in transparent coloured substances, it does not reflect any light; and when, by intercepting the light which was transmitted, it is hindered from passing through such substances, they do not vary from their former colour to any other, but become entirely black (a). This incapacity of the colouring particles of transparent bodies to reflect light, being deduced from very numerous experiments, may therefore be held as a general law. It will appear the more extensive, if we consider that, for the most part, the tinging particles of liquids or other transparent substances are extracted from opaque bodies; that the opaque bodies owe their colours to those particles, in like manner as the transparent substances do; and that by the loss of them they are deprived of their colours.

For making his experiments, Mr Delaval used small vials.

(a) Here our author observes, that he makes use of the word colour only to express those called primary; such a mixture of them as does not compose white, or any of the gradations between white and black; such as are called by Sir Isaac Newton, grey, dun, or ruflet brown.
Apparatus for making the experiments.

Experiments to determine the proportion of tinge- 

6. When a lighted candle is placed near one of those coloured plates, the flame is reflected by the medium which is diffused over the anterior surface. The image thus reflected entirely resembles the flame in size and colour; being fearfully diminished, and not in the least tinged by the coloured glass.

7. If the plate be not so intensely coloured, or so mally, as to hinder the transmision of the light of the candle, there appears a secondary image of the flame, which is reflected by the medium contiguous to the farther surface of the glass; and as the light thus reflected passes through the coloured glass, it is tinged very vividly.

8. When the glass used in this experiment is of a green colour, the image of the flame is always of a bright green; and when glasses of other colours are used, that of a secondary flame is always the same with that of the glass.

9. The secondary image is less than that reflected from the anterior surface. This diminution is occasioned by the loss of that part of the light which is absorbed in passing through the coloured glasses. For whenever any medium transmits one part of rays more copiously than the rest, it stops a great part of the different coloured rays. Much more light also is lost in passing through coloured than transparent substances. In making these observations, it is proper to choose coloured plates of glasses which are not in every part of an equal thickness, that the secondary image may not coincide with that reflected from the anterior surface, and be intercepted by it.

10. When the plates are so thick, and so copiously coloured, that the light cannot penetrate to their far-
CHROMATICS.

734

Hence again it is manifest, that the colouring particles do not possess any share of reflective power; for if they had any share in this reflection, they would certainly impart some share of colour to the light they reflected. Hence also it appears, that transparent coloured bodies, in a solid state, possess no more reflective power than those in a fluid state.

Our author next considers the colouring particles themselves, pure, and unmixed with other media. In order to procure masses made up of such particles, several transparent coloured liquids were reduced to a solid consistence by evaporation. By employing a gentle heat, the colouring matter may thus remain unimpaired; and is capable of having its particles again separated by water or other liquids, and tincting them as before.

In this state the colouring particles reflect no light, and therefore appear uniformly black, whatever substance they have been extruded from. In the course of his experiments, Mr Delaval made use of the infusions of brazil wood, logwood, fuffle, turmeric, red sanders, alkane, sap-green, kernes, and all the other transparent coloured liquors he had tried before, among which were infusions of red and yellow flowers, without observing the least variation in the result.

Some liquids are apt to become totally opaque by evaporation: the reason of which may be the crystallization of saline matters, or the coalescence of the particles into masses, differing considerably in density from the menstrua in which they were dissolved. When this opacity takes place, our author has constantly observed, that they become incapable of entering the pores of wool, silk, or other matters of that kind, or of adhering to their surface; and consequently unfit for the purposes of dyeing. This he supposes to arise from their increased bulk; for the attractive force by which the particles cohere together is weakened in proportion as their bulk increases: so that the degree of magnitude of the colouring particles, which is essential to the opacity of liquors, is inconsistent with the minuteness requisite for dyeing. An instance of this is given in an infusion of fuffle. Having infused some of this wood in such a quantity of water, that the latter was saturated with the colouring particles, he evaporated the liquor to a solid consistence with an uninterrupted, but very gentle heat. During every part of the process the liquor continued transparent, and the fluid extract yielded by it was transmitted a yellow colour when spread thin, but appeared black when thicker masses were viewed. Having prepared another pint of this liquor, he evaporated half the water, and allowed the remainder to become cold. In this state it became turbid and opaque; on filtering, a transparent tincture passed through an opaque fecula remaining on the paper. This fecula did not adhere to the paper, but was easily separable from it: on being dried, it appeared white with a slight tinge of yellow; but was nevertheless soluble in water, and by solution gave a liquid in all respects similar to the original infusion.

From these circumstances (says he) it appears that a given proportion of water, or a sufficient degree of heat, is requisite to the solution of the colouring particles of fuffle. And experience evinces, that those particles which are too gross to pass through filtering paper, are incapable of entering the pores or firmly cohering to the surface of bodies. Many ingredients, such as the colouring particles of logwood, kernes, and various other matters, are soluble in water in every proportion; and therefore their infusions are not subject to become opaque or turbid during their evaporation. The solid extracts obtained by evaporation reflect no colour, but are black.

Our author also formed solid masses by mixing a small quantity of drying oil with pigments which confit chiefly of colouring matter; as Prussian blue, indigo, and sap-green. These paints likewise exhibit their respective colours only by transmitted light; appearing entirely black when viewed by reflection. Instances of blackness arising from this density of the colouring matter may be observed in several kinds of fruits, as black currants, cherries, &c. For the juices of these appear red when spread thin on a white ground, or otherwise viewed by transmitted light.

Mr Delaval's next attempt was to consider the action and properties of the colouring particles of opaque bodies themselves, and the means by which these colours are produced. Here our author endeavours to prove, that these colours of opaque bodies appear on the same principles as those already mentioned, which seem black when very dense, but show their proper tinge when spread thin upon a white ground. On this subject the following experiments were made.

1. Grass, and other green leaves of plants, were digested in rectified spirit of wine; by which means a transparent green tincture was obtained. One of the vials formerly mentioned being filled with this liquor, it was observed to transmit a vivid green colour; but the other part of the tincture, which was contiguous to the uncovered side of the vial, reflected no light, and therefore appeared black.

2. Having poured some of the tincture into a China cup, the bottom was thereby made to look green, exactly resembling the colour which had been extracted from the leaves.

3. After the colour had been totally absorbed by the vinous spirit, the leaves remained apparently unaltered, either as to figure or texture; but were entirely white, or had their whiteneys slightly tinged with brown.

4. Red, purple, and blue flowers, were also digested in spirit of wine; all of which yielded their colouring matter to the spirit, and became white by being deprived of it. From most of these flowers, however, the spirit acquired either no tinge at all, or only a very faint one; but when acidulated, it became red, and by the addition of an alkali appeared blue, purple, or green, according to the quantity of alkali and the nature of the infusion. In these states, all of them, when viewed...
viewed by transmitted light, or poured upon a white ground, showed their colours, but universally appeared black by reflection.

5. Red, purple, and blue flowers, were digested in water slightly acidulated with nitrous acid. Thus, red infusions were obtained, which, by saturation with sea salt, might be preferred for many years.

6. The same liquors were changed, green, blue, or purple, by the addition of an alkali; but here the case was the same as before; all of them yielding vivid colours by transmutation, but none by reflection. In making this experiment, care must be taken to add the alkali very gradually; for if too much is put in at once to the red liquor, the intermediate colours between the red and the green will be wanting. To half an ounce of the red infusion it is proper to add, at once, only the smallest quantity that can be taken up on the point of a pen; repeating this addition slowly, until each of the colours be produced.

7. The flowers, after having been repeatedly macerated in acidulated water, loft their colouring matter, and became white.

8. Yellow flowers also communicated their colours to water and to spirit of wine. The infusions and tinctures of these flowers were subjected to the same experiments as had been employed in the examination of the liquors already mentioned; and appeared yellow by transmitted light, but did not reflect any colour.

9. White paper, linen, &c. may be tinged of any of these colours, by dipping them in the infusions; and the consideration of the manner in which the colours are imparted to the linen, affords much insight into the manner in which natural colours are produced. It has already been observed, that, when the colouring matter of plants is extracted from them, the solid fibrous parts, thus divulged of their covering, display their natural whiteness. White linen, paper, &c. are formed of such fibrous vegetable matter; which is bleached by dissolving and detaching the heterogeneous colouring particles. When these are dyed or painted with vegetable colours, it is evident that they do not differ in their manner of acting on the rays of light from natural vegetable bodies; both yielding their colours by transmitting, through the transparent coloured matter, the light which is reflected from the white ground. This white matter frequently exists, without any confiderable mixture, in plants, while they are in a state of vegetation; as cotton, white flowers, the pith, wood, seeds, roots, and other parts of several kinds of vegetables. When decayed trees, &c. have been long exposed to the atmosphere, their coloured juices are sometimes so perfectly extracted, that the fibres appear white. This white matter is not distinct from the vegetable earth to which plants are reduced by burning. Mr. Delaval has rendered ashes intensely white, by carefully calcining them, and afterwards grinding with a small proportion of nitre, and exploiting them to such a degree of heat as would cause the nitre deflagrate with the remaining quantity of phlogiston. Lastly, the ashes were digested with marine acid, in order to dissolve the ferruginous matter diffused through them, and repeatedly washing the remainder in water. Mixing ashes thus purified with borax, and applying a vitrifying heat, an opaque enamel is obtained, remarkable for its whiteness.

Hence it appears, that the earth which forms the white substance of plants is white, and separable from that of other plants, the only substance in these which gives to each its peculiar colour; that whenever it is pure and unmixed, or diffused through colourless media, it shows its native whiteness; and is the only vegetable matter endowed with a reflecting power. It may be discovered, however, by other means than that of burning; thus, roses may be whitened by expounding them to the vapour of burning sulphur; an effect which cannot be attributed to the vitriolic acid, but to the phlogiston contained in that vapour. This was proved to be the case, by expounding several kinds of red and purple flowers to the phlogistic vapour issuing from hepatic sulphur; and by this every one of them was whitened; their colour being afterwards restored by the addition of an acid either mineral or vegetable.

"Thus (says Mr. Delaval) it appears, that the colouring matter of the flowers is not discharged or removed, but only dissolved by the phlogiston; and dissolved thereby divided into particles too minute to exhibit any colour. In this state, together with the vegetable juice in which they are diffused, they form a colourless transparent covering, through which the white matter of the flowers is seen untinged. The colouring particles of plants consist principally of inflammable matter; and their solubility in phlogiston, and union with it, are analogous to the action of other inflammable bodies upon each other. Thus, ether dissolves all essential and expressed oils, animal empirical oils, and resins. Sulphur, camphor, and almost all substances abounding in phlogiston, are soluble in oils, ardent spirits, or other inflammable matters. The manner in which the red colour of vegetable flowers is restored, appears to be explicable from known chemical laws. When acids are applied to the whitened flowers, they unite with the phlogiston which the sulphur had communicated, and disengage from the colouring particles; which, being thus extracted, resume their original magnitude and hue. A change of the same kind is also produced by fixed alkali, which, like the acid, has a strong attraction for phlogiston, always changes the whitened flowers to blue, purple, or green colour.

4. In like manner, the action of the rays of light operate on coloured bodies. Thus, dyed silk, or other fibres by substances of that kind, when exposed to the sun's light, are deprived of their colour in every part on which the rays are allowed to act; whilst those prefered their colour which are defended from the light by the fibres of the cloth, or interposition of any opaque body. The colours, thus impaired, may be restored if acids are applied while the injury is recent; but they are afterwards apt to fly off, on account of that volatility which is constantly imparted by inflammable matter to any other with which it is united."

Our ather now proceeds, at considerable length, to prove the identity of the solar light and phlogiston: but as recent experiments have shown that these two are essentially distinct, we omit his argumentation upon his head. The effect of his theory in this respect, however, does not in the least affect the doctrine concerning colours above laid down: on the contrary, the latest
latest experiments have determined, that phlogiston, in its grosser form, viz. that of common charcoal, manifests a surprising power of whitening various substances; which, according to Mr Delaval's theory, proceeds from the power it has of dissolving the colouring matter with which they are impregnated. This solvent power, according to our author, is manifested in many other instances besides those already mentioned. Silk is whitened by the phlogistic vapours of sulphur; and this operation does not appear to differ from the change effected on flowers by the same vapour. The light of the sun is found to be a necessary and essential agent in bleaching linen, wax, and various other substances; some part of the colouring matter which impairs the whiteness of these bodies not yielding to any other solvent. Red flowers are whitened by the electric spark, of whose inflammable nature we cannot entertain the least doubt; for the spark itself is a bright flame, and yields the fame smell which all other phlogistic matters impart. The electric spark, in like manner, changes the blue infusion of turmeric to red (a). The effects which it produces on the turmeric, and on red flowers, do not differ from each other, except in degree only. For when vegetable matter is dissolved, it is changed from blue to red; and, when further dissolved, it is divided into particles too minute to exhibit any colour.

Solutions effected by means of phlogiston frequently are wrongly attributed to the operation of supposed acid menstrua, as several kinds of substances are capable of being dissolved indiscriminately both by acids and phlogiston. For the purpose of distinguishing, therefore, in any case between the action of the acid solvent and that of the inflammable menstruum, it is proper to examine the nature of the matter by which either of these principles are furnished. It appears from various chemical processes, that alkalis are rendered mild, and capable of crystallization, in proportion as they are united to phlogiston. The phlogisticated alkaline lixivium, when lathered, is perfectly mild; and by a slight evaporation is reduced to a concrete crystalline mass, which does not deliquesce or imbibe the leaf moisture from the air, and no longer retains any alkaline property. M. Beaumé, by an elegant and ingenious experiment, has proved the presence of phlogiston in mild alkalis, and has shown that their power of crystallizing depends upon their union with that principle. He heated in a silver vessel a lixivium of mild alkali, which imparted to the silver a covering or coating of inflammable matter, by which its surface was tarnished and became black. The lixivium was several times poured out of the silver vessel; and after the surface of the metal had been freed from the tarnish, the lixivium was replaced in it, and again heated, by which the tarnish was renewed; and this was repeated till the lixivium no longer communicated any stain to the silver. The causticity of the lixivium was increased in proportion as it imparted its phlogiston to the silver; and at the end of the process the alkali became perfectly caustic, and incapable of crystallizing.

Our author now goes on to prove, that fixed air is not an acid, nor a compound of air and phlogiston, as is now generally believed, but rather entirely of a phlogistic nature. For an account of his arguments in favour of this opinion, see the article Fixed Air: here we shall only consider his further experiments on colours.

"From the preceding experiments (says he) it appears, that the colouring particles of flowers and leaves are soluble in acid, alkaline, and phlogistic menstrua. The other parts of vegetables consist of materials similar to those which are contained in their flowers and leaves, and undergo the same changes from the same causes. Having extracted from logwood its colouring particles by repeatedly boiling it in water, the wood was thus deprived of its yellow colour, and assumed a brown hue similar to that of oak-wood. Some pieces of it thus deprived of its colour were then macerated in aquafortis; and after they had undergone the action of that acid, they were washed in a sufficient quantity of water. The wood was thus reduced to whiteness."

Here our author observes, that though most authors logwood who treat of colouring substances describe logwood as affords on of a red colour, he was never able to procure any other colour from it but yellow. It imparts yellow and orange colours to distilled water. Other waters extract a red tinge from it by means of the alkali which they contain. These observations are also applicable to the other dyecing woods, kernes, and various other articles of the materia tintoria. By a familiar treatment, sulplic wood also lost its colouring matter, and became white.

The results of all the experiments above related are, that the colouring matter of plants does not exhibit any colour by reflection, but by transmission only; that their solid earthy substance is a white matter; and that it is the only part of vegetables which is endowed with a reflective power; that the colours of vegetables are produced by the light reflected from this white matter, and transmitted from thence through the coloured coat or covering which is formed on its surface by the colouring particles; that whenever the colouring matter is either discharged or divided by solution into particles too minute to exhibit any colour, the solid earthy substance is exposed to view, and displays that whiteness which is its distinguishing characteristic.

Mr Delaval next proceeds to examine the coloured parts of animal substances, and finds them exactly similar, with regard to the manner in which the colour is produced, to the vegetable bodies already treated of. The tinctures and infusions of cochineal and of kernes yield their colours when light is transmitted through them, but show none by reflection. On diluting fresh ox-gall with water, and examining it in the phials already mentioned, that part of it which was in the neck of the phial, and viewed by transmitted light, was yellow; but the anterior surface was black, and reflected no colour. Flesh derives its colour entirely from the blood, and when deprived of it the fibres and vellies are perfectly white; as are likewise the membranes.

(a) This effect of the electric spark is now known to be produced, not by its phlogistic nature, but by the generation of an acid.
CHROMATICS.

35 Of the colour of blood.

Of the colour of blood.

36 Of the colour of blood.

On examining blood diluted with water in one of the phials formerly described, it transmitted a red colour, and the anterior surface was almost, but not entirely, black; for it received a slight hue of brown from some coagulated particles that were suspended in the liquor. In order to procure blood sufficiently diluted, and at the same time equally and perfectly dissolved, he mixed as much crux with spirit of sal ammoniac as imparted a bright colour to it. The liquor being then viewed in the phial, that part which was contained in the neck, and transmitted the light, appeared of a fine red; but the anterior part reflecting no light, was intensely black. Hence it appears, that the florid red colour of the flesh arises from the light which is reflected from the white fibrous substance, and transmitted back through the red transparent covering which the blood forms on every part of it.

Blood, when recently drawn, does not assume the appearance common to transparent coloured liquors; for these, when too maily to transmit light from their farther surfaces, always appear black; but blood, when recently drawn, always shows a fine red colour, in whatever way it be viewed. This is occasioned by a white matter diffused through the blood; and which is easily separated from the crux, by dividing it after coagulation into a number of thin pieces, and washing in a sufficient quantity of pure water. Thus the water acquires a red colour, and ought to be changed daily.

In a few days it will acquire no more tinge, and the remaining masses of the crux are no longer red, but white.

In like manner, the red colour of the shells of lobsters, after boiling, is no more than a mere superficial covering spread over the white calcareous earth of which the shells are composed, and may be easily removed from the surface by scraping or filing. Before the application of heat, this superficial covering is much denser; inasmuch that, in some parts of the shell, it appears quite black, being too thick to admit the passage of the light to the shell like before; but where this transparent blue colour of the unboiled lobster is thinner, it constantly appears like a blue film. In like manner, the colours of the eggs of certain birds are entirely superficial, and may be scraped off, leaving the white calcareous earth exposed to view.

The case is the same with feathers, which owe their colours entirely to a very thin layer of some transparent matter upon a white ground. Our author ascertained this by scraping off the superficial colours from certain feathers which were strong enough to bear the operation; and thus separated the coloured layers from the white ground on which they had been naturally spread. The last fibres of the feathers cannot endure to have their surfaces separated in this manner; but their texture, when viewed by a microscope, seems to indicate, that the colours are produced on them by no other means than those already related. In the examination of some animal subjects where the colouring matter could not be separated by chemical means, our author had recourse to mechanical division; but this can only be employed when the principal part of the white substance is unmixed with the coloured coat or covering which is spread upon its surface. All of them, however, by whatever means their colours could be separated, showed that they were produced in the same manner, namely, by the transmission of light from a white ground through a transparent coloured medium.

The coloured substances of the mineral kingdom are very numerous, and belong principally to two classes, viz. earths and metals. The former, when pure, are all perfectly white, and their colours arise from phlogitic or metallic mixtures. Calcareous earths, when indurated, constitute marble, and may be tinged with various colours by means of metallic solutions; all which are similar in their nature to the dyes put upon silk, cotton, or linen, and invariably proceed from the same cause, viz. the transmission of light through a very thin and transparent coloured medium. Flints are formed from siliceous earth, and owe their colour to phlogiston. When sufficiently heated, they are rendered white by the loss of the inflammable matter which produced their colour. When impregnated with metals, they form agates, cornelians, jasper, and coloured crystals. The coloured gems also receive their different hues from metals; and all of them may be imitated by glasses tinged with such phlogistic or metallic matters as enter into the composition of the original substances.

Thus our author concludes, that the coloured earths, gems, &c. exhibit their various tints in the same manner with other substances; viz. by the transmission of light reflected from a white ground. Our author, however, proceeds farther; and affirms, that even the colours of metals themselves are produced in the same manner.

"Gold (says he) exhibits a white light, which is tinged with yellow. I have used this expression, because it appears from experiment that gold reflects a white light, and that its yellow colour is a tinge superadded to its whiteness. The experiment is thus set forth by Sir Isaac Newton. Gold in this light (that is, a beam of white light) appears of the same yellow colour as in day light; but by intercepting at the lens a due quantity of the yellow-making rays, it will appear white like silver, and I have affirmed, which follows, that its yellowness arises from the excess of the intercepted rays, tinging that whiteness with their colour when they are let pass.

"I have already shown, by numerous experiments, in what manner coloured tinges are produced; and it uniformly appears, from all these experiments, that colours do not arise from reflection, but from transmission only. A solution of silver is pellucid and colourless. A solution of gold transmits yellow, but reflects no colour. This metal also, when united with glass, yields no colour by reflection, but by transmission only. All these circumstances seem to indicate, in a manner similar to that of the yellow colour of gold, which arises from a yellow transparent matter, which is a confluent part of that metal; that it is equally mixed with the white particles of the gold, and transmits the light which is reflected by them, in like manner as when silver is gilt, or foils are made by covering white metals with transparent colours. But these fictitious coverings are only superficial; whereas the yellow matter of gold is diffused throughout the whole substance of the metal, and
and appears to envelope, and cover each of the white particles. In whatsoever manner the yellow matter of gold is united to its white substance, it exists in a rare state; for it bears only the same proportion to the white particles of the gold as that of the yellow-making rays which were intercepted bears to all the other rays comprised in the white light of the sun.

Sir Isaac Newton has shewn, that when spaces or interstices of bodies are replenished with media of different densities, the bodies are opaque; that those superficies of transparent bodies reflect the greatest quantity of light which intercede media that differ most in their refractive densities; and that the reflections of very thin transparent substances are considerably stronger than those made by the same substances of a greater matter.

Hence the minute portions of air, or of the rarer medium, which occupies spaces void of other matter, reflect a vivid white light whenever their surfaces are contiguous to media whose densities differ considerably from their own; so that every small mass of air, or of the rarer medium, which fills the pores or interstices of dense bodies, is a minute white substance. This is manifest in the whiteness of froth, and of all pelliculour bodies; such as glaizes, crystal, or fables, reduced to powder, or otherwise flawed; for in all these instances a white light is reflected from the air or rarer medium which intercedes the particles of the denser substances whose interstices they occupy.

From these principles our author takes occasion to explain the reason why the particles of metals which yield no colour by incident light when suspended in their solvents, are disposed to exhibit colours when separated from them. Hence also we see why opaque white substances are rendered pelliculour by being reduced to uniform masses whose component parts are everywhere nearly of the same density; for as all pelliculour substances are rendered opaque and white by the admixture of pelliculour colourless media of considerably different densities, they are again deprived of their opacity by extricating these media which kept their particles at a distance from each other: thus froth or snow, when resolved into water, lose their whiteness, and assume their former pelliculour appearance.

In like manner, by proper fluxes, the opaque white earths are reduced to pelliculour glaizes; because all reflections are made at the surfaces of bodies differing in density from the ambient medium, and in the confines of equally dense media there is no reflection.

As the calces of metals are enabled to reflect their colours by the intervention of the particles of air; so, when mixed with oil in the making of paints, they always assume a darker colour, because the excess of the density of oil over that of air forms a sensible difference when comparatively considered with respect to the specific gravity of the rarer metals. From this cause perceptibly less light is reflected from the molecule of oil than from the whole of air, and consequently the mass appears darker. The colour, however, is different with such paints as are formed of the denser metals; as vermillion, minium, &c.: for though oil differs very considerably from air in its specific density, yet it also differs very much in this respect from the denser metallic powders; and the molecule of oil which divides their particles acts upon the light so strongly, that the reflection occasioned by them cannot be distinguished from those which are caused by rarer media. Hence, though we mix vermilion or minium with oil, the colour is not sensibly altered.

This part of our author's theory, however, seems liable to objection: for though it be true that the calces of some metals are denser than others, yet that is, of me-

compared speaking, but in a very small proportion; nor is even the difference of density between oil and the calces of the heavier metals all comparable to that between the density of air and oil. Thus, tho' the calx of iron may be 10 or 11 times more dense than oil; yet, as the latter is between 300 and 600 times denser than air, the small difference between the oil and metallic calx ought to be imperceptible. In this respect, indeed, there are considerable differences with regard to the oils employed, which cannot be supposed to arise from the mere circumstance of density.

Thus the colour of vermilion, when mixed with turpentine-varnish, is much brighter than with linseed-oil; and yet the difference between the densities of linseed-oil and turpentine-varnish is very trifling. The mere action of heat like-wis has a surprising effect in this case. Thus the red calx of iron, called foyret okeer, by being only heated a certain degree, appears of a very dark purple, retaining its red colour when cold; and this variation may be induced as often as we please by only heating it over the fire in a hollow. In like manner, by gradually heating red lead, it may be made to assume a most beautiful crimson colour; which growing gradually darker, becomes at last almost quite black. On cooling, if the heat has not been raised too high, it gradually returns through the same shades of colour, until at last it fixes in its original hue. These immense differences in colour cannot by any means be attributed either to the expulsion of air or to an alteration in density. The fire indeed does certainly expand these calces as well as other bodies; but as the medium interfered between their particles is thus also expanded, the colour ought at least to remain the same, if not to become lighter, on account of the superior expansion of air to that of metal by the same degree of heat. It would seem, therefore, that the action of the element of fire itself has a considerable share in the production of colours; and indeed its share in the operations of nature is so great, that we might well think it strange if it should be entirely excluded from this.

With regard to semipellucid substances, which appear of one colour by incident and another by transmitted light, our author likewis endeavours to show, that no reflection is made by the coloured matter, but only by the white or colourless particles. They consist of pellucid media, throughout which white or colourless opaque particles are dispersed. The latter are disposed at such distances from each other, that some of the incident rays of light are capable of passing through the intervals which intercede them, and thus are transmitted through the semipellucid masses. Some rays penetrate through such masses, while others which differ from them in their refrangibility are reflected by the white or colourless particles; and from thence are transmitted through the pelliculour part of the medium which intervenes between the reflecting particles and the anterior surface of the mass. On the same principle our author explains the blue colour of the
CHROMATICS.

42 Flow colours are shown by transmittal light

the sky, the green colour of the sea, and other natural phenomena; and from his numerous experiments on this subject at least concludes, that the power by which the several rays of light are transmitted through different media is inherent in the particles themselves, and therefore is not confined to the surfaces of such media. For if the transmissive force was exerted at the surface only, the thinner plates of coloured substances would act upon the rays as powerfully as thicker plates. But it appears from experiment, that in passing through the particles of transparent coloured substances, they exhibit colours differing not only in degree, but frequently in species also.

The sun's light, by which bodies are illuminated, consists of all the rays by which a white light is compounded. These rays, in their entire and undivided state, are incident upon the opaque particles of semipellucid substances, and upon the colouring particles of transparent-coloured substances, whenever these media are exposed to the light. When the rays accede to the opaque particles of semipellucid substances, some of the rays are reflected back from the anterior surface of those particles: the other sorts of rays which are not reflected back, are diverted from the direction which is opposite to the anterior surface of the opaque particles, and passing through the intervals between the particles, are transmitted through the media.

When the rays are incident upon the particles of transparent coloured bodies, none of them are reflected back; because the colouring particles are not endowed with any reflective power: but some of the rays are either stopped at the anterior surface of the particles, or are diverted into such directions as render them incapable of passing towards the farther side of the media; and consequently such rays cannot be transmitted. The rays which are not thus intercepted or dispersed, are transmitted in the same manner as those which pass through semipellucid media. Thus it is evident, that the coloured rays which are transmitted through semipellucid substances are reflected by the opaque particles: and those which are transmitted through transparent-coloured substance are reflected by the colouring particles. From the preceding observations likewise it appears, that the particles of coloured media infect the several sorts of rays according to the several sizes and densities of the particles; also in proportion to the inflammability of the media which owe their colour to them; and it is manifest that the transmutation of coloured rays depends upon their refraction. All these observations are conformable to Sir Isaac Newton's doctrine, that the rays of light are refracted, reflected, and infected, by one and the same principle acting variously in various circumstances.

The most remarkable part of Mr. Delaval's doctrine is that concerning the metals; for the better understanding of what we shall premise a short account of his general doctrine concerning white bodies, and the manner in which light is reflected by them. All the earths (he observes), which in their natural state are of pure white, constitute transparent colourless media when vitrified with proper fluxes, or when dissolved in colourless menstrua; and the saline masses obtainable from their solutions are transparent and colourless while they retain the water which is essential to their crystallization, and are not flawed or reduced to powder; but after their pores and interfaces are opened in such a manner as to admit the air, they become then white and opaque by the entrance of that rare medium. The earthy particles which form the solid parts of bodies generally exceed the others in density; consequently these particles, when contiguous to the rare medium already mentioned, must reflect the rays of light with a force proportionate to their density. The refractive power of bodies does not depend merely upon their outer coats, but also upon their difference of density, with respect to the surrounding media. Transparent colourless particles, whose density is greatly inferior to that of the medium they come between, also powerfully reflect all sorts of rays, and thereby become white. Of this kind are the air or other rare fluids which occupy the interfaces of liquors; and in general of all denser media into whose interfaces such rare particles are admitted.

Hence we may conclude, that white opaque bodies are constituted by the union or contiguity of two or more transparent colourless media differing considerably from each other in their refractive powers. Of these substances we have examples in froth, emulsions, or other imperfect combinations of pellucid liquors, milk snow, calcined or pulverized fats, gla$. or crystal reduced to powder, white earths, paper, linen, and even those metals which are called white by mineralogists and chemists: for the metals just mentioned do not appear white unless their surfaces be rough; as in that case only there are interfaces on their surface sufficient to admit the air, and thus make a reflection of a white and vivid light.

But the polished surfaces of metallic mirrors reflect the incident rays evenly and regularly, according to their several angles of incidence; so that the reflected rays do not interfere with each other, but remain separate and unmixed, and therefore distinctly exhibit their several colours. Hence it is evident, that white surfaces cannot act upon the light as mirrors: because all the rays which are reflected from them are blended in a promiscuous and disorderly manner.

The abovementioned phenomena give much instruction into the nature and cause of opacity; as they cause of clear circumstances. In the same way, that even the rarest transparent colourless substances, when their surfaces are adjacent to media differing greatly from them in refractive power, may thereby acquire a perfect opacity, and may assume a refraction and hue so similar to that of white metals, that the rarer pellucid substances cannot by the light be distinguished from the dense opaque metals. And this similarity to the surface of metals occurs in the rare pellucid substances, not only when, from the roughness of their surfaces, they resemble unpolished metals in whiteness, but also when, from their smoothness, they resemble the polished surfaces of metals.

Metals seem to consist entirely of transparent matter, and to derive their apparent opacity and lustre solely from the copious reflection of light from their surfaces. The analogy between the metals and transparent media, as far as respects their optical properties, will appear from the following considerations.

1. All metals dissolved in their proper menstrua are transmitted light, and therefore have no part in the reflection we observe in polished metallic surfaces. They are entirely different from the metallic elements which form the solid parts of opaque bodies, for they do not reflect the rays of light with the force necessary to reflect the rare medium which constitutes the surface of white bodies.
CHROMATICS.

Entertaining Experiments, founded on the preceding Principles.

I. Out of a single coloured ray of light to produce seven others, which shall paint, on a white body, the seven primary colours of nature.

Procure of an optician a large glass prism DEF, Plate well polished, two of whose sides must contain an angle of about sixty-four degrees. Make a room quite dark, fig. 1 and in the window shutter AB, cut a round hole, about one-third of an inch in diameter, at C, through which a ray of light LI passing, falls on the prism DEF; by that it is refracted out of the direction IT, in which it would have proceeded into another GH; and, falling on the paper MNSX, will there form an oblong spectrum PQ, whose ends will be semicircular, and its sides straight; and if the distance of the prism from the paper be about eighteen inches, it will be ten inches long, and two inches wide. This spectrum will exhibit all the primary colours: the rays between P and V, which are the most refracted, will paint a deep violet; those between V and I, indigo; those between I and B, blue; those between B and G, green; those between G and Y, yellow; those between Y and O, orange; and those between O and R, being the least refracted, an intense red. The colours between these spaces will not be everywhere uniform, but will incline to the neighbouring colour: thus the part of the orange next to R, will incline to a red; that next to Y, to a yellow; and so of the rest.

II. From two or more of the primary colours, to compose others that shall, in appearance, resemble those of the former.

By mixing the two homogeneous colours red and yellow, an orange will be produced similar in appearance to that in the series of primary colours; but the light of the one being homogeneal, and that of the other heterogeneous, if the former be viewed through a prism it will remain unaltered, but the other will be resolved into its component colours red and yellow. In like manner other contiguous homogeneous colours may compound new colours: as by mixing yellow and green, a colour between them is formed; and if blue be added, there will appear a green that is the middle colour of those three. For the yellow and blue, if they are equal in quantity, will draw the intermediate green equally toward them, and keep it, at it were, in equilibrio, that it verge not more to the one than to the other. To this compound green there may be added some red and violet; and yet the green will not immediately cease, but grow less vivid; till by adding more red and violet it will become more dulled; and at last by the prevalence of the added colours, it will be overcome, and turned into some anomalous colour.

If the sun's white, composed of all kinds of rays, he added

(c) From hence it arises, that black bodies, when exposed to the sun, become sooner heated than all others.
ad. to any homogenous colour, that colour will not vanish, nor change its species, but be diluted; and by adding more white, it will become continually more diluted. Lastly, if red and violet be mixed, there will be generated, according to their various proportions, various purples, such as are not like, in appearance, to the colour of any homogenous light; and of these purples, mixed with blue and yellow, other new colours may be composed.

III. Out of three of the primary colours, red, yellow, and blue, to produce all the other prismatic colours, and all that are intermediate to them.

Provide three panes of glass of about five inches square; and divide each of them, by parallel lines, into five equal parts. Take three sheets of very thin paper; which you must paint, lightly, one blue, another yellow, and the third red. Then paste on one of the glasses five pieces of the red paper; one of which must cover the whole glass, the second only the four lower divisions, the third the three lower, the fourth the two lowest, and the fifth the last division only. On the other two glasses five pieces of the blue and yellow papers must be pasted in like manner. You must also have a box of about six inches long, and the same depth and width as the glasses; it must be black on the inside; let one end be quite open, and in the opposite end there must be a hole large enough to see the glasses completely. It must also open at the top, that the glasses may be placed in it conveniently.

When you have put any one of these glasses in the box, and the open end is turned toward the sun, you will see five distinct shades of the colour it contains. If you place the blue and yellow glasses together, in a similar direction, you will see five shades of green distinctly formed. When the blue and red glasses are placed, a bright violet will be produced; and by the red and yellow, the several shades of orange.

If, instead of placing these glasses in a similar position, you place the side AB of the yellow glass against the side BD of the blue, you will see all the various greens that are produced by nature (e); if the blue and red glasses be placed in that manner, you will have all the possible varieties of purples, violets, &c.; and, lastly, if the red and orange glasses be so placed, there will be all the intermediate colours, as the marygold, aurora, &c.

IV. By means of the three primary colours, red, yellow, and blue, together with light and shade, to produce all the gradations of the prismatic colour.

On seven square panes of glass, paste papers that are painted with the seven prismatic colours, in the same manner as in the last experiment. The colours for the orange, green, indigo, and violet, may be made by mixing the other three. Then with bistre (r), well diluted, shade a sheet of very thin paper, by laying it light on both its sides. With pieces of this paper cover four-fifths of a glass, of the same size with the others, by laying one piece on the four lowest divisions, another on the three lowest, a third on the two lowest, and the fourth on the lowest division only, and leaving the top division quite uncovered. When one of the coloured glasses is placed in the box, together with the glass of shades, so that the side AB of the one be applied to the side BC of the other, as in fig. 3. the several gradations of colours will appear shaded in the same manner as a drapery judiciously painted with that colour.

It is on this principle that certain French artists have proceeded in their endeavours to imitate, by designs printed in colours, paintings in oil: which they do by four plates of the same size, on each of which is engraved the same design. One of these contains all the shades that are to be represented, and which are painted either black or with a dark grey. One of the other plates is coloured with blue, another with red, and the third with yellow; each of them being engraved in those parts only which are to represent that colour (c); and the engraving is either stronger or weaker, in proportion to the tone of colour that is to be represented (n).

These four plates are then passed alternately under the press, and the mixture of their colours produces a print that bears no small resemblance to a painting. It must be confessed, however, that what has been hitherto done of this kind falls far short of that degree of perfection of which this art appears susceptible. If they who engrave the best in the manner of the crayon were to apply themselves to this art, there is reason to expect.

(p) Water-colours must be used for this purpose: the blue may be that of Prussia, and very bright; the red, carmine; and the yellow, gamboge, mixed with a little saffron. These colours must be laid very light and even, on both sides of the paper.

(e) In the first position of the glasses, the quantity of blue and yellow being equal, the same sort of green was constantly visible: but by thus inverting the glasses, the quantity of the colours being constantly unequal, a very pleasing variety of tints is produced.

(r) The bistre here used must be made of root, not that in flene.

(c) When a red drapery is required, it is engraved on the plate assigned to that colour; and so of yellow and blue: but if one of the other colours be wanting, sapphire violet, it must be engraved on those plates that print the red and blue; and so of the rest. The plates of this kind have been hitherto engraved in the manner of mezzotinto; but these, unless they are skilfully managed, soon become smutty. Engravings in the manner of the crayon will perhaps answer better.

(n) The principal difficulty in this sort of engraving arises from a want of a skilful management, in giving each plate that precise degree of engraving which will produce the tone of colour required. If a bright green is to be represented, there should be an equal quantity of graving on the red and yellow plates: but if an olive green, the yellow plate should be engraved much deeper than the red.
expect they would produce far more finished pieces than we have hitherto seen.

V. To make figures appear of different colours successively.

Make a hole in the window-shutter of a dark room, through which a broad beam of light may pass, that is to be refracted by the large glass prism \( \text{ABC} \), which may be made of pieces of mirrors cemented together, and filled with water. Provide another prism \( \text{DEF} \), made of three pieces of wood; through the middle of this there must pass an axis on which it is to revolve. This prism must be covered with white paper; and each of its sides cut through in several places, so as to represent different figures, and those of each side should likewise be different. The inside of this prism is to be hollow, and made quite black, that it may not reflect any of the light that passes through the sides into it. When this prism is placed near to that of glass, as in the figure, with one of its sides \( \text{EF} \) perpendicular to the ray of light, the figures on that side will appear perfectly white: but when it comes into the position \( \text{gh} \), the figures will appear yellow and red; and when it is in the position \( \text{kl} \), they will appear blue and violet. As the prism is turned round its axis, the other sides will have a similar appearance. If instead of a prism, a four or five sided figure be here used, the appearances will be still further diversified.

This phenomenon arises from the different refrangibility of the rays of light. For when the side \( \text{EF} \) is in the position \( \text{gh} \), it is more strongly illuminated by the least refrangible rays; and wherever they are predominant, the object will appear red or yellow. But when it is on the position \( \text{kl} \), the more refrangible rays being then predominant, it will appear tinged with blue and violet.

VI. The solar magic lantern.

 procure a box, of about a foot high, and eighteen inches wide, or such other similar dimensions as you shall think fit; and about three inches deep. Two of the opposite sides of this box must be quite open; and in each of the other sides let there be a groove, wide enough to pass a stiff paper or pasteboard. This box must be fastened against a window on which the sun's rays fall directly. The rest of the window should be closed up, that no light may enter. Provide several sheets of stiff paper, which must be blacked on one side. On these papers cut out such figures as you shall think proper; and placing them alternately in the grooves of the box, with their blacked sides towards you, look at them through a large and clear glass prism; and if the light be strong, they will appear to be painted with the most lively colours in nature. If you cut on one of these papers the form of the rainbow, about three quarters of an inch wide, you will have a lively representation of that in the atmosphere.

This experiment may be further diversified, by pasting very thin papers, lightly painted with different colours, over some of the parts that are cut out: which will appear to change their colours when viewed through the prism, and to stand out from the paper, at different distances, according to the different degrees of refrangibility of the colours with which they are painted. For greater convenience, the prism may be placed in a stand on a table, at the height of your eye, and made to turn round on an axis, that when you have got an agreeable prospect, you may fix it in that position.

VII. The prismatic camera obscura.

Make two holes \( \text{F}, \text{f} \), in the shutter of a dark Fig. 5. chamber, near to each other; and against each hole place a prism \( \text{ABC} \), and \( \text{a} \ & \text{c} \), in a perpendicular direction, that their spectrums \( \text{NM} \) may be cast on the paper in a horizontal line, and coincide with each other; the red and violet of the one being in the same part with those of the other. The paper should be placed at such a distance from the prisms that the spectrum may be sufficiently dilated. Provide several papers nearly of the same dimensions with the spectrum, cross these papers, and draw lines parallel to the divisions of the colours. In these divisions cut out such figures as you shall find will have an agreeable effect, as flowers, trees, animals, &c. When you have placed one of these papers in its proper position, hang a black cloth or paper behind it, that none of the rays that pass through may be reflected and confine the phenomenon. The figures cut on the paper will then appear strongly illuminated with all the original colours of nature. If while one of the prisms remains at rest, the other be revolved on its axis, the continual alteration of the colours will afford a pleasing variety; which may be further increased by turning the prism round in different directions.

When the prisms are so placed that the two spectrums become coincident in an inverted order of their colours, the red end of one falling on the violet end of the other; if they be then viewed through a third prism \( \text{DH} \), held parallel to their length, they will no longer appear coincident, but in the form of two distinct spectrums, \( \text{p} \ & \text{n} \) (Fig. 6.), crossing one another in the middle, like the letter \( \text{X} \): the red of one spectrum and the violet of the other, which were coincident at \( \text{NM} \), being parted from each other by a greater refraction of the violet to \( \text{p} \) and \( \text{m} \), than that of the red to \( \text{n} \) and \( \text{t} \).

This experiment may be further diversified by adding two other prisms, that shall form a spectrum in the same line, and contiguous in the other; by which not only the variety of figures, but the vividness of colours, will be considerably augmented.

The diatonic scale of colours.

The illustrious Newton, in the course of his investigations of the properties of light, discovered that the length of the spaces which the seven primary colours possess in the spectrum, exactly corresponds to those of chords that found the seven notes in the diatonic scale of music. As is evident by the following experiment.

On a paper in a dark chamber, let a ray of light be Fig. 7. largely refracted into the spectrum \( \text{AFTMGPS} \), and mark the precise boundaries of the several colours, as \( \text{a} \ & \text{b} \ & \text{c} \ & \text{e} \ & \text{c} \). Draw lines from those points perpendicular to the opposite side, and you will find that the spaces \( \text{M} \ & \text{F} \), by which the red is bounded: \( \text{g} \ & \text{e} \), by which the orange is bounded: \( \text{g} \ & \text{p} \ & \text{d} \), by which the yellow is bounded: \( \text{e} \ & \text{c} \). will be in exact proportion.
to the divisions of a musical chord for the notes of an octave; that is, as the intervals of those numbers $1$, $\frac{3}{2}$, $\frac{5}{2}$, $\frac{7}{2}$, $\frac{9}{2}$.

IX. Colorific music.

FATHER CASTEL, a Frenchman, in a curious book he has published on chromatics, supposes the note A to answer to blue in the prismatic colours; the note C to yellow, and Mi to red. The other tones he refers to the intermediate colours; from whence he constructs the following gamut of colorific music:

<table>
<thead>
<tr>
<th>Note</th>
<th>Colour</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ut</td>
<td>Blue</td>
</tr>
<tr>
<td>Ut sharp</td>
<td>Sea-green</td>
</tr>
<tr>
<td>Re</td>
<td>Bright green</td>
</tr>
<tr>
<td>Re sharp</td>
<td>Olive green</td>
</tr>
<tr>
<td>Mi</td>
<td>Yellow</td>
</tr>
<tr>
<td>Fa</td>
<td>Aurora</td>
</tr>
<tr>
<td>Fa sharp</td>
<td>Orange</td>
</tr>
<tr>
<td>Sol</td>
<td>Red</td>
</tr>
<tr>
<td>Sol sharp</td>
<td>Crimson</td>
</tr>
<tr>
<td>La</td>
<td>Violet</td>
</tr>
<tr>
<td>La sharp</td>
<td>Blue Violet</td>
</tr>
<tr>
<td>Si</td>
<td>Sky blue</td>
</tr>
<tr>
<td>Ut</td>
<td>Blue</td>
</tr>
</tbody>
</table>

This gamut, according to his plan, is to be continued in the same manner for the following octaves; except that the colours are to be more vivid.

He supposes these colours, by striking the eye in the same succession as the sounds (to which he makes them analogous) do the ear, and in the same order of time, they will produce a correspondent sensation of pleasure in the mind. It is on these general principles, which F. Castel has elucidated in his treatise, that he has endeavoured, though with little success, to establish his ocular harpsichord.

The construction of this instrument, as here explained, will show that the effects produced by colours by no means answer those of sounds, and that the principal relation there is between them consists in the duration of the time that they respectively affect the senses.

Between two circles of pasteboard, of ten inches diameter, AB and CD, inclose a hollow pasteboard cylinder E, 18 inches long. Divide this cylinder into spaces half an inch wide, by a spiral line that runs round it from top to bottom, and divide its surface into six equal parts by parallel lines drawn between its two extremities; as is expressed in the figure.

Let the circle AB, at top, be open; and let that at bottom, CD, be closed, and supported by an axis or screw, of half an inch diameter, which must turn freely in a nut placed at the bottom of a box we shall presently describe. To the axis just mentioned adjust a wooden wheel G, of two inches and a half in diameter, and that has 12 or 15 teeth, which take the endless screw H. Let this cylinder be inclosed in a box ILMN (fig. 9.) whose base is square, and at whose bottom there is a nut in which the axis turns. Observe that the endless screw H should come out of the box, that it may receive the handle O, by which the cylinder is to be turned.

This box being closed all round, place over it a tin covering A, which must be perforated in different parts; from this cover there must hang three or four lights, so placed that they may strongly illuminate the inside of the cylinder. In one side of this box (which should be covered with pasteboard) cut eight apertures, a, b, c, d, e, f, g, h, of half an inch wide, and $\frac{1}{2}$ of an inch high; they must be directly over each other, and the distance between them must be exactly two inches. It is by these openings, which here correspond to the musical notes, that the various colours analogous to them are to appear; and which being placed on the pasteboard cylinder, as we have shown, are reflected by means of the lights placed within it.

It is easy to conceive, that when the handle O is turned, the cylinder in consequence rising half an inch, if it be turned five times round, it will successively show, at the openings made in the side of the box, all the notes that are in the cylinder itself, and which are ranged according to the direction of the inclined lines drawn on it. It is therefore according to the duration of the notes which are to be expressed, that the apertures on the cylinder are to be cut. Observe, that the space between two of the parallel lines drawn vertically on the cylinder, is equal to one measure of time; therefore, for every turn of the cylinder, there are six measures, and thirty measures for the air that is to be played by this instrument.

The several apertures being made in the side of the cylinder, in conformity to the notes of the tune that is to be expressed, they are to be covered with double pieces of very thin paper, painted on both sides with the colours that are to represent the musical notes.

This experiment might be executed in a different manner, and with a much greater extent; but as the entertainment would not equal the trouble of expense, we have thought it sufficient to give the above piece, by which the reader will be enabled to judge how far the analogy supposed by F. Castel really exists.

Furthermore, Mr Robertson's doubts and observations respecting the authenticity of the Parian Chronicle, one or two publications have since appeared in answer, but none of them calculated to remove the objections or materially to affect the arguments that had been stated with so much learning and ingenuity against it. The following stricture, however, with which the Monthly Reviewers have concluded their critique of Mr Robertson's performance, seem to merit consideration.
Chronicle. On Objection 1. That the characters have no certain or unequivocal marks of antiquity, the Reviewers remark, that this seems rather to be an answer to a defender of the inscription, than an objection. If a zealous partisan of the marble should appeal to its characters and orthography, as decisive proofs of its being genuine, it would be proper enough to answer, that these circumstances afford no certain criterion of authenticity. But in this word certain feeks an unlucky ambiguity. If it means demonstrative, it must be allowed that no inscription can be proved to be certainly genuine from these appearances; but if it means no more than highly probable, many inscriptions possess sufficient internal evidence to give their claims this degree of certainty. The true question is, Has not the Parian Chronicle every mark of antiquity that can be expected in a monument claiming the age of 2000 years? The letters ร and แ are, by Mr R’s own confession, such as occur in genuine inscriptions; and to say in answer, that an imposter might copy the forms of these letters from other inscriptions, is already to suppose the inscriptions forged, before it is rendered probable by argument. The learned author of the Dissertation somewhat betrays some doubt of his own conclusion; for he adds, p. 56, "that the antiquity of an inscription can never be proved by the mere form of the letters, because the most ancient characters are as easily counterfeited as the modern." But this objection is equally applicable to all other ancient inscriptions; and is not to the purpose, if the present inscription has any peculiar marks of imposture in its characters and orthography. "The characters do not resemble the Sigean, the Nemean, or the Delian inscriptions." Mr R. answers this objection himself, by adding, "which are supposed to be of a more ancient date." The opposite reason to this will be a sufficient answer to the other objection, "that they do not resemble the Parthian pillars or the Alexandrian MS." If "they differ in many respects from the Marmor Sandvicenæ," they may be presumed to agree in many. "They seem to resemble, more than any other, the alphabet taken by Montfaucon from the Marmor Cyzicensum." Thus it appears that the Parian Chronicle most nearly resembles the two inscriptions, to whose age it most nearly approaches.

When Mr R. adds, that the letters "are such as an ordinary stone-cutter would probably make, if he were employed to engrave a Greek inscription, according to the alphabet now in use," he must be understood. The engraver of a fac simile generally omits some nice and minute touches in taking his copy; but, even with this abatement, we dare appeal to any adept in Greek calligraphy, whether the specimen facing p. 56, will justify our author’s observation? "The small letters อ, ง, น intermixed among the larger, have an air of affectation and artifice." Then has the greater part of ancient inscriptions an air of affectation and artifice. For the อ is perpetually engraved in this diminutive size; and น being of a kindred found, and ง of a kindred shape, how can we wonder that all three should be represented of the same magnitude? In the inscription which immediately follows the marble in Dr Chandler’s edition, N° xxiv, these very three letters are never so large as the rest, and often much smaller; of which there are instances in the three first lines. See also Chronicle, two medals in the second part of Dorville’s Sica, Tab. xvi. Numb. 7, 9.

"From the archaism, such as ร and แ, etc, etc, no conclusion can be drawn in favour of the authenticity of the inscription." Yet surely every thing common to it with other inscriptions, confidedly genuine, creates a reasonable presumption in its favour. "But what reason could there be for these archaism in the Parian Chronicle? We do not usually find them in Greek writers of the same age, or even of a more early date." The reason is, according to our opinion, that such archaism were then in use: this we know from other inscriptions, in which such archaism (or, as our author afterward calls them, barbarisms) are frequent. Nothing can be inferred from the Greek writers, unless we had their autographs. The present system of orthography in our printed Greek books is out of the question. As to, "The inscription sometimes adopts and sometimes neglects these archaism, as in lines 4, 12, 27, 52, 63, 67." This inconsistency either is no valid objection, or if it be valid, will demolish not only most every other inscription, but almost every writing whatever. For example, in the inscription just quoted, N° xxiv. we find ร and แ, and น in p. 54. A little farther, N° xxvi. l. 31, we have ร and แ, p. 57. 73. 81. ร and แ, and น, น and แ, p. 106. 108. ร and แ, p. 106. The Corycian inscription (Montfaucon, Diar. Ital. p. 420) promiscuously uses ร and แ, and น and แ, น. In English, who is surprised to find has and hath, a hand and an hand, a useful and an useful, in the works of the same author? We could produce instances of this inaccuracy from the same page, nay from the same sentence.

"The authenticity of those inscriptions, in which these archaism appear, must be established, before they can be produced in opposition to the present argument." This is, we cannot help thinking, rather too severe a refutation. If no inscription may be quoted before it be proved genuine, the learned author of the Dissertation need not be afraid of being confuted; for nobody will engage with him on such conditions. Perhaps the reverse of the rule will be thought more equitable; that every inscription be allowed to be genuine, till its authenticity be rendered doubtful by probable arguments. We will conclude this head with two short observations. In Selden’s copy, l. 26, was written ร and แ, which the later editors have altered to ร and แ, but without reason, the other being the more ancient way of writing, common in MSS, and sometimes found on inscriptions. (See G. Koen’s Notes on Gregoryus de Diadeta, p. 30.) In l. 83, the marble has ร and แ, for which Palmer wished to substituate ร and แ. Dr Taylor retires him from the Marmor Sandvicenæ, observing at the same time, that this orthography occurs in no other place whatever except in these two monuments. Is it likely that two engravers should by chance coincide in the same mistake, or that the forger of the Parian Chronicle (if it be forged) should have seen the Marmor Sandvicenæ, and taken notice of this peculiarity with the intention of afterward employing it in the fabrication of an imposture?

The
CHR.

The Reviewers next proceed to consider, but more briefly, the other objections.

II. It is not probable that the Chronicle was engraved for private use. 1. Because it was such an expense, as few learned Greeks were able to afford. If only a few were able to afford it, some of their few might be willing to incur it. But let Mr. R. consider how likely it is that a modern, and probably a needy Greek, should be more able to afford it in the last century, than a learned Greek 2000 years ago. 2. A manuscript is more readily circulated. Do men never prefer cumbrous splendor to cheapness and convenience? And if this composition, instead of being engraved on marble, had been committed to parchment, would it have had a better chance of coming down to the present age? Such a flying sheet would soon be lost; or, if a copy had, by miracle, been preserved to us, the objections to its being genuine would be more plausible than any that have been urged against the inscription. What Mr. R. says about the errors to which an inscription is liable, &c. will only prove that chronological inscriptions ought not to be engraved; but not that they never were engraved. We allow that the custom of writing in the reign of Ptolemy Philadelphia was not on stones. But it was common enough to occur to the mind of any person who wished to leave behind him a memorial at once of his learning and magnificence.

III. This objection, that the marble does not appear to be engraved by public authority, we shall readily admit, though Bentley (Diff. on Phalaris, p. 257.) leans to the contrary opinion. In explaining this objection, the learned dissertator observes, that though the expression, περιστατικα της Παρους, would lead us to suppose that the inscription related to Paros, not a single circumstance in the history of that island is mentioned. But this expression only shows that the author was an inhabitant of Paros, and intended to give his readers a clue, or παραγεμα, by the aid of which they might adjust the general chronology of Greece to the dates of their own history. "It is as absurd as would be a marble in Jamaica containing the revolutions of England." We see no absurdity in supposing a book to be written in Jamaica containing the revolutions of England. The natives of Paros were not uninterested in events relating to the general history of Greece, particularly of Athens; and how can we tell whether the author were an inhabitant of the island; whether he thought it a place beneath his care; or whether he had devoted a separate inscription to the chronology of Paros?

IV. It has been frequently observed, that the earlier periods of the Grecian history are involved in darkness and confusion. Granted. It follows then, that "an author who should attempt to settle the dates of the earlier periods would frequently contradict preceding, and be contradicted by subsequent, writers: he would naturally fall into mistakes: and at best could only hope to adopt the most probable system. But the difficulty of the task, or the impossibility of success, are not sufficient to prove that no man has been rash or mad enough to make the attempt." On the contrary, we know that many have attempted it. What a number of different periods has Mr. R. himself given us from the ancients concerning the age of Homer? This consideration will in part obviate another objection, that the Parian Chronicle does not agree with any ancient author. The fact is, that while the ancients contradicted one another, how could it follow more than one of them? and why might not the author, without any imputation of ignorance or rackless, sometimes depart from them all? If indeed he disagrees with them when they are unanimous, it might furnish matter for infelicity; though even this would be far from a decisive argument, unless the ancients were extremely unlike the moderns, as never to be found of singular and paradoxical positions.

V. This Chronicle is not one mentioned by any writer of antiquity. How many of those inscriptions, which are preferred to the present day, are mentioned by classical authors? Verres' Places composed a Roman calendar, which, as a monument of his learning and industry, was engraved on marble, and fixed in the most public part of Preneile. Fragments of this very calendar were lately dug up at Preneile, and have been published by a learned Italian. Now, if the paflage of Suetonius, which informs us of this circumstance, had been lost, would the silence of the Latin writers prove that the fragments were not genuine remains of antiquity? It may be said that the copies are paralleled; for not a single author mentions the Parian Chronicle, whereas Suetonius does mention Verres' Roman calendar. To this we answer. It is dangerous to deny the authenticity of any monument on the slender probability of its being casually mentioned by a single author. We shall also observe, that this fact of the Hemicycloium of Verres will answer some part of the Dissertator's second objection: «The Parian Chronicle is not an inscription that might have been concealed in a private library." Why not? It is of no extraordinary bulk; and might formerly have been concealed in a private library, or in a private room, with as much care as many inscriptions are now concealed in very narrow space. But unless the monument were placed in some conspicuous part of the island, and obviated itself on the notice of every traveller, the wonder will in great measure cease why it is never quoted by the ancients. Of the nine authors named in p. 109, had any one ever visited Paros? If Paupanias had travelled thither, and published his description of the place, we might perhaps expect to find some mention of this marble in so curious and inquitive a writer. But though the inscription existed, and were famous at Paros, there seems no necessity for any of the authors whose works are still extant to have known or recorded it. If there be, let this learned antiquit point out the place where this mention ought to have been made. If any persons were bound by a stronger obligation than others to speak of the Parian inscription, they must be the professed chronologers; but alas! we have not the entire works of so much as a single ancient chronologer: it is therefore impossible to determine whether this Chronicle were quoted by any ancient. And supposing it had been seen by some ancient, whose writings still remain, why should he make particular mention of it? Many authors, as we know from their remains, very freely copied their predecessors without naming them. Others, finding only a collection of facts, events in the inscription, without historical proofs or critics, naturally neglect it, as deserving no credit. Mr. R. seems to lay much stress on the precise, exact, and particular
Objection VII. With respect to the paraphrasmits that Mr. R. produces, we shall without hesitation grant, that the author of the inscription may have committed some mistakes in the chronology, as perhaps concerning Phidias, whom he seems to have confounded with another of the same name, &c. But these mistakes will not conclude against the antiquity of the inscription, unless we at the same time reject many of the principal Greek and Roman writers, who have been convicted of similar errors. We return therefore to Objection VI. Some of the facts seem to have been taken from authors of a later date. We have endeavoured impartially to examine and compare the passages quoted in proof of this objection; but we are obliged to confess, that we do not perceive the faintest traces of theft or imitation. One example only deserves to be excepted to which we shall therefore pay particular attention.

"The names of six; and, if the lacunae are properly supplied, the names of twelve cities, appear to have been engraved on the marble, exactly as we find them in Pausanias's Various History. But there is not any imaginable reason for this particular arrangement. It does not correspond with the time of their foundation, with their situation in Ionia, with their relative importance, or with the order in which they are placed by other eminent historians."

The chance of six names, says Mr. R. being placed by two authors in the same order, is as 1 to 720; of 12, as 1 to 479,901,600. "It is therefore utterly improbable that these names would have been placed in this order on the marble, if the author of the inscription had not transcribed them from the historian."

On this argument we shall observe, 1. That the very contrary conclusion might possibly be just, that the historian transcribed from the inscription. Yet we shall grant that in the present case this is improbable, especially if the author of the Various History be the same Pausanias, who, according to Philostratus, Vit. Soph., II. 31, never quitted Italy in his life. But an intermediate writer might have copied the marble, and Pausanias might have been indebted to him. 2dly, We see no reason to allow, that the lacunae are properly supplied. Suppose we should affirm, that the names stood originally thus: Miletus, Ephesus, Erythrae, Clazomenae, Lebedos, Chios, Phoca, Colophon, Myus, Priene, Samos, Teos. In this arrangement, only four names would be together in the same order with Miletus; and from these Miletus must be excepted, because there is an obvious reason for mentioning that city first. Three only will then remain; and surely that is too slight a resemblance to be considered into an imitation. For Pausanias and Paterculus, quoted by our author, p. 154, have both enumerated the twelve cities, and both agree in placing the five last in the same order; nay, the six first, if Voluitt's conjecture that TEUM ought to be inserted in Paterculus after Myam & EM be as true as it is plausible. But who imagines that Pausanias had either opportunity or inclination to copy Paterculus? 3dly, Allowing that the names were engraved on the marble exactly in the order that Pausanias has chosen, is there no way of solving the phenomenon but by supposing that one borrowed from the other? Seven authors at least (Mr. R. seems to say more, p. 154, 5.) mention the colonization of the same cities: how many authors now left may we reasonably conjecture to have done the same? If therefore the compiler of the Chronicle and Pausanias lightened on the same author, the former would probably preserve the same arrangement that he found, because in transferring a list of names, he could have no temptation to deviate; and the latter would certainly adhere faithfully to his original, because he is a notorious and fertile plagiarist. Mr. R. indeed thinks, p. 158, that if a succeeding writer had borrowed the words of the inscription, he would not have suppressed the name of the author. This opinion must fail to the ground, if it be shown that Pausanias was accustomed to suppress the names of the authors to whom he was obliged. Pausanias has given a list of fourteen celebrated gluttons; and, elsewhere, another of twenty-eight drunkards (from which, by the way, it appears, that people were apt to eat and drink rather too freely in ancient as well as modern times); and both these lists contain exactly the same names in the same order with Atheneus. Now, it is improbable that fourteen names may be transposed 8,717,291,200 different ways, and that twenty-eight names admit of 304,885,134,861,713,901,504,000,000 different transpositions, &c. &c. Pausanias therefore transcribed them from Athenaeus? yet Pausanias never mentions Athenaeus in his Various History. So that whether Pausanias copied from the marble, or only drew from a common source, he might, and very probably would, conceal his authority.

VIII. The history of the discovery of the Marbles is obscure and unsatisfactory. In p. 169, it is said to be "related with suspicious circumstances, and without any of those clear and unequivocal evidences which always discriminate truth from falsehood." The question then is finally decided. If the inscription has not any of those evidences which truth always possesses, and which falsehood always wants, it is most certainly forged. The learned diffluent seeks for a moment to have forgotten the necessity of a doubt, and to permutate the dogmatist. But waving this, we shall add, that as far as we can see,
Much truth is observable in this remark. But the Chronicles of sundry authors are applied to particular cases. In the first place, it must be observed, that no forged books will exactly suit Sir R.'s purpose, but such as pretend to be the author's own handwriting; nor any inscriptions, but such as are still extant on the original materials, or such as were known to be extant at the time of their pretended discovery. Let the argument be bounded by these limits, and the number of forgeries will be very much reduced. We are not in possession of Cicero's Anonitius's book; but if we were governed by authority, we should think that the testimony of Reinsius in his favour greatly overbalances all that Augtinus has said to his prejudice. The opinion of Reinsius is of the more weight, because he inspects Urinus of publishing counterfeit monuments. We likewise find the most eminent critics of the present age quoting Cicero without suspicion (Fid. Ruuihui. in Timaeu Lex. Plat. p. 10. apud Cen. ad Gregor. p. 140. ) The doctrine advanced in the Introduction from Hardouin is exactly conformable to that writer's usual paradoxes. He wanted to destroy the credit of all the Greek and Latin writers. But inscriptions hung like a millstone about the neck of his project. He therefore resolved to make fore work, and deny the genuineness of as many as he could conveniently; to effect which purpose, he introduces himself in a general accusation. If the author of the dissertation had quoted a few more paragraphs from Hardouin, in which he endeavours, after his manner, to throw the forgery of some inscriptions, he would at once have administered the poison and the antidote. But to the reverses of that learned madman, respecting Greek spurious compositions of this nature, we shall content ourselves with opposing the sentiments of a modern critic, whose judgment on the subject of spurious inscriptions will not be disputed.

Maffi, in the introduction to the third book, c. t. p. 51. of his admirable, though unfinished, work de Arte Critica Lapidaria, uses these words: Inscriptiores Graeci, aequitatem communitiis, sic cum Latini comparabantur, reprehendi posuerat, nonque enim manu saevo es, in tanta debacchantium falsiarum libidinis, monumentis esse, in quod ille, nisiDic nonce peruenire. Argumenta esse, paucisimas, atque in hanc dim ab eruditissimis, et in hoc literarum generi plurimum vasis nostris refutamina esse, falsae damnatas.

Books of Chronicles, a canonical writing of the Old Testament. It is uncertain which were written first, The Books of Kings, or The Chronicles, since they each refer to the other. However it be, the latter is often more full and comprehensive than the former. Whereas the Greek interpreters call these two books Paralipomena, Supplements, Additions, because they contain some circumstances which are omitted in the other historical books. Th. J. S. make but one book of the Chronicles, under the title of Libros Hiatamim, i.e. Journals or Annals. Ezra is generally believed to be the author of these books. It is certain they were written after the end of the Babylonian captivity and the first year of the reign of Cyrus, whom mention is made in the last chapter of the second book.

The Chronicles, or Paralipomena, are an abridge-
CHRONOLOGY.

TREATS of time, the method of measuring its parts, and adapting the same, when distinguished by proper marks and characters, to past transactions, for the illustration of history. This science therefore consists of two parts. The first treats of the proper measurement of time, and the adjustment of its several divisions; the second of fixing the dates of the various events recorded in history, and ranging them, according to the several divisions of time, in the order in which they happened.

Chronology, comparatively speaking, is but of modern date. The ancient poets appear to have been entirely unacquainted with it; and Homer, the most celebrated of them all, mentions nothing like a formal calendar in any part of his writings. In the most early periods, the only measurement of time was by the seasons, the revolutions of the sun and moon; and many ages must have elapsed before the mode of computation by dating events came into general use. Several centuries intervened between the era of the Olympic games and the first historians; and several more between these and the first authors of chronology. When time first began to be reckoned, we find its measures very indeterminate. The succession of Judea’s priests at Argos served Helenicus for the regulation of his narrative; while Ephorus reckoned his generations. Even in the history of Herodotus and Thucydides, we find no regular date for the events recorded; nor was there any attempt to establish a fixed era, until the time of Ptolemy Philadelphus, who attempted it by comparing and correcting the dates of the Olympiads, the kings of Sparta, and the succession of the priests of Juno at Argos. Eratosthenes and Apollodorus digested the events recorded by them according to the succession of the Olympiads and of the Spartan kings.

The uncertainty of the measures of time in the most early periods renders the histories of those times equally uncertain; and even after the invention of dates and eras, we find the ancient historians very inattentive to them, and inaccurate in their computations. Frequently their eras and years were reckoned differently without their being sensible of it, or at least without giving the reader any information concerning it; a circumstance which has rendered the fragments of their works now remaining of very little use to posterity. The Chaldean and Egyptian writers are generally acknowledged to be fabulous; and Strabo acquaints us, that Diodorus Siculus, and the other early historians of Greece, were ill informed and credulous. Ancient historians not being able to explain satisfactorily the events recorded by them according to their genealogies; nor was there any attempt to establish a fixed era, until the time of Ptolemy Philadelphus, who attempted it by comparing and correcting the dates of the Olympiads, the kings of Sparta, and the succession of the priests of Juno at Argos. Eratosthenes and Apollodorus digested the events recorded by them according to the succession of the Olympiads and of the Spartan kings.

Eratosthenes and Apollodorus digested the events recorded by them according to the succession of the Olympiads and of the Spartan kings.

From these observations it is obvious how necessary a utility of chronology must be for the right understanding of history, and likewise how very difficult it must be to establish such a system. In this, however, several learned men have excelled, particularly Julius Africanus, Eusebius of Caesarea, George Cypselus, John of Patmos, Dennis, Peron, Clavius, Calvin, Usher, Simson Martiam, Blair, and Playfair. It is founded, 1. On astronomical observations, particularly of the eclipses of the sun and moon, combined with the calculations of the stars and planets of different nations. 2. The testimonies of credible authors. 3. Those epochs in history which are so well attested and determined, that they have never been controverted. 4. Ancient medals, coins, monuments, and inscriptions. None of these, however, can be sufficiently intelligible without an explanation of the first part, which we have already observed, confessing the divisions of time, and of which therefore we shall treat in the first place.

The most obvious division of time is derived from the apparent revolutions of the celestial bodies, particularly of the sun, which by the vicissitudes of day and night becomes evident to the most barbarous and ignorant nations. In strict propriety of speech the word day signifies only that portion of time during which the sun diftincts light on any part of the earth; but in the most comprehensive sense, it includes the night also, and is called by chronologists a civil day; by astronomers a natural, and sometimes an artificial, day.
By a civil day is meant the interval between the sun's departure from any given point in the heavens and next return to the same, with as much more as answers to its diurnal motion eastward, which is at the rate of 59 minutes and 8 seconds of a degree, or 3 minutes and 57 seconds of time. It is also called a *solar* day, and is longer than a *sidereal* one, inasmuch that, if the former be divided into 24 equal parts or hours, the latter will be but just over 23 hours. From this apparent inequality in the sun's motion, likewise arising from the obliquity of the ecliptic, produces another inequality in the length of the days: and hence the difference between real and apparent time, so that the apparent motion of the sun cannot always be a true measure of time. Those inequalities, however, are capable of being reduced to a general standard, which furnishes an exact measure throughout the year; whence arises the difference between real and apparent time, as is explained under the article Astronomy.

There have been very considerable differences among nations with regard to the beginning and ending of their days. The beginning of the day was called by the Jews, at sunrise; by the Babylonians, Syrians, Persians, and Indians. The civil day of the Jews was begun from sunrise, and their sacred one from sunset; the latter mode of computation being followed by the Athenians, Arabs, ancient Gauls, and other European nations. According to some, the Egyptians began their day at sunset, while others are of opinion that they computed from noon or from sunrise; and Pliny informs us that they computed their civil day from one midnight to another. It is probable, however, that they had different modes of computing in different provinces or cities. The Assemblies, the most ancient inhabitants of Italy, computed the day from midnight; and the astronomers of Cathay and Hindostan reckoned in their manner. This mode of computation was adopted by Hipparchus, Copernicus, and other astronomers, and is now in common use among ourselves. The *astronomical* day, however, as it is called, on account of its being used in astronomical calculations, commences at noon, and ends at the same time the following day. The Mahometans reckon from one twilight to another. In Italy, the civil day commences at some indeterminate point after sunset: whence the time of noon varies with the season of the year. At the summer solstice, the clock strikes 15 at noon, and 19 at the time of the winter solstice. Thus also the length of each day differs by several minutes from that immediately preceding or following it. This variation requires a considerable difficulty in adjusting their time by clocks. It is accomplished, however, by a sudden movement which corrects the difference when it amounts to a quarter of an hour; and this it does sometimes at the end of eight days, sometimes at the end of 15, and sometimes at the end of 40.

Information of all this is given by a printed calendar, which announces, that from the 16th of February, for instance, to the 24th, it will be noon at a quarter past 18; from the 24th of February to the 6th of March, it will be noon at 19 o'clock precisely; from the first of June to the 13th of July, the hour noon will be at 16 o'clock; on the 13th of July it will be at half an hour after 16; and so on throughout the different months of the year. This method of measuring the day continues, notwithstanding several attempts to supplant it, throughout the whole of Italy, a few provinces only excepted.

The subdivisions of the day have not been left various than the computations of the day itself. The most subdivisions obvious division, and which could at no time, nor in the day, no age, be mistaken, was that of morning and evening. In process of time the two intermediate points of noon and midnight were determined; and this division into quarters was in use long before the invention of hours.

From this subdivision probably arose the method used by the Jews and Romans of dividing the day and night into four vigils or watches. The first began at sun-rising, or six in the morning; the second at nine; the third at twelve; and the fourth at three in the afternoon. In like manner the night was divided into four parts; the first beginning at six in the evening, the second at nine, the third at twelve, and the fourth at three in the morning. The first of these divisions the third hour of the day; the second the sixth; the third the ninth; and the fourth the twelfth, and sometimes the *eleventh*. Another division in use, not only among the nations above-mentioned, but the Greeks also, was that which reckoned the first quarter from sunset to midnight; the second from midnight to sunset; the third, or morning watch, from morning to noon; and the fourth from noon to sunset.

It is uncertain at what time the more minute subdivision of the day into hours first commenced. If does not appear from the writings of Moses that he was acquainted with it, as he mentions only the morning, midday, evening, and night. Hence we may conclude, that the Egyptians at that time knew nothing of it, as Moses was well skilled in their learning. According to Herodotus, the Greeks received the knowledge of the twelve hours of the day from the Babylonians. It is probable, however, that the division was actually known and in use before the name *hour* was applied to it; as Censorinus informs us that the term was not made use of in Rome for 300 years after its foundation; nor was it known at the time the twelve tables were constructed.

The eastern nations divide the day and night in a very singular manner: the origin of which is not easily discovered. The Chinese have five watches in the night, which are announced by a certain number of strokes on a bell or drum. They begin by giving one stroke, which is answered by another; and this is repeated at the distance of a minute or two, until the second watch begins, which is announced by two strokes; and so on throughout the rest of the watches. By the ancient Tartars, Indians, and Persians, the day was divided into eight parts, each of which contained seven hours and a half. The Indians on the coast of Malabar divide the day into six parts, called *najika*; each of these six computations is subdivided into 60 others, called *veenas*; the first *veena* into 60 *birpe*; the *birpe* into 10 *kanka*; the *kanka* into four *mathies*; the *mathis* into eight *karnas* or *caignades*; which divisions, according to our mode of computation, stand as follows.

Najika...
The modern divisions of the hour in use among us are into minutes, seconds, thirds, fourths, &c., each being a sixtieth part of the former subdivision. By the Chaldeans, Jews, and Arabians, the hour is divided into 1080 scorpules; so that one hour contains 60 minutes, and one minute 18 scorpules. The ancient Persians and Arabs were likewise acquainted with this division; but the Jews are so fond of it, that they pretend to have received it in a supernatural manner. “Hecateus (say they) ascended into heaven, and brought from thence 1080 parts for the benefit of the nation.”

The division of the day being ascertained, it soon became an object to indicate in a public manner the expiration of any particular hour or division; as without some general knowledge of this kind, it would be in a great measure impossible to carry on business. The methods of announcing this have been likewise very different. Among the Egyptians it was customary for the priests to proclaim the hours like watchmen among us. The same method was followed at Rome; nor was there any other method of knowing the hours until the year 303 B.C. when Papirius Cursor first set up a sun-dial in the Capitol. A similar method is practised among the Turks, whose priests proclaim from the top of their mosques, the cock-crowing, day-break, mid-day, three o’clock in the afternoon, and twilight, being their appointed times of worship.

As this mode of proclaiming the hour could not but be very inconvenient as well as imperfect, the introduction of an instrument which every one could have in his possession, and which might answer the same purpose, must have been considered as a valuable acquisition. One of the first of these was the clepsydra or water clock. Various kinds of these were in use among the Egyptians at a very early period. The invention of the instrument is ascribed to Thoth or Mercury, and it was afterwards improved by Cleobius of Alexandria. It was a common measure of time among the Greeks, Indians, and Chaldeans, as well as the Egyptians, but was not introduced into Rome till the time of Sulpicius Naicus. The Chaldean astronomers have long made use of it; and by its means divided the zodiac into twelve parts; but it is a very inaccurate measure of time, varying, not only according to the quantity of water in the vessel, but according to the state of the atmosphere.

The clepsydra was succeeded by the gnomon or sun-dial.—This, at first, was no more than a little erected perpendicularly to the horizon; and it was a long time before the principles of it came to be thoroughly understood. The invention is with great probability attributed to the Babylonians, from whom the Jews received it before the time of Ahaz, when we know that a sun-dial was already erected at Jerusalem. The Chaldeans and Egyptians also were acquainted with the use of the dial at a very early period, and it was considerably improved by Anaximander or Anaximenes; one of whom is for that reason looked upon to be the inventor. Various kinds of dials, however, were invented and made use of in different nations long before their introduction at Rome. The first erected in that city, as has been already mentioned, was that by Papirius Cursor; and 50 years after, Valerius Mutila brought one from Sicily, which was used in Rome for no less than 99 years, though constructed for a Sicilian latitude, and consequently incapable of showing the hours exactly in any other place; but at last another was constructed by L. Philippus, capable of measuring time with greater accuracy.

It was long after the invention of dials before mankind began to form any ideas of clocks; nor is it well known at what period they were first invented. A clock was sent by Pope Paul I. to Pepin king of France, which at that time was supposed to be the only one in the world. A very curious one was also sent to Charles the Great from the Khalif Haroun Ar-Rashid, which the historian of the time speaks of with surprise and admiration; but the greatest improvement was that of Mr Huygens, who added the pendulum to it. Still, however, the instruments for dividing time were found to be inaccurate for nice purposes. The expansion of the materials by heat, and their contraction by cold, would cause a very perceptible alteration in the going of an instrument in the same place at different times of the year, and much more if carried from one climate to another. Various methods have been contrived to correct this; which indeed can be done very effectually at land by a certain construction of the pendulum; but at sea, where a pendulum cannot be used, the inaccuracy is of consequence much greater; nor was it thought possible to correct the errors arising from these causes in any tolerable degree, until the late invention of Mr Harrison’s time-piece, which may be considered as making perhaps as near an approach to perfection as possible.

Having thus given an account of the more minute divisions of time, with the methods of measuring them, we must now proceed to the larger; which more properly belong to chronology, and which must be kept on record, as no instrument can be made to point them out. Of these the division into weeks of seven days is one of the most ancient, and probably took place from the creation of the world. Some, indeed, are of opinion, that the week was invented some
Some time after for the more convenient notation of time; but whatever may be in this, we are certain that it is of the highest antiquity, and even the most rude and barbarous nations have made use of it. It is singular indeed that the Greeks, notwithstanding their learning, should have been ignorant of this division; and M. Goguet informs us, that they were almost the only nation who were so. By them the month of 30 days was divided into three times ten, and the days of it named accordingly. Thus the 15th day of the month was called the second fifth, or fifth of the second tenth; the 24th was called the third fourth, or the fourth day of the third tenth. This method was in use in the days of Hebræod, and it was not until several ages had elapsed, that the use of weeks was received into Greece from the Egyptians. The inhabitants of Cathay, in the northern part of China, were likewise unacquainted with the week of seven days, but divided the year into six parts of 60 days each. They had also a cycle of 15 days, which they used as a week. The week was likewise unknown to the ancient Persians and to the Mexicans; the former having a different name for every day of the month, and the latter making use of a cycle of 13 days. By almost all other nations the week of seven days was adopted.

17 Of holidays. It is remarkable, that one day in the week has always been accounted as sacred by every nation. Thus Saturday was consecrated to pious services, and to religious feasts, and authors are of opinion, that the origin of our Feria or Feriati, that is, holy, or sacred days; and in process of time the days of other weeks came to be distinguished by the same appellation, for the two following reasons: 1. Because every day ought to be holy in the estimation of a Christian. 2. Because all days are holy to ecclesiastics, whose whole time ought to be entirely devoted to religious worship. The term week is sometimes used to signify seven years, not only in the prophetic writings, but likewise by profane authors; thus Varro, in his book inscribed Hebdonades, informs us, that he had then entered the 12th week of his years.

18 Of months. The next division of time superior to weeks, is that of months. This appears to have been, if not coeval with the creation, at least in use before the flood. As this division is naturally pointed out by the revolution of the moon, the months of all nations were originally lunar; until after some considerable advances had been made in science, the revolutions of that luminary were compared with the sun, and thus the limits of the month fixed with greater accuracy. The division of the year into 12 months, as being founded on the number of full revolutions of the moon in that time, has also been very general; though Sir John Chardin informs us, that the Persians divided the year into 24 months; and the Mexicans into 18 months of 20 days each. The months generally contained 30 days, or 29 and 30 days alternately; though this rule was far from being without exception. The months of the Latins consisted of 16, 18, 22, or 30 days; and Romulus gave his people a year of 10 months and 304 days. The Kamichalades divide the year into 10 months; reckoning the time proper for labour to be nine months, and the winter feasts, when they are obliged to remain inactive, only as one month.

It has been a very ancient custom to give names to the different months of the year, though this appears to have been more modern than the departure of the Israelites out of Egypt, as they would otherwise undoubtedly have carried it with them; but for a considerable time after their settlement in Canaan, they distinguished the months only by the names of frist, second, &c. After their return from the Babylonish captivity, they adopted the names given to the months by the Chaldeans. Other nations adopted various names, and arranged the months themselves according to their fancy. From this last circumstance arises the variety in the dates of the months; for as the year has been reckoned from different signs in the ecliptic, neither the number nor the quantity of months have been the same, and their situation has likewise been altered by the intercalations necessary to be made.

These intercalations became necessary on account of the excess of the solar above the lunar year, and the months composed of intercalary days are likewise called embolismal. These embolismal months are either natural or civil. By the former, the solar and lunar years are adjusted to one another; and the latter arises from the defect of the civil year itself. The ador of the Jews, which always consists of 30 days, is an example of the natural embolismal month.

The Romans had a method of dividing their months into kalends, none, and ides. The first was derived from an old word calt, "to call"; because, at every new moon, one of the lower clafs of priests assembled the people, and called over, or announced, as many days as intervened between that and the nones, in order to notify the difference of times and the return of festivals. The 20, 2d, 4th, 5th, 6th, and 7th of March, July, and October, were the nones of those months; but in the other months were the 2d, 3d, 4th and 5th days only. Thus the 5th of January was its nones; the 4th was pride nonarum; the third, tertio nonarum, &c. The ides contained eight days in every month, and were nine days distant from the nones. Thus the 15th day of the four months already mentioned was the ides of them; but in the others the 15th was accounted as such; the 12th was pride iduum, and the 10th tertio iduum. The ides were succeeded by the kalends; the 14th of January, for instance, being the 19th kalend of February; the 15th was the 18th kalend; and so on till the 31st of January, which was pride kalendarium; and February 1st was the kalends.

Among the European nations the month is either astronomical or civil. The former are measured by the motion of the heavenly bodies; the civil consists of a certain number of days specified by the laws, or by the civil institutions of any nation or society. The astronomical months, being for the most part regulated by the motions of the sun and moon, are thus divided into solar and lunar, of which the former is sometimes also called civil. The astronomical solar month is the time
time which the sun takes in passing through a sign of the ecliptic. The lunar month is periodical, syno-
dical, sidereal, and civil. The sidereal lunar month is the time that passes between any conjunction of the moon with the sun and the conjunction following. It omits the motion of the moon during the same time; so that a mean lunar confluence consists of 29d. 12h. 4m. 2s. 921s. The sidereal lunar month is the time of the mean revolution of the moon with regard to the fixed stars. As the equinoctial points go backwards about 4° in the space of a lunar month, the moon must, in consequence of this retrocession, arrive at the equinox sooner than at any fixed star, and consequently the mean sidereal revolution must be longer than the mean periodical one. The latter consists of 27d. 7h. 43m. 95s. 6850. The civil lunar month is computed from the moon, to answer the ordinary purposes of life; and as it would have been inconvenient, in the computation of lunar months, to have reckoned odd parts of days, they have been composed of 30 days, or of 29 and 30 alternately, as the nearest round numbers. When the month is reckoned from the first appearance of the moon after her conjunction, it is called the month of illumination. The Arabs, Turks, and other nations, who use the era of the Hegira, follow this method of computation. As twelve lunar months, however, are 11 days less than a solar year, Julius Caesar ordained that the month should be reckoned from the course of the sun, and not of the moon; and that they should consist of 30 and 31 days alternately. February only excepted, which was to consist of 28 days commonly, and of 29 in leap-years. The highest natural division of time is into years. At first, however, it is probable that the course of the sun through the ecliptic would not be observed, but that all nations would measure their time by the revolutions of the moon. We are certain, at least, that the Egyptian year consisted originally of a single lunation; though at length it included two or three months, and was determined by the fixed returns of the feacions. As the eastern nations, however, particularly the Egyptians, Chaldeans, and Indians, applied themselves in very early periods to astronomy, they found, by comparing the motions of the sun and moon together, that one revolution of the former included nearly 12 of the latter. Hence a year of 12 lunations was formed, in every one of which were reckoned 30 days; and hence also the division of the ecliptic into 360 degrees. The lunisolar year, consisting of 360 days, was in use long before any regular intercalations were made; and historians inform us, that the year of all ancient nations was lunisolar. Herodotus relates, that the Egyptians first divided the year into 12 parts by the assistance of the stars, and that every part consisted of 30 days. The Thebans corrected this year by adding 5 intercalary days to it. The old Chaldean year was also reformed by the Medes and Persians; and of some of the Chinese missionaries we have informed us, that the lunisolar year was also corrected in China: and that the solar year was ascertained in that country to very considerable exactness. The Latin year, before Numa’s correction of it, consisted of 360 days, of which 304 were divided into ten months; to which were added two private months not mentioned in the calendar.

The imperfection of this method of computing time is now very evident. The lunisolar year was about 5 days shorter than the true solar year, and as much longer than the lunar. Hence the months could not long correspond with the seacons, and even in future time as 54 years, the winter months would have changed places with those of summer. From this rapid variation, Mr Playfair takes notice that a passage in Herodotus, by which the learned have been excessively puzzled, may receive a satisfactory solution, viz. that “in the time of the ancient Egyptian kings, the sun had twice arisen in the place where it had formerly set, and twice set where it had arisen.” By this he supposes it is meant, “that the beginning of the year had twice gone through all the signs of the ecliptic; and that the sun had risen and set twice in every day and month of the year.” This, which some have taken for a proof of most extravagant antiquity, he further observes, might have happened in 138 years only; as in that period there would be a difference of nearly two years between the solar and lunar year. Such evident imperfections could not but produce a reformation everywhere; and accordingly we find that there was no nation which did not adopt the method of adding a few intercalary days at certain intervals. We are ignorant, however, of the person who was the first inventor of this method. The Theban priests attributed the invention to Mercury or Thoth; and it is certain that they were acquainted with the year of 365 days at a very early period. The length of the solar year was represented by the celebrated golden circle of Osymandyas of 365 cubits circumference; and on every cubit of which was inscribed a day of the year, together with the heliacal risings and settings of the stars. The monarch is supposed to have reigned in the 11th or 13th century before the Christian era.

The Egyptian solar year being almost six hours greater than the true one, this inaccuracy, in process of time produced another revolution; for some circum-
stances attending which serve to fix the date of the dif-
certical cy-
covery of the length of the solar year, which from the above description of the golden circle, we may suppose to have been made during the reign of Osymandyas. The inundation of the Nile was annually announced by the heliacal rising of Sirius, to which the reformers of the calendar adjourned the beginning of the year, supposing that it would have remained immovable. In a number of years, however, it appeared that their suppositions in this were ill-founded. By reason of the inequality abovementioned, the heliacal risings of Sirius gradually advanced nearly at the rate of one day in four years; so that in 1461 years it completed a revolution, by arising on every succeeding day of the year, and returning to the point originally fixed for the beginning of the year. This period, equal to 1460 Julian years, was termed the great Egyptian year, or cir- cular cycle. From the accounts we have of the time that the circular cycle was renewed, the time of its original commencement may be gathered with to considerable certainty. This happened, according to Cen.

The accounts have of the time that the cicular cycle was renewed, the time of its original commencement may be gathered with certainty. This happened, according to Cen.
solfice, which happened on July 5th. The Egyptians used no intercalation till the time of Augustus, when the corrected Julian year was received at Alexandria by his order; but even this order was obeyed only by the Greeks and Romans who resided in that city, the superstitious natives refusing to make any addition to the length of a year which had been so long established among them.

We are not informed at what precise period the true year was observed to consist of nearly six hours more than the 365 days. Though the priests of Thebes claim the merit of the discovery, Herodotus makes no mention of it; neither did Thales, who introduced the year of 365 days into Greece, ever use any intercalation. Plato and Eudoxus are said to have obtained it as a secret from the Egyptians about 80 years after Herodotus, and to have carried it into Greece; which showed, that the knowledge of this form of the year was at that time recent, and only known to a few learned men.

The year of the ancient Jews was lunisolar; and we are informed by tradition, that Abraham preferred in his family, and transmitted to posterity, the Chaldean form of the year, consisting of 360 days; which remained the same without any correction until the date of the era of Nabonassar. The solar year was adopted among them after their return from the Babylonish captivity; but when subjected to the successors of Alexander in Syria, they were obliged to admit the lunar year into their calendar. In order to adjust this year to the course of the sun, they added a month to Adar, formerly mentioned, and called it Ve Adar. They composod also a cycle of 19 years, in seven of which they intercalated the intercalary month. This correction was intended to regulate the months in such a manner, as to bring the 15th of Nisan to the equinoctial point; and likewise the courses of the feasons and feasts in such a manner, that the corn might be ripe at the passover as the law required.

We shall not take up the reader's time with any further account of the years made use of by different nations, all of which are resolved at last into the lunisolar, it will be sufficient to mention the improvement made by the two great reformers of it, Julius Caesar, and Pope Gregory XIII. The institution of the Roman year by Romulus has been already taken notice of; but it is evident that Numa, on his advancement to the throne, undertook to reform it. With a deligh to make a complete lunar year of it, he added 50 days to the 304 of Romulus; and from every one of his months, which consisted of 31 and 30 days, he borrowed one day. Of these additional days he composed two months; calling the one January, and the other February. Various other corrections and adjustments were made; but when Julius Caesar obtained the sovereignty of Rome, he found that the months had considerably receded from the seasons to which Numa had adjusted them. To bring them forward to their places, he formed a year of 15 months, or 445 days; which, on account of its length, and the delay with which it was formed, has been called the year of confusion. It terminated on the first of January 45 B.C. and from this period the civil year and months were regulated by the course of the sun. The year of Numa being ten days shorter than the solar year, two months were added by Julius to every one of the months of January, August, and December; and, or to April, June, September, and November. He ordered likewise, that an intercalary day should be added every fourth year to the month of February, by reckoning the 24th day, or sixth of the kalends of March, twice over. Hence this year was styled bissextil, and also leap-year, from its leaping a day more than a common year.

The Julian year has been used by modern chronologists, as being a measure of time extremely simple and sufficiently accurate. It is still, however, somewhat imperfect; for as the true solar year consists of 365 5/6 days, it appears that in 131 years after the Julian correction, the sun must have arrived one day too soon at the equinoctial point. During Caesar's reign the vernal equinox had been observed by Soigne on the 25th of March; but by the time of the Nicene council it had gone backward to the 21st. The cause of the error was not then known; but in 1582, when the equinox happened on the 11th of March it was thought proper to give the calendar its last correction. Pope Gregory XIII having invited to Rome a considerable number of mathematicians and astronomers, employed ten years in the examination of their several formulae, and at last gave the preference to that of Alphio and Antoninus Lucius, who were brothers. Ten days were now cut off in the month of October, and the 4th of that month was reckoned the 15th. To prevent the feasons from receding in time to come, he ordained that one day should be added every fourth or bissextile year as before; and that the 1600th year of the Christian era, and every fourth century thereafter, should be a bissextile or leap year. One day therefore is to be intercalated in the years 2000, 2400, 2800, &c. but in the other centuries, as 1700, 1800, 1900, 2100, &c. it is to be suppressed, and there are to be reckoned as common years. Even this correction, however, is not absolutely exact; but the error must be very inconsiderable, and scarce amounting to a day and a half in 5000 years.

The commencement of the year has been determined by the date of some memorable event or occurrence, such as the creation of the world, the universal deluge, a conjunction of planets, the incarnation of our Saviour, &c. and of course has been referred to different points in the ecliptic. The Chaldeans and the Egyptian years were dated from the autumnal equinox. The ecclesiastical year of the Jews began in the spring; but in civil affairs, they retained the epoch of the Egyptian year. The ancient Chinese reckoned from the new moon nearest to the middle of Aquarius; but, according to some recent accounts, the beginning of their year was transferred (B.C. 1749) to the new moon nearest to the winter solstice. This likewise is the date of the Japanese year. Densifch, or Gemisch, king of Persea, observed, on the day of his public entry into Persepolis, that the sun entered into Aries. In commemoration of this fortunate event and coincidence, he ordained the beginning of the year to be removed from the autumnal to the vernal equinox. This epoch was denominated Neurex, viz. new-year, and is still celebrated with great pomp and festivity.
CHRONOLOGY.

(See Epochs). The ancient Swedish year commenced at the winter solstice, or rather at the time of the sun's appearance in the horizon, after an absence of about 40 days. The feast of this epoch was solemnized on the 20th day after the solstice. Some of the Greek states computed from the vernal, some from the autumnal equinox, and others from the former tropic. The year of Romulus commenced in March, and that of Numa in January. The Turks and Arabs date the year from the 16th of July and the American Indians reckon from the first appearance of the new moon of the vernal equinox. The church of Rome has fixed new-year's-day on the Sunday that corresponds with the full moon of the same feast. The Venetians, Florentines, and Pilans in Italy, and the inhabitants of Treves in Germany, begin the year at the vernal equinox. The ancient clergy reckoned from the 25th of March; and this method was observed in Britain, until the introduction of the new style (A.D. 1752), after which the year commenced on the 1st day of January.

Besides the natural divisions of time arising immediately from the revolutions of the heavenly bodies, there are others formed from some of the less obvious consequences of these revolutions, which are called cycles, from the Greek κύκλος, a circle. The most remarkable of these are the following:

1. The cycle of the sun is a revolution of 28 years, in which time the days of the months return again to the same days of the week; the sun's place to the same signs and degrees of the ecliptic on the same months and days, so as not to differ one degree in 100 years; and the leap-years begin the same course over again with respect to the days of the week on which the days of the months fall. The cycle of the moon, commonly called the golden number, is a revolution of 19 years; in which time the conjunctions, oppositions, and other aspects of the moon, are within an hour and a half of being the same as they were on the same days of the months 19 years before. The indiction is a revolution of 15 years, used only by the Romans for indicating the times of certain payments made by the subjects to the republic: It was established by Constantine, A.D. 312.

To find the year of any vulgar cycle.

The year of our Saviour's birth, according to the vulgar calendar, was the 9th of the solar cycle, and the 31st year after his birth was the first year of the Roman indiction. Therefore, to find the year of the solar cycle, add 9 to any given year of Christ, and divide the sum by 28, the quotient is the number of cycles elapsed since his birth, and the remainder is the cycle for the given year; if nothing remains, the cycle is 0. To find the lunar cycle, add one to the given year of Christ, and divide the sum by 19; the quotient is the number of cycles elapsed in the interval, and the remainder is the cycle for the given year: if nothing remains, the cycle is 19. Lastly, subtract 312 from the given year of Christ, and divide the remainder by 15; and what remains after this division is the indiction for the given year: if nothing remains, the indiction is 15.

Although the above deficiency in the lunar circle of an hour and an half every 19 years be but small, yet in time it becomes so sensible as to make a whole natural day in 310 years. So that, although this cycle be of use, when the golden numbers are rightly placed against the days of the months in the calendar, as in the Common Prayer Books, for finding the days of the mean conjunctions or oppositions of the sun and moon, and consequently the times of Easter: it will only serve for 310 years, old style. For as the new and full moons anticipate a day in that time, the golden numbers ought to be placed one day earlier in the calendar for the next 310 years to come. These numbers were rightly placed again the days of new moon in the calendar, by the council of Nice, A.D. 325; but the anticipation, which has been neglected ever since, is now grown almost into 5 days: And therefore all the golden numbers ought now to be placed five days higher in the calendar for the old stil than they were at the time of the said council; or 6 days lower for the new style, because at present it differs 11 days from the old.

In the first of the following tables the golden numbers to find the under the months stand against the days of new moon in golden number.

The cycle of Easter, also called the Dionysian period, Dionysian is a revolution of 522 years, found by multiplying the period, or solar cycle 28 by the lunar cycle 19. If the new moons of this cycle did not anticipate upon this cycle, Easter-day would al-
always be the Sunday next after the first full moon which follows the 21st of March. But, on account of the above anticipation, to which no proper regard was had before the late alteration of the style, the ecclesiastic Easter has several times been a week different from the true Easter within this last century; which inconvenience is now remedied by making the table, which is used to find Easter for ever, in the Common Prayer Book, of no longer use than the lunar difference from the new style will admit of.

The earliest Easter possible is the 22d of March, the latest the 25th of April. Within these limits are 35 days, and the number belonging to each of them is called the number of direction; because thereby the time of Easter is found for any given year.

The first seven letters of the alphabet are commonly placed in the annual almanacs, to shew on what days of the week the days of the months fall throughout the year. And because one of those seven letters must necessarily stand against Sunday, it is printed in a capital form, and called the dominoal letter; the other six being inserted in small characters, to denote the other six days of the week. Now, since a common Julian year contains 365 days, if this number be divided by 7 (the number of days in a week) there will remain one day. If there had been no remainder, it is plain the year would constantly begin on the same day of the week: but since one remains, it is plain, that the year must begin and end on the same day of the week; and therefore the next year will begin on the day following. Hence, when January begins on Sunday, A is the dominoal or Sunday letter for that year: then, because the next year begins on Monday, the Sunday will fall on the seventh day, to which is annexed the seventh letter G, which therefore will be the dominoal letter for all that year: and as the third year will begin on Tuesday, the Sunday will be on the sixth day: therefore F will be the Sunday letter for that year. Whence it is evident, that the Sunday letters will go annually in a retrograde order, thus, G, F, E, D, C, B, A. And, in the course of seven years, if they were all common ones, the same days of the week and dominoal letters would return to the same days of the months. But because there are 366 days in a leap-year, if this number be divided by 7, there will remain two days over and above the 52 weeks of which the year consists. And therefore, if the leap-year begins on Sunday, it will end on Monday; and the next year will begin on Tuesday, the first Sunday whereof must fall on the sixth of January, to which is annexed the letter F, and not G, as in common years. By this means, the leap-year: returning every fourth year, the order of the dominoal letter is interrupted; and the series cannot return to its first state till after four times seven, or 28 years; and then the same days of the months return in order to the same days of the week as before.

From the multiplication of the solar cycle of 28 years into the lunar cycle of 19 years, and the Roman indiction of 15 years, arises the great Julian period, consisting of 7980 years, which had its beginning 764 years before Strachio's supposed year of the creation (for no later could all the three cycles begin together), and it is not yet completed. And therefore it includes all other cycles, periods, and eras. There is but one year in the whole period that has the same numbers for the three cycles of which it is made up: And therefore, if historians had remarked in their writings the cycles of each year, there had been no dispute about the time of any action recorded by them.

The Dionysian or vulgar era of Christ's birth was about the end of the year 4713, and consequently the first year of his age, according to that account, was the 4714th year of the said period. Therefore, if to the current year of Christ we add 4713, the sum will be the year of the Julian period. So the year 1789 will be found to be the 6502d year of that period. Or, to find the year of the Julian period answering to any given year before the first year of Christ, subtract the number of that given year from 4471, and the remainder will be the year of the Julian period. Thus, the year 585 (before the first year of Christ) which was the 584th before his birth) was the 4129th year of the said period. Lastly, to find the cycles of the fun, moon, and indiction for any given year of this period, divide the given year by 28, 19, and 15; the three remainders will be the cycles sought, and the quotients the numbers of cycles run since the beginning of the period. So in the above 4714th year of the Julian period, the cycle of the fun was 10, the cycle of the moon 2, and the cycle of the indiction 4; the solar cycle having run through 168 courses, the lunar 248, and the indiction 314.

The vulgar era of Christ's birth was never settled till the year 527, when Dionysius Exiguus, a Roman Chrift's abbot, fixed it to the end of the 4713th year of the birth when Julian period, which was four years too late; for our settled. Saviour was born before the death of Herod, who sought to kill him as soon as he heard of his birth. And, according to the testimony of Josephus [B. xvii. ch. 8.), there was an eclipse of the moon in the time of Herod's last illnesses; which eclipse appears by our astronomical tables to have been in the year of the Julian period 4716, March 13th, at 3 hours past midnight, at Jerusalem. Now, as our Saviour must have been born some months before Herod's death, since in the interval he was carried into Egypt, the latest time in which we can fix the true era of his birth is about the end of the 4709th year of the Julian period.

As there are certain fixed points in the heavens from Eras or Em which astronomers begin their computations, so there posts are
are certain points of time from which historians begin to reckon; and these points or roots of time are called eras or epochs. The most remarkable eras are, those of the Creation, the Greek Olympiads, the building of Rome, the era or Nabonassar, the death of Alexander, the birth of Christ, the Arabian Hegira, and the Persian Jafetegird: All which, together with several others of less note, have their beginnings fixed by chronologers to the years of the Julian period, to the age of the world at those times, and to the years before and after the year of Christ's birth.

Having thus treated, as fully as our limits will admit, of the various divisions of time, we must now consider the second part of chronology, viz. that which more immediately relates to history, and which has already been observed to have the four following foundations: 1. Astronomical observations, particularly of eclipses. 2. The testimonials of credible authors. 3. Epochs in history universally allowed to be true. 4. Ancient medals, coins, monuments, and inscriptions. We shall consider these four principal parts in the order they here stand.

I. Of eclipses of the sun and moon.

It is with great reason that the eclipses of the sun and moon, and the aspects of the other planets, have been called public and celestial characters of the times, as their calculations afford chronologers infallible proofs of the precise epochs in which a great number of the most signal events in history have occurred. So that in chronological matters we cannot make any great progress, if we are ignorant of the use of astronomic tables, and the calculation of eclipses. The ancients regarded the latter as prognostics of the fall of empires, of the loss of battles, of the death of monarchs, &c. And it is to this superstition, to this wretched ignorance, that we happily owe the vast labour that historians have taken to record so great a number of them. The most able chronologers have collected them with still greater labour. Calvillus, for example, founds his chronology on 144 eclipses of the sun, and 127 of the moon, that he says he had calculated. The grand conjunction of the two superior planets, Saturn and Jupiter, which, according to Kepler, occurs once in 800 years in the same point of the zodiac, and which has happened only eight times since the creation (the last time in the month of December (1603)), may also furnish chronology with incontestable proofs. The same may be said of the transit of Venus over the sun, which has been observed in our days, and all the other uncommon positions of the planets. But among these celestial and natural characters of times, there are also some that are named civil or artificial, and which, nevertheless, depend on astronomic calculation.

Such are the solar and lunar cycles; the Roman indiction; the feast of Easter; the bimillenary year; the jubilees; the sabbatic years; the combats and Olympic games of the Greeks; and Hegira of the Mahometans, &c. And to these may be added the periods, eras, epochs, and years of different nations, ancient and modern. We shall only remark on this occasion, that the period or era of the Jews commenced with the creation of the world; that of the ancient Romans with the foundation of the city of Rome; that of the Greeks at the establishment of the Olympic games; that of Nebuchadnezzar, with the advancement of the first king of Babylon to the throne; the Yazdegerdian years, with the last king of the Persians of that name; the Hegira of the Turks with the flight of Mahomet from Mecca to Medina, &c. The year of the birth of Christ was the 4713th year of the Julian period, according to the common method of reckoning. Astronomical chronology teaches us to calculate the precise year of the Julian period in which each of these epochs happened.

II. The testimony of authors is the second principal of the second part of historic chronology. Though no man what- ever has a right to pretend to infallibility, or to authors being regarded as a sacred oracle, it would, however, be making a very unjust judgment of mankind, to treat them all as dupes or impostors; and it would be an injury offered to public integrity, were we to doubt the veracity of authors universally esteemed, and of facts that are in themselves right worthy of belief. It would be even a kind of infatuation to doubt that there have been such cities as Athens, Sparta, Rome, Carthage, &c. or that Xerxes reigned in Perlia, and Augustus in Rome; whether Hannibal ever was in Italy; or that the emperor Constantine built Constantinople, &c. The unanimous testimony of the most respectable historians will not admit any doubt of these matters. When an historian is allowed to be completely able to judge of an event, and to have no intention of deceiving by his relation, his testimony is irre- cusable. But to avoid the danger of adopting error for truth, and to be satisfied of a fact that appears doubtful in history, we may make use of the four following rules, as they are founded in reason.

1. We ought to pay a particular regard to the testimonies of those who wrote at the same time the events happened, and that have not been contradicted by any contemporary author of known authority. Who can doubt, for example, of the truth of the facts related by admiral Ancon, in the history of his voyage round the world? The admiral saw all the facts there mentioned with his own eyes, and published his book when two hundred companions of his voyage were still living in London, and could have contradicted him immediately, if he had given any false or exaggerated relations.

2. After the contemporary authors, we should give more credit to those who lived near the time the events happened, than those who lived at a distance.

3. Those doubtful histories, which are related by authors that are but little known, can have no weight if they are at variance with reason, or established tradition.

4. We must distrust the truth of a history that is related by modern authors, when they do not agree among themselves in several circumstances, nor with ancient historians, who are to be regarded as original sources. We should especially doubt the truth of those brilliant portraits, that are drawn at pleasure by such as never knew the persons they are intended for, and even made several centuries after their decease.

The most pure and most fruitful source of ancient history
history is doubtless to be found in the Holy Bible. Let
us here for a moment cease to regard it as divine, and
let us presume to consider it as a common history.
Now, when we regard the writers of the books of the
Old Testament, and consider them sometimes as au-
thors, sometimes as ocular witnesses, and sometimes
as respectable historians; whether we reflect on the
simplicity of the narration, and the air of truth that
is there constantly visible; or, when we consider the
care that the people, the governments, and the
learned men of all ages, have taken to preserve the
true text of the Bible; or that we have regard to the
happy conformity of the chronology of the holy scrip-
tures with that of profane history: or, if we observe
the admirable harmony that is between these books
and the most respectable historians, as Josephus and
others: and lastly, when we consider that the books
of the holy scripture furnish us alone with an accurate
history of the world from the creation, through the
line of patriarchs, kings, judges, and princes of the
Hebrews; and that we may, by its aid, form an al-
most entire series of events down to the birth of
Christ, or the time of Augustus, which comprehends a
space of about 4000 years, some small interruptions
excepted, and which are easily supplied by profane
history: when all these reflections are justly made, we
must constantly allow that the scriptures form a
book which merits the first rank among all the
sources of ancient history. It has been objected, that
this book contains contradictions; but the most able
interpreters have reconciled these seeming contra-
dictions. It has been said, that the chronology of the
Hebrew text and the Vulgate do not agree with the
chronology of the version of the Septuagint; but the
soundest critics have shown that they may be made to
agree. It has been observed, moreover, that the
scriptures abound with miracles and prodigies; but
they are miracles that have really happened: and
what ancient history is there that is not filled with
miracles, and other marvellous events? And do we for
that reject their authority? Cannot the true God be
supposed to have performed those miracles which
Pagan historians have attributed to their false divini-
ties? Must we pay no regard to the writings of
Livy, because his history contains many fabulous re-
lations?

III.

The epochs form the third principal part ofchrono-
ology. These are those fixed points in history that
have never been contested, and of which there can,
in fact, be no doubt. Chronologers fix on the events
that are to serve as epochs, in a manner quite arbi-
trary; but this is of little consequence, provided the
dates of these epochs agree, and that there is no con-
tradiction in the facts themselves. When we come
to treat expressly on history, we shall mention, in our
progress, all the principal epochs.

IV.

Medals, &c. Medals, monuments, and inscriptions, form the
fourth and last principal part of chronology. It is
scarce more than 130 years since close application has
been made to the study of these; and we owe to the
celebrated Spanheim the greatest obligations, for the
progress that is made in this method: his excel-
 lent work, De praecellentia et usu nummorum anti-
guorum, has shown the great advantages of it; and
it is evident that these monuments are the most au-
thentic witnesses that can be produced. It is by the
aid of medals that M. Vailant has composed his judi-
cious history of the kings of Syria, from the time of
Alexander the Great to that of Pompey: they have
been, moreover, of the greatest service in elucidating
all ancient history, especially that of the Romans; and
even sometimes that of the middle age. Their use is
more fully spoken of in the article Medals. What we
here lay of medals, is to be understood equally, in
its full force, of ancient inscriptions, and of all other
authentic monuments that have come down to us.

Every reader, endowed with a just discernment
will readily allow that these four parts of chronology
afford clear lights, and are excellent guides to con-
duct us through the thick darkness of antiquity. That
impartiality, however, which directs us to give a
faithful relation of that which is true and false, of the
certainty and uncertainty of all the sciences, obliges
us here freely to confess, that these guides are not in-
falible, nor the proofs that they afford mathematical
demonstrations. In fact, with regard to history in
general, and ancient history in particular, something
must be always left to conjecture and historic faith.
It would be an offence against common probity, were
we to suffer ourselves to pass over in silence those
objections which authors of the greatest reputation
have made against the certainty of chronology. We
shall extract them from their own works; and we
hope that their is no magistrate, theologian, or pub-
lie professor in Europe, who would be mean enough
to accuse us of a crime, for not unworthily discovering
the truth.

1. The prodigious difference there is between the
Septuagint Bible and the Vulgate, in point of chronol-
ogy, occasions an embarrassment, which is the more
difficult to avoid as we cannot positively say on which
side the error lies. The Greek Bible counts, for ex-
ample, from the creation of the world to the birth of
Abraham, 1500 years more than the Hebrew and La-
tin Bibles, &c. 2. How difficult is it to ascertain the
years of the judges of the Jewish nation, in the Bible?
What darkness is spread over the succession of the
kings of Judah and Israel? The calculation of time is
therefore inaccurate, that the scripture never marks if
they are current or complete years. For we cannot
suppose that a patriarch, judge, or king, lived ex-
actly 40, 90, 100, or 969 years, without any odd
months or days. 3. The different names that the
Assyrians, Egyptians, Persians and Greeks, have
given to the same prince, have contributed not a little
to embarrass all ancient chronology. Three or four
princes have borne the name of Assuerus, though they
had also other names. If we did not know that Na-
bucodonosor, Nabucodrofor, and Nabucolassar, were
the same name, or the name of the same man, we
should scarcely believe it. Sargon is Senacherib;
Ozias is Azarias; Sedecias is Mathanias; Joschas is
also called Selium; Astaraddon, which is pronounced
indifferently Estabarond and Asarhaddon, is called
Afenaphar by the Cuthians; and by an oddity of which
we do not know the origin, Sardanapalus is called
by
CHRONOLOGY.

4008 The creation of the world, and Adam and Eve. 4007 The birth of Cain, the first who was born of a woman.

3017 Enoch, for his piety, is translated to heaven.
3527 The old world is destroyed by a deluge which continued 377 days.
2247 The tower of Babel is built about this time by Noah's posterity; upon which God miraculously confounds their language, and thus disperses them into different nations.
2237 About this time, Noah is, with great probability, supposed to have parted from his rebellious offspring, and to have led a colony of some of the more tractable into the east, and there either he, or one of his successors, gave birth to the ancient Chinese monarchy.
2234 The celestial observations are begun at Babylon, the city which first gave birth to learning and the sciences.

1985 The covenant of God made with Abraham, when he leaves Haran to go into Canaan, which begin, the 430 years of sojourning.
1961 The cities of Sodom and Gomorrah are destroyed for their wickedness by fire from heaven.
1836 The kingdom of Argos, in Greece, begins under Inachus.
1822 Memnon, the Egyptian, invents the letters.
1715 Prometheus first strikes fire from flints.
1635 Joseph dies in Egypt.
1574 Aaron born in Egypt; 1490, appointed by God first high-priest of the Israelites.
1556 Mofes, brother to Aaron, born in Egypt, and adopted by Pharaoh's daughter, who educates him in all the learning of the Egyptians.
1556 Cecrops brings a colony of Saites from Egypt into Attica, and begins the kingdom of Athens in Greece.
1555 Mofes performs a number of miracles in Egypt; and departs from that kingdom, together with 600,000 Israelites, besides children, which completed the 430 years of sojourning. They miraculously pass through the Red Sea, and come to the desert of Sinai, where Mofes receives from God, and delivers to the people, the Ten Commandments, and the other laws, and sets up the tabernacle, and in it the ark of the covenant.

1546 Scamander comes from Crete into Phrygia, and begins the kingdom of Troy.
1515 The Israelites, after sojourning in the wilderness forty years, are led under Joshua into the land of Canaan, where they fix themselves, after having subdued the natives; and the period of the sabbatical year commences.
1503 The deluge of Deucalion.
1496 The council of Amphitheatrons established at Thermopylae.
1493 Cadmus carried the Phoenician letters into Greece and built the citadel of Thebes.
1490 Sparta built by Lacedemou.
Before Christ.

1485 The first slav that appeared in Greece was brought from Egypt by Danaus, who arrived at Rhodes, and brought with him his fifty daughters.
1480 Troy built by Dardanus.
1432 The Pentateuch, or five first books of Moses, are written in the land of Moab, where he died the year following, aged 110.
1406 Iron is found in Greece, from the accidental burning of the woods.
1344 The kingdom of Mycenae begins.
1326 The Ithmian games instituted at Corinth.
1325 The Egyptian eanecular year began July 2oth.
1307 The Olympic games instituted by Pelops.
1300 The Lupercalia instituted.
1294 The first colony came from Italy into Sicily.
1264 The second colony came from Italy into Sicily.
1252 The city of Tyrre built.
1243 A colony of Arcadians conducted by Evander into Italy.
1223 Carthage founded by the Tyrians.
1225 The Argonautic expedition.
1204 The rape of Helen by Paris, which gave rise to the Trojan war, ending with the destruction of the city in 1184.
1176 Salamis in Cyprus built by Teucer.
1152 Acanthis builds Alba Longa.
1150 The kingdom of Sicyon ended.
1124 Thebes built by the Boeotians.
1115 The mariner's compass known in China.
1104 The expedition of the Heraclidae into Peloponnesus; the migration of the Dorians thither; and the end of the kingdom of Mycenae.
1102 The kingdom of Sparta commenced.
1070 The kingdom of Athens ended.
1051 David besieged and took Jerusalem.
1044 Migration of the Ionian colonies.
1008 The Temple is solemnly dedicated by Solomon.
996 Solomon prepared a fleet on the Red Sea to send to Ophir.
986 Sames and Utica in Africa built.
979 The kingdom of Israël divided.
974 Jerusalem taken and plundered by Shishak king of Egypt.
901 The prophet Elijah flourished.
894 Money first made of gold and silver at Argos.
884 Olympic games restored by Iphitus and Lycurgus.
873 The art of sculpture in marble found out.
869 Scales and measures invented by Phidon.
864 The city of Carthage, in Africa, enlarged by queen Dido.
821 Nineveh taken by Arbaces.
814 The kingdom of Macedon begins.
801 The city of Capua in Campania built.
799 The kingdom of Lydia began.
786 The ships called Triremes invented by the Corinthians.
779 The race of kings in Corinth ended.
776 The era of the Olympiads began.
760 The Ephori established at Sparta.
758 Syracuse built by Archias of Corinth.
754 The government of Athens changed.
753 Era of the building of Rome in Italy by Romulus, first king of the Romans.
747 The era of Nabonassar commenced on the 26th of February, the first day of Thoth.
746 The government of Corinth changed into a republic.
743 The first war between the Messenians and Spartans.
724 Mycenae reduced by the Spartans.
723 A colony of the Messenians settled at Rhegium in Italy.
720 Samaria taken, after three years siege, and the kingdom of Israel finished by Salmanaser king of Assyria, who carries the ten tribes into captivity.
The first eclipse of the moon on record.
713 Gela in Sicily built.
703 Corycya, now Corfu, founder of the Corinthians.
702 Ecbatana in Media built by Doloes.
685 The second Messenian war under Aristomenes.
670 Byzantium (now Constantinople) built by a colony of Athenians.
666 The city of Alba destroyed.
648 Cyrene in Africa founded.
634 Cyaxares besieges Nineveh, but is obliged to raise the siege by an incursion of the Scythians, who remained masters of Asia for 28 years.
624 Draco published his inhuman laws at Athens.
610 Pharaoh Necho attempted to make a canal from the Nile to the Red Sea, but was not able to accomplish it.
607 By order of the same monarch, some Phenicians failed from the Red Sea round Africa, and returned by the Mediterranean.
606 The first captivity of the Jews by Nebuchadnezzar. Nineveh destroyed by Cyaxares.
600 Thales, of Miletus, travels into Egypt, consults the priests of Memphis, acquires the knowledge of geometry, astronomy, and philosophy; returns to Greece, calculates eclipses, gives general notions of the universe, and maintains that an only Supreme Intelligence regulates all its motions.
Maps, globes, and the signs of the zodiac, invented by Anaximander, the scholar of Thales.
598 Jehoiakin, king of Judah, is carried away captive, by Nebuchadnezzar, to Babylon.
594 Solon made Archon at Athens.
591 The Pythian games instituted in Greece, and tragedy first acted.
588 The first irruption of the Gauls into Italy.
586 The city of Jerusalem taken, after 1 siege of 16 months.
582 The last captivity of the Jews by Nebuchadnezzar.
581 The Ithmian games restored.
580 Money first coined at Rome.
571 Tyre taken by Nebuchadnezzar after a siege of 13 years.
566 The first census at Rome, when the number of citizens was found to be 84,000.
562 The first comedy at Athens acted upon a movable scaffold.
559 Tyrus the first king of Persia.
538 The kingdom of Babylon finished; that city being.
CHRONOLOGY.

151 The foundation of the temple laid by the Jews.
152 Learning is greatly encouraged at Athens, and a public library first founded.
153 The second edict to rebuild Jerusalem.

CHRONOLOGY.

Before

Christ.

Anthony and Cleopatra are totally defeated by
Octavius, nephew to Julius Cæsar.
30 Alexandria, in Egypt, is taken by Octavius, upon
which Anthony and Cleopatra put themselves
to death, and Egypt is reduced to a Roman
province.
29 A census at Rome. The number of citizens
4,101,017.
27 Octavius, by a decree of the senate, obtains the
title of Augustus Cæsar, and an absolute ex-
emption from the laws, and is properly the
first Roman emperor.
The pantheon at Rome built.
19 Rome at the height of its glory.
The temple of Jerusalem rebuilt by Herod.
Agrippa contracted the magnificent aqueducts
at Rome.
8 A census at Rome. The number of citizens
4,233,000.
5 The temple of Janus is shut by Augustus, as an
emblem of universal peace, and
JESUS CHRIST is born, on Monday, December
25.
1 The Vulgar Christian era commenced from Ja-
uary, the Saviour of the world being then
five years of age.
8 Jesus Christ disputes with the doctors in the
temple.
14 A census at Rome, 4,037,000 citizens.
16 Mathematicians and magicians expelled from
Rome.
17 Twelve cities in Asia destroyed by an earth-
quake.
27 Pilate made governor of Judea.
29 Jesus baptized in Jordan by John.
33 He is crucified at Jerusalem.
35 St Paul converted.
39 St Matthew writes his Gospel.
Pontius Pilate kills himself.
A conjunction of Saturn, Jupiter, and Mars.
40 The name of Christians first given at Antioch
by the followers of Christ.
43 Claudius Cæsar’s expedition into Britain.
44 St Mark writes his Gospel.
45 London is founded by the Romans: 368, sur-
rrounded by ditches with a wall, some parts of
which are still observable.
51 Caractacus, the British king, is carried in chains
to Rome.
53 The council of the Apostles at Jerusalem.
55 St Luke writes his Gospel.
56 Rotterdam built.
59 The emperor Nero puts his Mother and brothers
to death.
———Persecutes the Druids in Britain.
60 Christianity introduced into Britain.
61 Boadicea, the British queen, defeats the Romans;
but is conquered soon after by Suetonius, go-
gernor of Britain.
62 St Paul is sent in bonds to Rome—writes his
epistles between 51 and 66.
A great earthquake in Asia.
64 Rome set on fire, and burned for six days; upon
which began (under Nero) the first persecu-
tion against the Christians.
65 Many prodigies occur about Jerusalem.
66 St Peter and St Paul put to death.
70 While the furious Jews are destroying one an-
other with mutual fury, Titus, the Roman ge-
neral, takes Jerusalem, which is raised to the
ground, and the plough made to pass over it.
73 The philosophers banished from Rome by Ver-
pal.
79 The cities of Pompeii and Herculaneum de-
stroyed by an eruption of Vesuvius.
80 The Capitol and Pantheon at Rome destroyed
by fire.
83 The philosophers expelled Rome by Domitian.
85 Julius Agricola, governor of South-Britain, to
protect the civilized Britons from the incurs-
ions of the Caledonians, builds a line of forts
between the rivers Forth and Clyde; defeats
the Caledonians under Galgacus on the Gram-
pian hills; and first falls round Britain, which
he discovers to be an island.
86 The Capitoline games instituted by Domitian.
88 The secular games celebrated at Rome.
93 The empire of the Huns in Tartary destroyed
by the Chinese.
96 St John the Evangelist wrote his Revelation—
his Gospel in 97.
103 Dacia reduced to a Roman province.
105 A great earthquake in Asia and Greece.
107 The third persecution of the Christians under
Trajan.
114 Armenia reduced to a Roman province.
An earthquake in China.
115 Assyria subdued by Trajan.
An insurrection of the Jews, who murder
200,000 Greeks and Romans.
A violent earthquake at Antioch.
120 Nicomedia and other cities swallowed up by an
earthquake.
121 The Caledonians reconquer from the Romans all
the southern parts of Scotland; upon which
the emperor Adrian builds a wall between
Newcastle and Carlisle; but this also proving
ineffectual, Pollius Urbicus, the Roman ge-
neral, about the year 134, repairs Agricola’s forts,
which he joins by a wall four yards thick.
130 Jerusalem rebuilt by Adrian.
132 The second Jewish war commenced.
135 The second Jewish war ends, when they were all
banished Jews.
139 Justin writes his first apology for the Christians.
141 A number of heresies appear about this time.
146 The worship of Serapis introduced at Rome.
152 The emperor Antoninus Pius drops the persecu-
tion against the Christians.
An inundation of the Tyber, and an earth-
quake at Rhodes.
163 The fourth persecution of the Christians, under
Marcus Aurelius Antoninus.
166 The Romans sent Ambassadors to China.
CHRONOLOGY.

168 A plague over the known world.
169 The Capitol at Rome destroyed by lightning.
170 A great part of Rome destroyed by fire.
173 The fifth persecution of the Christians, under Severus.
205 An earthquake in Wales.
206 Severus’s wall in Britain built.
218 Two comets appeared at Rome. The course of the most remarkable from east to west.
222 About this time the Roman empire begins to decline. The Barbarians begin their irruptions, and the Goths have annual tribute not to molest the empire.
225 Mathematicians allowed to teach publicly at Rome.
236 The sixth persecution of the Christians, under Maximin.
241 The Franks first mentioned in history.
250 The seventh persecution, under Decius.
252 A dreadful persecution broke out in Ethiopia, and spread over the world.
253 Europe ravaged by the Scythians and Goths.
258 The ninth persecution, under Valerian.
260 Valerian is taken prisoner by Sapor, king of Persia, and fed alive.
263 The Scythians ravaged the Roman empire.
264 The eighth persecution of the Christians.
267 The temple of Diana at Ephesius burnt.
268 A great plague throughout the Roman empire.
269 Earthquakes in Europe, Asia, and Africa, and three days of darkness.
270 The Romans took Palmyra.
274 Silk first brought from India; the manufactory of it introduced into Europe by some monks, first worn by the clergy in England, 1534.
276 Wines first made in Britain.
277 The Franks settled in Gaul.
284 The Diocletian era commenced August 29th, or September 17th.
287 Carausius proclaimed emperor of Britain.
289 A great comet visible in Mesopotamia for 29 days.
291 Two emperors and two Caesars march to defend the four quarters of the empire.
297 Alexandria destroyed by Diocletian.
303 The tenth persecution, under Diocletian.
306 Constantine the Great begins his reign.
308 Cardinals first began.
312 Peftilence all over the East.
313 Cycle of induction began.
314 The tenth persecution ends by an edict of Constantine, who favours the Christians, and gives full liberty to their religion.
315 Three bishops, or fathers, are sent from Britain to affit at the council of Arles.
315 Crucifixion abolished.
321 Observation of Sunday enjoined.
323 The first general council at Nice, when 318 fathers attended, against Arius, the founder of Arianism, where was composed the famous Nicene Creed, which we attribute to them.
329 Constantine removes the seat of empire from Rome to Byzantium, which is thereafter called Constantinople.
CHRONOLOGY.

452 The city of Venice founded.
455 The Saxons having expelled the Scots and Picts, invite over more of their countrymen, and begin to establish themselves in Kent, under Hengist.

476 The western empire is finished, 533 years after the battle of Pharsalia; upon the ruins of which several new states arise in Italy and other parts, consisting of Goths, Vandals, Huns, and other barbarians, under whom literature is extinguished, and the works of the learned are destroyed.

480 A great earthquake at Constantinople, which lasted 40 days.

1712 Duke of Hamilton and Lord Mohun killed in a duel in Hill-Park.

1713 The peace of Utrecht, whereby Newfoundland, Nova Scotia, New Britain, and Hudson's bay, in North America, were yielded to Great Britain; Gibraltar and Minorca, in Europe, were also confirmed to the said crown by this treaty.

1714 Queen Anne dies, at the age of 50, and is succeeded by George I.

1715 Interest in England reduced to five per cent.

1716 The Pretender married the princess Sobieska, grand-daughter of John Sobieski, late king of Poland.

1717 An act passed for septennial parliaments.

1718 Sardinia erected into a kingdom, and given to the duke of Savoy.

1719 The Mississippi scheme at its height in France. Lombe's silk-throwing machine, containing 26,586 wheels, erected at Derby in England: takes up one-eighth of a mile; one water-wheel moves the rest; and in 24 hours it works 318,054,660 yards of organzine silk thread.

1720 The south-fsea scheme in England begun April 7, was at its height at the end of June, and quite sunk about September 29.

A great earthquake in China.

1724 An earthquake in Denmark.

1727 King George dies, in the 68th year of his age; and is succeeded by his only son, George II.

1728 The Jesuits expelled from Paraguay.

1729 The order of the Knights of St. John is established in the Duchy of Cornwall.

1730 Kouli Khan upsurps the Persian throne, conquers the Mogul empire, and returns with two hundred thirty-one millions Sterling; several public-spirited gentlemen begin the settlement of Georgia in North America.

1731 The beginnings of the French Society of arts, manufactures, and commerce; instituted in London.

1732 Damien attempted to assassinate the French king. The King of Prussia invades Bohemia. Defeats the Austrians at Reichenberg, April 21st, and at Prague, May 6th. Repelled by Count Daun at Kolín, June 18th.

1733 The allies defeated by the French at Haslau-Beck, July 26th.

1734 A dreadful plague in Sicily.

1735 War declared against France. — Commodore Anson returns from his voyage round the world.

1736 The allies lose the battle at Fontenoy.

1737 The Pretender's army defeated by the Duke of Cumberland at Culloden, April 16, 1746.

1738 The British Linen Company erected.

1739 The battle of Dettingen won by the English and allies in favour of the Queen of Hungary.

1740 Lima destroyed by an earthquake.

1741 The Peace of Aix-la-Chapelle, by which a re-creation of all places taken during the war was to be made on all sides.

1742 The interest on the British funds reduced to 3 per cent.

1743 British herring-fishery incorporated.

1744 The colony of Nova Scotia founded.

1745 Earthquake in England.

1746 Frederic prince of Wales, father to his present majesty, died.

1747 The new filo introduced into Great Britain; the 3d of September being counted the 14th.

1748 The British museum erected at Montague-house.

1749 Society of arts, manufacturers, and commerce, instituted in London.

1750 A dreadful eruption of mount Etna.

1751 An earthquake at Constantinople, Cairo, &c. Sept. 2d.

1752 Quito in Peru destroyed by an earthquake, April 28th.

1753 Lisbon destroyed by an earthquake, Nov. 1st.

1754 The British fleet destroyed in the black hole at Calcutta in the East Indies by order of the Nabob, and 123 found dead next morning.

1755 Marine society established at London.

1756 Englishmen are confined in the black hole at Calcutta in the East Indies by order of the nabob, and 123 found dead next morning.

1757 Damien attempted to assassinate the French king. The King of Prussia invades Bohemia. Defeats the Austrians at Reichenberg, April 21st, and at Prague, May 6th. Repelled by Count Daun at Kolín, June 18th.

1758 The allies defeated by the French at Haslau-Beck, July 26th.

1759 Convention of Closter Seven, Sep. 8th.

1760 The king of Prussia defeats the French and Austrians at Rößbach, Nov. 5. The Prussians defeated near Breslaw, Nov. 22d. The Austrians defeated at Lissa, Dec. 5th.

1761 Senegal taken by the British, May 1st. They take Louisbourg, July 27th.

1763 General Wolfe is killed in the battle of Quebec, which is gained by the British. The French defeated by Prince Ferdinand at Bergen, April 13th.

1764 Guadaloupe taken by the British, May 1st. King of Prussia defeated by the Russians at Cournerkov, Aug. 12th.
CHRONOLOGY.

1759 The French fleet defeated by Admiral Hawke, Nov. 20th.
1760 King George II. dies October 25th, in the 77th year of his age, and is succeeded by his present majesty, who, on the 22d of September 1761, married the princess Charlotte of Mecklenburgh Strelitz.
1761 Pondicherry taken by Colo. Coote Jan. 15th.
1762 War declared against Spain.
1763 The definitive treaty of peace between Great Britain, France, Spain, and Portugal, concluded at Paris February 10th, which confirms to Great Britain the extensive provinces of Canada, East and West Florida, and part of Louisiana, in North America: also the islands of Granada, St Vincent, Dominicæ, and Tobago, in the West Indies.
1764 The parliament granted 10,000 l. to Mr Harrison for his discovery of the longitude by his time-piece.
1765 His majesty's royal charter passed for incorporating the society of artists.
1766 April 21st, a spot or macula of the sun, more than thrice the bigness of our earth, passed the sun's centre.
1767 The Jesuits expelled from Bohemia and Denmark.
1768 Academy of painting established in London.
1769 Paoli fled from Corsica June 13th. The island then reduced by the French.
1770 An earthquake at St Domingo.
1771 Dr Solander and Mr Banks, in his Britannic majesty's ship the Endeavour, Lieut. Cook, return from a voyage round the world, having made several important discoveries in the South seas. An emigration of 500,000 Tourgouths from the coasts of the Caspian Sea to the frontiers of China.
1772 The King of Sweden changes the constitution from autocracy to a limited monarchy.
1773 Captain Phipps is sent to explore the North Pole; but having made 81 degrees, is in danger of being locked up by the ice, and his attempt to discover a passage in that quarter proves fruitless.
1774 Peace is proclaimed between the Russians and the Turks.
1776 The American war commences. Action at Bunker's Hill June 7th.
1777 Philadelphia taken by the British Oct. 3d.
1778 Philadelphia evacuated by the British, June 18th.
1779 A most extraordinary eruption of Vesuvius August 8th.
1780
CHRONOLOGY.

1780 Jan. 14th, 6 h. A. M. the thermometer suspended in the open air at Glasgow, stood at 46° below.

The Spanish fleet defeated by Admiral Rodney Jan. 16th.

Charlestown surrendered to the British May 12th.

A dreadful incursion in London, and riots in many other places of the kingdom.

A great number of British ships taken by the combined forces of France and Spain.

Lord Cornwallis defeats the Americans at Camden.

A dreadful hurricane in the Leeward Islands.

Oct. 9th.

An extraordinary storm of wind in England.

War declared against the Dutch Dec. 20th.

A terrible engagement between the Dutch and British fleet near the Dogger Bank Aug. 5.

Lord Cornwallis with his army surrender to the unified forces of France and America Oct. 18th.

Minorca surrendered to the Spaniards February 4th.

The French fleet under De Grasse defeated and almost destroyed by Admiral Rodney April 12th.

The Spanish floating batteries before Gibraltar entirely destroyed Sept. 12th.

1783 Preliminaries of a peace signed. America declared independent Jan. 20th.

A dreadful earthquake, attended with many extraordinary circumstances, in Italy and Sicily. The sun obscured by a kind of fog during the whole summer.

A volcanic eruption in Iceland surpassing anything recorded in history. The lava spouted up in three places to the height of two miles perpendicular, and continued thus for two months; during which time it covered at least of 3600 square miles of ground, in some places more than 100 feet deep.

A large meteor appears to the northward of Shetland, and takes its direction southward, with a velocity little inferior to that of the earth in its annual course round the sun. Its track observed for more than 1000 miles.

A dreadful earthquake, attended with many extraordinary circumstances, in Italy and Sicily. The sun obscured by a kind of fog during the whole summer.

A volcanic eruption in Iceland surpassing anything recorded in history. The lava spouted up in three places to the height of two miles perpendicular, and continued thus for two months; during which time it covered at least of 3600 square miles of ground, in some places more than 100 feet deep.

1787 General Convention meet at Philadelphia for the purpose of forming a new constitution, which was afterwards adopted by all the states.

1789 First Congress meet under the federal constitution. March 4th.

States General opened at Paris April 25th.

Battle demolished by the people July 14th.

Constitution of France framed August 6th.

CHRONOMETER, in general, denotes any instrument or machine used in measuring time; such are dials, clocks, watches, &c. See Dial, &c.

The term chronometer, however, is generally used in a more limited sense, for a kind of clock so contrived as to measure a small portion of time with great exactness, even to the sixteenth part of a second; of such a one there is a description in DeFagulier's experimental philosophy, invented by the late ingenious Mr George Graham; which must be allowed to be of great use for measuring small portions of time in astronomical observations, the time of the fall of bodies, the velocity of running waters, &c. But long spaces of time cannot be measured by it with sufficient exactness, unless its pendulum be made to vibrate in a cycloid; because, otherwise it is liable to err considerably, as all clocks are which have short pendulums that swing in large arches of a circle.

There have been several machines contrived for measuring time, under the name of chronometers, upon principles very different from those on which clocks and watches are constructed.

Plate CXXXVI. fig. 1, represents an air-chronometer, which is constructed in the following manner. Provide a glass tube of about an inch in diameter, and three or four feet long; the diameter of the inside of this tube must be precisely equal in every part; at the bottom must be a small hole, closely covered with a valve. In the tube place a piston E, fig. 2, which is made to fit it exactly, and must be oiled, that it may move in the tube with the greatest freedom: in this piston there is a cock that shuts quite close; and from the top of it there goes a cord F, which pulls through the handle G. The cock of the piston being closed, it is to be let down to the bottom of the tube, and being then drawn up to the top, the valve will then run in by the valve at the bottom of the tube, and support the piston. You are then to turn the cock, so as to make every small vent; and the air passing slowly through that vent, the piston will gradually descend, and show the hour, either by lines cut in the tube with a diamond, or marked with print, or by small slips of paper painted on the glass. If this chronometer should go too fast or two slow, it may be easily regulated by altering the position of the cock in the piston, as it is on that the whole depends.

If, instead of marking the tube, you would have the time shown by a dial, it may be easily effected by placing an axis to which the hand of the dial is fixed, directly over the tube, and winding the string to which the piston is joined round that axis; for then, as the piston descends, the axis will gradually turn the hand, and show the hour: but it must be observed, that as the descent of the piston is not constantly regular, on account of the decrease of resilience from the quantity of the subjacent air as the piston descends, the axis therefore must not be a regular cylinder, but conical like the fuse of a watch, as in fig. 3, by which means the motion of the hand of the dial will be constant and regular.

Fig. 4, represents a lamp-chronometer. It consists of a chamber lamp A, which is a cylindrical vessel about three inches high, and one inch diameter, placed in the stand B. The inside of this vessel must be every where exactly of the same diameter. To the stand B is fixed the handle C, which supports the frame DEF, about 12 inches high, and four wide. This frame is to be covered with oiled paper, and divided into twelve equal parts by horizontal lines; at the end of which are wrote the numbers for the hours, from 1 to 12, and between the horizontal lines are diagonals that are divided into halves, quarters, &c. On the handle B, and close to the glass, is fixed the stylus or gnomon H. Now, as the defance of the stylus from the flame of the lamp is only half an inch, if the distance of the frame from the style is only six inches, then, while the float that contains the light descends,
defends, by the decrease of the oil, one inch, the
shadow of the style on the frame will ascend twelve
inches, that is, its whole length, and show by its pro-
gression the regular increase of the hours, with their
several divisions. It is absolutely necessary, however,
that the oil used in this lamp be always of the same
fort and quite pure, and that the wick, also, be con-
stantly of the same size and substance, as it is on these
circumstances, and the uniform figure of the vessel,
that the regular, progress of the shadow depends.

Chronometers, among musicians, an instrument
invented by Loutte, a French musician, for the pur-
purpose of measuring time by means of a pendulum. The
form of the instrument, as described by him, is that of
an ionic piaffer, and is thus described by Malcolm in
his Treatise of Music, p. 407. — The chronometer
consists of a large ruler or board, six feet or 72 inches
long, to be set on end; it is divided into its inches,
and the numbers set so as to count upwards; and at
every division there is a small round hole, through
whose centre the line of division runs. At the top
of this ruler, about an inch above the division 72, and
perpendicular to the ruler, is inserted a small piece of
wood, in the upper side of which there is a groove,
hollowed along from the end that stands out to that
which is fixed in the ruler, and near each end of it a
hole is made: through these holes a pendulum cord is
drawn, which runs in the groove: at that end of the
cord which comes through the hole further from the
ruler, the ball is hung: and at the other end there is
a small wooden pin, which can be put in any of the
holes of the ruler: when the pin is in the uppermost
hole at 72, then the pendulum from the top to the centre
of the ball must be exactly 72 inches; and therefore,
whatever hole of the ruler it is put in, the pendulum
will be just so many inches as that figure at the hole
denotes. The manner of using the machine is this:
the composer lengthens or shortens his pendulum, till
one vibration be equal to the designated length of his
bar, and then the pin stands at a certain division,
which marks the length of the pendulum; and this
number being set with the cliff at the beginning of
the song, is a direction for other compasses to use.
In measuring the time according to the
composer's design: for with the number is set the
note, crotchet, or minim, whose value he would have
the vibration to be: which in brisk duple time is best
a minim or half bar, or even a whole bar, when that
is a minim; and in flow time a crotchet. In
triple time, it would do well to be the third part
or half, or fourth part of a bar; and in the simple triples
that are allegro, let it be a whole bar. And if,
every time that is allegro, the vibration is applied to
a whole or half bar, practice will teach us to subdi-
vide it justly and equally. Observe, that, to make this
machine of universal use, some canonical measure of the
divisions must be agreed upon, that the figure may give
a certain direction for the length of the pendulum.

Chrostasima, in natural history, a genus of
pellucid gems, comprehending all those which appear
of one simple and permanent colour in all lights; such
are the diamond, carbuncle, ruby, garnet, amethyst,
emerald, and the topaz. See Diamond, Carbuncle, &c.

Chrysa, (anc. geog.), a town of Mytilis, on the
sinus Adramyttium; extinct in Pliny's time: it had
a temple of Apollo Sinthinus (Homer, Strabo). The
country of the fair Chrysea, who gave first rite to
the quarrel between Agamemnon and Achilles.

Chrysalis, or Aurelia, in natural history, a
fable of red and seeming invisibility, which butterflies,
moths, and several other kinds of insects, must
pass through before they arrive at their winged or
mottled perfect state.

In this state, no creature afford to beautiful a va-
riety as the butterfly kinds, and they all pass through
this middle state without one exception. The figure
of the aurelia or chrysalis generally approaches to that
of a cone, or at least the hinder part of it is in this
shape; and the creature, while in this state, seems to
have neither legs nor wings, nor has any power of
walking. It seems indeed to have hardly so much as
life. It takes no nourishment in this state, nor has it
any organs for taking any; and indeed its posterior part
is all that seems animated, this having a power of giving
itself some motions. The external covering of the
chrysalis is cartilaginous, and considerably large, and
is usually smooth and glossy; but some few of them
have a few hairs; some are also as hairy as the cater-
pillars from which they are produced; and others
are rough, and, as it were, shagreened all over.

In all of these there may be distinguished two fides;
the one of which is the back, the other the belly of
the animal. On the anterior part of the latter, there
may always be distinguished certain little elevations
running in ridges, and resembling the fillets wound
about mummies: the part whence these have their
origin, is esteemed the head of the animal. The other
side, or back, is smooth, and of a rounded figure in
most of the chrysalides; but some have ridges on the
anterior part, and fides of this part; and these usually
terminate in a point, and make an angular appearance
on the chrysalis.

From this difference is drawn the first general dif-
tinction of these bodies. They are by this divided into
two classes: the round and the angular kinds. The
first are, by the French naturalists, called feer: from
this common custom to divide, the chrysalis of the folk-
worm, which is round, by this name.

There is something more regular in this distinction
than might at first be conceived; for the division is
continued from the fly-flate: the rounded chrysalides
being almost all produced by the phaline, or moths;
and the angular ones by the papilio, or day-flies.
There are several subordinate distinctions of these
kinds; but, in general, they are less different from
one another than the caterpillars from whence they are
produced.

The head of those of the first class usually termi-
nates itself by two angular parts, which stand separate
one from the other, and resemble a pair of horns.
On the back, eminences and marks are discovered,
which imagination may form into eyes, nofe, chin,
and other parts of the human face.

There is a great variety and a great deal of beauty
in the figures and arrangement of the eminences and
spots on the other part of the body of the chrysalides
of different kinds. It is a general observation, that those
chrysalides which are terminated by a single horn, af-
ford day-butterflies of the kind of those which have
buttoned
The general colour of the chrysalis of the common butterflies, however, is brown.

Some are also of a fine deep black; and of these many are so smooth and glossy, that they are equal to the snuff Indian japa. The common caterpillar of the fig-tree gives an instance of one of these most beautiful, glossy ones; the caterpillar of the vine affords another of these fine black chrysalis.

The round chrysalis do not afford any thing of that variety of coloring so Remarkably beautiful in the angular ones; they are usually of a dark yellow, in different shades, and are often variably spotted with black; but these, as well as all other chrysalis, before they arrive at their fixed colour, pass through several other temporary ones; some being of a different colour when first produced from the caterpillar, from what they are a few days afterwards; and some varying greatly, though only in degree, as not to be distinguishable, even by the most conversant eye, from what they were when first produced. The green rough caterpillar of the cabbage has a chrysalis which is green at first; and from that gradually goes through all the shades of green to faint yellow, which is its lasting colour; and one of the oak caterpillars yields a chrysalis beautifully spotted with red at its first appearance; but these spots change to brown for their fixed colour: the third day from their formation usually fixes their lasting colours; and if they are observed to turn black in any part after this time, it is a sign that they are dead or dying.

The several species of insects, as a fly, spider, and an ant, do not differ more evidently from one another in regard to appearance, than do a caterpillar, its chrysalis, and a butterfly produced from it; yet it is certain, that these are all the same individual egg; and nothing is more certain, than that the creature which was for a while a caterpillar, is, after a certain time, a chrysalis, and then a butterfly. These great changes produced in so sudden a manner, seem like the metamorphoses recorded in the fables of the ancients; and indeed it is not improbable that those fables first took their origin from such changes.

The parts being distinguishable in the chrysalis, we easily find the difference of the species of the fly that is to proceed from it. The naked eye shows whether it be one of those that have, or of those that have not, a trunk; and the assistance of a microscope shows the antennæ distinctly, that we are able to discern whether it belongs to the day or night class; and often to what genus, if not the very species: may, in the plume horned kinds, we may see, by the antennæ, whether a male or female phalaena is to be produced from the chrysalis; the horns of the female being in this state evidently narrower, and appearing less elevated above the common surface of the body, than those of the male.

All these parts of the chrysalis, however, though seen very distinctly, are laid close to one another, and seem to form only one mass; each of them is covered with its own peculiar membrane in this state, and all are surrounded together by a common envelope, only through these that we see them; or rather we see on these the figures of all the parts moulded within.
Chrysalis. and therefore it requires attention to distinguish them. The chrysalis is soft when first produced, and is wetted on the front with a viscous liquor; its skin, though very tender at first, dries and hardens by degrees: but this viscous liquor, which surrounds the wings, legs, &c. hardens almost immediately; and in consequence falls all those limbs, &c. into a mass, which were before loose from one another; this liquor, as it hardens, loses its transparency, and becomes brown; so that it is only while it is yet moist that these parts are to be seen distinct.

It is evident from the whole, that the chrysalis is no other than a butterfly, the parts of which are hid under certain membranes which darken them together; and, when the limbs are arrived at their due strength, they become able to break through these membranes, and then expand and arrange themselves in their proper order.

The first metamorphosis, therefore, differs nothing from the second, except that the butterfly comes from the body of the caterpillar in a weak state, with limbs unable to perform their offices, whereas it comes from the chrysalis perfect.

Reaumur has given us many curious observations on the structure and uses of the several coverings that attend the varieties of the caterpillar-kind in this state.

The creatures in general remain wholly immovable in this state, and seem to have no business in it but a patient attendance on the time when they are to become butterflies; and this is a change that can happen to them only as their parts, before extremely soft and weak, are capable of hardening and becoming firm by degrees, by the transpiration of that abundant humidity which before kept them soft: and this is proved by an experiment of M. Reaumur, who, inclosing some chrysalises in a glass tube, found, after some time, a small quantity of water at the bottom of it; which could have come there in no other way, but from the body of the inclosed animal. This transpiration depends greatly on the temperature of the air; it is increased by heat, and diminished by cold; but it has also its peculiarities in regard to the several species of butterfly to which the chrysalis belongs.

According to these observations, the time of the duration of the animal in the chrysalis state must be, in different species, very different; and there is indeed this wide difference in the extremes, that some species remain only eight days in this state, and others eight months.

We know that the caterpillar changes its skin four or five times during its living in that state; and that all these skins are at first produced with it from the egg, lying closely over one another. It parts with, or throws off all these one by one, as the butterfly, which is the real animal, all this time within, grows more and more perfect in the several first changes. When it throws off one, it appears in another skin exactly of the same form; but at its final change from this appearance, that is, when it throws off the last skin, as the creature within is now arrived at such a degree of perfection as to need no farther taking of nourishment, there is no farther need of teeth, or any of the other parts of a caterpillar. The creature, in this last change, proceeds in the very same manner as in all the former, the skin opening at the back, and the animal making its way out in this shape. If a caterpillar, when about to throw off this last skin, be thrown into spirits of wine, and left there for a few days, the membranes within will harden, and the creature may be afterwards carefully opened, and the chrysalis taken out, in which the form of the tender butterfly may be traced in all its lineaments, and its eyes, legs, &c. evidently seen. It is not necessary, however, to seize upon this exact method of proving the existence of the chrysalis or butterfly in the caterpillar: for if one of these animals be thrown into spirits of wine, or into vinegar, some days before that time, and left there for the skin to harden, it may afterwards be dissected, and all the lineaments of the butterfly traced out in it, the wings, legs, antennae, &c. being as evident here, and as large, as in the chrysalis.

It is very plain from this, that the change of the caterpillar into chrysalis, is not the work of a moment; but is carrying on for a long time before, even from the very hatching of the creature from the egg. The parts of the butterfly, however, are not disposed exactly in the same manner while in the caterpillar, as when first naked in the form of the chrysalis; for the wings are proportionally longer and narrower, being wound up in the form of a cord; and the antennae are rolled up on the head; the trunk is also twisted up and laid upon the head; but this in a very different manner from what it is in the perfect animal, and very different from that in which it lies within the chrysalis; so that the first formation of the butterfly in the caterpillar, by time arrives at a proper change of the disposition of its parts, in order to its being a chrysalis. The very eggs, hereafter to be deposited by the butterfly, are also to be found not only in the chrysalis, but in the caterpillar itself, arranged in their natural, regular order. They are indeed in this state very small and transparent; but after the change into the chrysalis, they have their proper colour.

As soon as the several parts of the butterfly, therefore, are arrived at a state proper for being exposed to the more open air, they are thrown out from the body of the caterpillar, surrounded only with their membranes; and as soon as they are arrived at this after a proper degree of strength and solidity, they labour to break through these thinner coverings, and to appear in their proper and natural form. The time of their duration in this state of chrysalis is very uncertain, some remaining in it only a few days, others several months, and some almost a year in appearance. But there is a fallacy in this that many are not aware of. It is natural to think, that as soon as the creature has inclosed itself in its shell, be that of what matter it will, it undergoes its change into the chrysalis state. And this is the case with the gener": yet there are some which are eight or nine months in the shell before they become chrysalises; so that their duration in the real chrysalis state is much shorter than it naturally appears to be. M. Reaumur carefully watched the auriculated caterpillar of the oak in its several changes, and particularly from its chrysalis, which is of this last kind, into the fly; and has given an account of the method of this as an instance
The membranes which envelope the creature in this chrysalis state are at first tough and firm, and immediately touch the several parts of the inclosed animal; but by degrees, as these parts harden, they become covered, some with hairs, and others with scales. These, as they continue to grow, by degrees fall off the several particular membranes which cover the parts on which they are placed, to a greater distance, and by degrees loosen them from the limbs. This is one reason of those membranes drying and becoming brittle. The middle of the upper part of the corselet is usually marked with a line which runs in a longitudinal direction; and this part is always more elevated than the rest, even in the conic kinds, which are no otherwise angular. This line is in some very bold and plain; in others it is so faint as not to be distinguishable without glafles; but it is always in the midst of that line that the shell begins to open. The motion of the head of the butterfly backwards first occasions this crack; and a few repetitions of the same motion open it the whole length of the line.

The clearing itself, however, entirely, is a work of more time in this case, than is the paling of the chrysalis out of the body of the caterpillar. In that case there is a crack sufficiently large in the skin of the back, and the whole chrysalis being loose comes out at once. But in this case, every particular limb, and part of the body, has its separate case; and these are almost inconceivably thin and tender, yet it is necessary that every part be drawn out of them before it appear naked to the open air. As soon as all this is effected, and the animal is at full liberty, it either continues some time upon the remains of its covering, or creeps a little way distant from it, and there refts. The wings are what we principally admire in this creature. These are at this time so extremely folded up, and placed in so narrow a compass, that the creature seems to have none at all: but they by degrees expand and unfold themselves; and, finally, in a quarter of an hour, or half an hour at the utmost, they appear at their full size, and in all their beauty. The manner of this sudden unfolding of the wings is this: the small figure they make when the creature first comes out of its membranes, does not prevent the observing that they are at that time ridiculously thick. This is owing to its being a large wing folded up in the nicest manner, and with folds so arranged as to be by no means sensible to the eye; for the wing is never seen to unfold; but, when observed in the most accurate manner, seems to grow under the eye to this extent. When the creature is first produced from the shell, it is everywhere most tender; even its wings have no strength or stiffness till they expand themselves; but they then do, by degrees, and, with the other parts, become rigid and firm. But if any accident prevents the wings from expanding at their proper time, that is, as soon as the creature is out of its shell, they never afterwards are able to expand themselves; but the creature continues to wear them in their contracted and wholly useless state and very often, when the wings are in no extended before such an accident happens, it stops them in a partial extension, and the creature must be contented to pass its whole life with them in that manner.

M. Reaumur has proved, that heat and cold make great differences in the time of hatching the butterfly from its chrysalis state: and he particularly tried with great accuracy and attention, by putting them in vesseis in warm rooms, and in ice-houses, and it seemed wholly owing to the hastening or retarding the evaporation of the abundant humidity of the animal in the chrysalis state, that it sooner or later appeared in the butterfly form. He varnished over some chrysaliss, in order to try what would be the effect of this wholly preventing their transpiration; and the consequence was, that the butterfly came forth from these two months later than their natural time. Thus was the duration of the animal in this state lengthened; that is, its existence was lengthened; but without any advantage to the creature, since it was in the time of its state of inaction, and probably of infensibility.

Though this was of no consequence, M. Reaumur deduces a hint from it; that seems to be of some ufe. He observes, that hens eggs, of which we make so many use, and eat in so many forms, are properly a fort of chrysalis of the animal; their germ, after they are impregnated by the cock, containing the young animal alive, and waiting only a due degree of warmth to be hatched, and appear in its proper form. Eggs transpire notwithstanding the hardness of their shells; and when they have been long kept, there is a road found near one of their ends, between the shell and the internal membrane; and it is a mark of their being flat, and is the effect of an evaporation of part of their humidity; and the same varnish which had been used to the chrysalis, being tried on eggs, was found to preserve them for two years, as fresh as if laid but the same day, and such as the nicest palate could not distinguish from those that were so. See Eggs.

It is not yet known how much farther this useful speculation might be carried, and whether it might not be of great ufe even to human life, to invent something that should act in the manner of this varnish, by being rubbed over the body, as the athlete did of old, and the fages of the Weft Indies do at this time, without knowing why and what beauty. The manner of this sudden unfolding of the wings is this: the small figure they make when the creature first comes out of its membranes, does not prevent the observing that they are at that time considerably thick. This is owing to its being a large wing folded up in the nicest manner, and with folds so arranged as to be by no means sensible to the eye, for the wing is never seen to unfold; but, when observed in the most accurate manner, seems to grow under the eye to this extent. When the creature is first produced from the shell, it is everywhere most tender; even its wings have no strength or stiffness till they expand themselves; but they then do by degrees, and, with the other parts, become rigid and firm. But if any accident prevents the wings from expanding at their proper time, that is, as soon as the creature is out of its shell, they never afterwards are able to expand themselves; but the creature continues to wear them in their contracted and wholly useless state; and very often, when the wings are in no extended before such an accident happens, it stops them in a partial extension, and the creature must be contented to pass its whole life with them in that manner.
Chrysanthemum

flowers. It grows to the height of three feet, with a single upright stalk divided into numerous branches, garnished with pinnated leaves, and crowned with elegant compound flowers of different colours and properties. The varieties are, single and double flowers of a cream-colour; yellow; yellow and white; brimstone-coloured; purplish, or quilled; or those with finely jagged leaves, and flowers of all the above colours and properties. All the varieties begin flowering in July: the flowers are exceedingly numerous, and exhibit a constant succession of full bloom till November; and both single and double are succeeded by abundance of seed. 1. The putecens is a native of the Canary islands. It rises with a shrubby stalk near two feet high, dividing into many branches, which are garnished with pretty thick succulent leaves, of a greyish colour, cut into many segments. The flowers come out from the wings of the leaves, growing upon naked footstalks singly, which greatly resemble those of chamomile. There is a confusion of flowers on the same plant for the greatest part of the year, for which it is chiefly esteemed. This plant will flower a month earlier bloom the following summer than those raised in the spring from seed; but when the pots are split, and two or three inches apart, give some water, and place them in the shade during the hot weather: by the end of October they will be rooted, when the pots are to be removed either into a greenhouse or garden-frame, for the winter; but the latter is the most eligible, where they may enjoy the full air in mild weather, and have occasional shelter from frost. In April they may be transplanted singly into borders and some in pots. The plants thus raised will flower early in six weeks sooner the succeeding summer than those raised in the spring from seed; but as they soon become barren, it is proper to have always a quantity of plants raised from the seed. The third fort may be raised either from seeds or cuttings, but requires to be sheltered in the greenhouse in winter.

CHRYSYES, the priest of Apollo, father of Alynome, called from him Chryseis. When Lycurgus was taken, and the spoils divided among the conquerors, Chryseis fell to the share of Agamemnon. Chryseis upon this went to the Grecian camp to solicit his daughter's restitution; and when his prayers were fruitless, he implored the aid of Apollo, who visited the Greeks with a plague, and obliged them to restore Chryseis.

CHRYSIPPUS, a Stoic philosopher, born at Solos in Cilicia, was disciple to Cleanthes, Zeno's successor. He wrote many books, several of which related to logic. None of the philosophers spoke in stronger terms of the fatal necessity of every thing, nor more pompously of the liberty of man, than the Stoics, Chrysippus in particular. He was so considerable among them, as to establish it into a proverb, that if it had not been for Chrysippus, the porch had never been. Yet the Stoics complained, as Cicero relates, that he had collected so many arguments in favour of the sceptical hypothesis, that he could not answer them himself; and thus had furnished Carneades, their antagonist, with weapons against them. There is an apodictism of this philosopher preferred, which does him honour. Being told that some perfons spoke ill of him, "It is no matter (said he), I will live so that they shall not be believed."

CHRYSIS, or GOLDEN-FLY, in natural history: A genus of insects belonging to the order of hymenoptera. The mouth is armed with jaws, but has no proboscis; the antennae are filiform, bent, and consist of 12 articulations; the abdomen is arched, with a scale on each side; the antennae are dilated, and armed with a flying; the wings lie plain; and the body appears as if gilt. There are several species; but the ignia, or flaming chrysis, is beautified with the most resplendent colours. The fore-part of its head is green and gold, and the hinder of a lovely azure. The thorax is likewise azured over, with a mixture of green, and terminates at its extremity with sharp points on both sides. The abdomen is green and gold before, and of a coppery-red behind, imitating molten copper highly polished. The whole insect is dotted on its upper part, which gives it a great resplendency of colour. The antennae are black, and legs green internmixed with gold. This species dwells in holes of walls between the stones, and in the mortar that cements them. It is often seen flying from such holes, where it nectiles and performs its work. The larve, which resemble those of the wasp, likewise inhabit the holes of decayed walls.

CHRYSITRIX, in botany: a genus of the diceria order, belonging to the polygama class of plants. In the hermaphrodite the flower is two-valved, the corolla from chaff numerous and brilily; many flaminia, one within each chaff; one pellillum. The male of the hermaphrodite: there is no pellillum.

CHRYSOBALANUS, COCOA PLANT: A genus of the monogama order, belonging to the ficandria class of plants; and in the natural method ranking under the 36th order, Pomeaeae. The calyx is quinquefoil, the petals five; plum-kernel five furrowed and five-valved. There is only one species, the icaco, which is a native of the Bahama islands and many other parts of America, but commonly grows near the fex. It rises with a shrubby stalk eight or nine feet high, fending out several side-branches, which are covered with a dark brown bark. The flowers are white, and are succeeded by plums like damsons; some blue, some red, and others yellow. The flower is shaped like a pear, and has five longitudinal furrows. The plums have a sweet luscious taste, and are brought to the tables of the inhabitants, by whom they are much esteemed.

CHRYSOCOMA, GOLDY-LOCKS: A genus of the polygama aequalis order, belonging to the syngenesis class of plants; and in the natural method ranking under the 49th order, Compositae. The receptacle is na-
CHRYSOLOGUS, in botany: A genus of the polygonia necessaria order, belonging to the syngeneia class of plants; and in the natural method ranking under the 49th order, Compositeae. The receptacle is paleaceous; the pappus monophyllous, and tridentated; the calyx pentaphyllous; the seeds wrapped up each in a tetraphyllous calycinus, or little cup.

CHRYSOLOGUS (Emanuel), one of those learned men in the 14th century who brought the Greek literature into the west. He was a man of rank; and defended an ancient family, said to have removed with Constantine from Rome to Byzantium. He was sent into Europe by the emperor of the east to compose the almanie of the Christian princes. He afterwards taught at Florence, Venice, Pavia, and Rome; and died at Constantinople, in 1415, aged 47. He wrote a Greek grammar, and some other small pieces.

CHRYSOLITE, or YELLOWISH-GREEN TOPAZ: A precious stone of a grafs green colour, found in the East Indies, Brazil, Bohemia, Saxony, Spain, in Auvergne and Bourbon in France, and in Derbyshire in England. Some are likewise found with volcanic lavas, as in the Vevarais, where some large humps have been seen of 20 or 30 pounds weight; but it is remarkable, that some of these chrysolites are partly decomposed into an argillaceous substance. All chrysolites, however, are far from being of the same kind. The oriental is the same with the peridot, and differs only by its green hue from the sapphires, topazes, and rubies of the same denomination. This becomes electric by being rubbed; has a prismatic form of six, or sometimes of five flattened faces; and does not lose its colour or transparency in the fire, which the common chrysolite often does; becoming either opaque, or melting entirely in a strong heat. The infiant it melts, it emits a phosphoric light like the basis of alum and gypsum spar; with borax it produces a thin colourless glass. Its specific gravity is between 3.6o0 and 3.7o0; according to Drifdon it is 2.7821, or 2.6923; and that of the Spanish chrysolite 3.0989.

The flourance of this precious stone is lamellated in the direction of the axis of its primitive form: but the chrysolite from Saxony is foliated in a perpendicular direction to the same axis. The chrysolite of the ancients was the same gem which is now called topaz, and the name of itself indicates that it ought to be so. Pliny says that the colour of the chrysolite is yellow like gold.

CHRYSOLITE-PASTE, a kind of glass made in imitation of natural chrysolite, by mixing two ounces of prepared crystal with ten ounces of red-lead, adding 12 grains of crocus martis made with vinegar; and then baking the whole for 24 hours, or longer in a well luted cucurbit.

CHRYSOMELA, in zoology, a genus of insects belonging to the order of coleoptera. The antennae are shaped like bracelets, and thicker on the outside; and neither the breast nor the elytra are margined. There are no less than 123 species enumerated by Linnaeus, principally distinguished by differences in their colour. They are to be found almost everywhere, in woods, gardens, &c. Their progressive motion is slow; and some when caught emit an oily liquor of a disagreeable smell. The glittering colours with which several species of Chrysoloe are adorned, and which seem to exhibit the brilliancy of gold and copper, have occasioned their bearing that pompous name. The larvae of these insects have in general an oval body, rather oblong and flat; on the fore-part of which are situated six feet, which are feety, as is also the head. They prey upon the substance of leaves, rejecting the fibrous part. Those of the leaping chrysoleme infest the cotyledons and tender leaves of plants. Of this genus is that very pernicious insect called by the country people the turnip fly, which infests turnips and many crops in the garden, destroying often whole fields while in their seeding leaves. In very hot summers they abound to an amazing degree, and, as you walk in a field or in a garden, make a pattering like rain, by jumping on the leaves of the turnips or cabbages. See Plate CXXX, p. 40.

CHRYSOPHYLLUM, or BULLY-TREE: A genus of the monogynia order, belonging to the pentandra class of plants; and in the natural method ranking under the 43d order, viz. Damiaceae. The corolla is campanulated, decussate, with the segments alternately a little patent. The fruit is a ten-seeded berry. There are two species, the cainiro and glabrum, both natives of the West Indies. The first attains 30 or 40 feet high, with a large trunk covered with a brown bark, and divides into many flexible slender branches, which generally hang downward, garnished with spear-shaped leaves, whose under sides are of a bright yellow colour. The flowers come out at the extremities of the branches, disposed in oblong branches, which are succeeded by fruit of the size of a golden pippin, that are very rough to the palate, and astringent; but when kept some time mellow, as is practised here with medlars, they have an agreeable flavour. The second sort never rises to the height of the first, nor do the trunks grow to half the size; but the branches are slender and garnished with leaves like those of the first. The flowers come out in clusters from the side of the branches, which are succeeded by oval smooth fruit about the size of a bergamot pear. This contains a white clammy juice when fresh; but after being kept a few days, it becomes sweet, soft, and delicious. Included are four or five black seeds about the size of thole of a pomkin. Both these plants are frequently preferred in gardens where there are large floyes, and are propagated by seeds, but the plants can never bear the open air in Britain.

CHRYSOPHLENIUM, in botany: a genus of the digynia order, belonging to the decandra class of plants; and in the natural method ranking under the 12th order, Succulentae. The calyx is quadrifid or quinquefid, and coloured; no corolla; the capsule bifidulate, unilocular and polypermous.

CHRYSOPRASUS, or CHRYSOPRASUS, the root of the precious stones mentioned in the Revelations, as forming
CHRYSOSTOM (St John), a celebrated patriarch of Constantinople, and one of the most admired fathers of the Christian church, was born of a noble family in Antioch about the year 347. He studied rhetoric under Libavins, and philosophy under Andragathus: after which he spent some time in solitude in the mountains near Antioch; but the anxieties he endured having impaired his health, he returned to Antioch, where he was ordained deacon by Meletius. Flavian, Meletius's successor, raised him to the office of prebendar five years after; when he distinguished himself so greatly by his eloquence, that he obtained the surname of Golden mouth. Nechtanis patriarch of Constantinople, dying in 397, St Chrysostom, whose fame was spread throughout the whole empire, was chosen in his room by the unanimous consent of both the clergy and the people. The emperor Arcadius confirmed this election, and caused him to leave Antioch privately, where the people were very unwilling to part with him. He was ordained bishop on the 25th of February 398; when he obtained an order from the emperor against the Eunomians and Montanists; reformed the abuses which subsisted amongst his clergy: retrenched a great part of the expenses in which his predecessors had lived, in order to enable him to feed the poor and build hospitals; and preached with the utmost zeal against the pride, luxury, and avarice of the great. But his pious liberty of speech procured him many powerful enemies. He differed with Theophilos of Alexandria, who got him deposed and banished; but he was soon recalled. After this, declining against the dedication of a statue erected to the empress, he banished him into Cucusia in Armenia, a most barren unhospitable place: afterwards, as they were removing him from Petrus, the soldiers treated him so roughly, that he died by the way, A.D. 407. The best edition of his works is that published at Paris in 1718, by Mouretson.

CHRISTAL. See Crystal.

CHUB, or CHUBB, in ichthyology. See Cyprinus.

The habits of this fish are easily found; for they are generally holes, overheard by trees, and this fish will often be seen floating in such a spot on the surface of the water in a hot day in great numbers. They are probably not a poor fish for the table, and are very full of bones; but they entertain the angler very much, and are of the number of those that are easily taken. The best manner of fishing for him is thus: prepare a very strong rod of a sufficient length; fix to the hook a glass hopper; place yourself so as to be perfectly out of sight of the fish, and drop in the bait about two feet from the place where a large chub lies; if he does not see the angler he very seldom fails biting, and is immediately taken; but he is so strong a fish that he should be taken carefully, after a great deal of playing, otherwise the tackle will be in danger; a beetle, or any large fly, will answer the purpose in the place of a glass hopper; and if none of them are to be had, the method of fishing must be altered, and the line be long enough for fishing at the bottom. In March and April this fish is to be caught with large red worms; in June and July with flies, flies, and cherries; but in August and September the proper bait is good cheese pounded in a mortar, with some saffron, and a little butter; some make a paste of cheese and Venice turpentine for the chub in winter, at which season this fish is better than at any other; the bones are less troublesome in this season, and the flesh is more firm and better tasted; the row is also well flavoured in general. The angler must keep this bait for this fish at the bottom in cold weather, and near the top in hot, and the fish will bite eagerly.

CHUBB (Thomas), a noted polemical writer, born at Elst Harnham, a village near Salisbury, England, in 1679. He was put apprentice to a glover at Salisbury, and afterwards entered into partnership with a tallow-chandler. Being a man of strong natural parts, he employed all his leisure in reading; and though a stranger to the learned languages, became tolerably versed in geography, mathematics, and other branches of science. His favourite study was divinity; and he formed a little society for the purpose of debating upon religious subjects, about the time that the Trinitarian controversy was so warmly agitated between Clarke and Waterland. This subject, therefore, filling under the coguience of Chubb's theological affi- mably, he at their request drew up and arranged his sentiments on it, in a kind of dissertation; which was published in 1706, with the title of The Supremacy of the Father asserted, &c. In this piece Mr. Chubb showed great talents in reasoning; and acquired so much
much reputation, that the late Sir Joseph Jekyll, ma-
ster of the rolls, took him into his family to enjoy his
conversation: but though he is said to have been
tempted to remain with him by the offer of a genteel
allowance, he did not continue with him many years;
but chose to return to his friends at Salisbury. He pub-
lished afterwards a 4to volume of tracts, which Mr Pope
informs his friend Gay, he “read through with admira-
tion of the writer, though not always with approba-
tion of his doctrine.” He died a single man in the
68th year of his age, and left behind him 2 vols. of
posthumous tracts, in which he appears to have had
little or no belief in revelation. But however licen-
tious his way of thinking may be deemed, nothing ir-
regular or immoral has been fairly imputed to him in
his life and actions.

CHUDLEIGH (Lady Mary), was born in 1656, and
married to Sir George Chudleigh, baronet, by whom
she had several children: her poems and essays
have been much admired for delicacy of style. She
died in 1716; and is said to have written several dra-
matic pieces, which, though not printed, are pre-
served in the family.

CHUPMESSAHITES, a sect among the Mahome-
tans, who believe that Jesus Christ is God, and the
ture Messiah, the Redeemer of the world; but with-
out rendering him any public or declared worship. The
word in the Turkish language signifies protector of the
Christians. Ricaut says, there are abundance of these
Chupmmessahites among the people of fashion in Tur-
key, and some even in the seraglio.

CHURCH, has different significations, according
to the different subjects to which it is applied.

1. It is understood of the collective body of Chris-
tians, or all those over the face of the whole earth
who profess to believe in Christ, and acknowledge him
to be the Saviour of mankind. This is what the an-
cient writers call the catholic or universal church.
Sometimes the word church is considered in a more ex-
tensive sense, and divided into several branches; as the
church militant is the assembly of the faithful upon
earth; the church triumphant, that of the faithful
already in glory; to which the Papists add the church
patient; which, according to their doctrines, is that
of the faithful in purgatory.

2. Church is applied to any particular congregation
of Christians, who associate together and concour in
the participation of all the institutions of Jesus Christ,
with their proper pastors and ministers. Thus we read
of the church of Antioch, the church of Alexandria,
the church of Thessalonica, and the like.

3. Church denotes a particular sect of Christians
distinguished by particular doctrines and ceremonies.
In this sense we speak of the Romish church, the
Greek church, the Reformed church, the church of
England, &c.

The Latin or Western church, comprehends all the
churches of Italy, France, Spain, Africa, the north,
and all other countries whither the Romans carried
their language. Great Britain, part of the Nether-
lands, of Germany, and of the North, have been se-
parated from hence ever since the time of Henry VIII.;
and continue what we call the Reformed church, and
what the Romanists call the western schism.

The Greek or Eastern church, comprehends the
churches of all the countries anciently subject to the
Greeks or eastern empire, and through which their lan-
guage was carried; that is, all the space extended from
Greece to Maphistania and Phœnis, and thence into
Egypt. This church has been divided from the Ro-
nan, ever since the time of the emperor Phœnas.

The Gallician church, denotes the church of France,
under the government and direction of their respective
bishops and pastors. This church has always enjoyed
several franchises and immunities; not as grants from
popes, but as derived from her from her first original,
and which she has taken care never to relinquish.

These liberties depend upon two maxims; the first,
that the pope has no authority or right to command
or order any thing either in general or in particular,
in which the temporalities and civil rights of the king-
dom are concerned; the second, that notwithstanding
the pope’s supremacy is owned in cafes purely spiritu-
al, yet in France his power is limited and regulated by the
decrees and canons of ancient councils received in the
realm.

4. The word church is used to signify the body of
ecclesiastics, or the clergy, in contradistinction to the
laity. See Clergy.

5. Church is used for the place where a particular
congregation or society of Christians assemble for
the celebration of divine service. In this sense churches
are variously denominated, according to the rank,
degree, discipline, &c. as Metropolitan church, Pa-
triarchal church, Cathedral church, Parochial church,
College church, &c. See Metropolitan, Patri-
arch, &c.

In ecclesiastical writers, we meet with grand church,
for the chief church of a place; particularly in the
Greek liturgy, for the church of St Sophia at Con-
fantineople, the see of the patriarch, founded by Con-
fantine, and consecrated under Julian. It was at
that time so magnificent, that Julian is said to have
cried out in the consecration thereof, Μετεπιστολή; I
have outdone thee, Solomon. The dome, which is
said to have been the first that was built, is 330 feet
diameter.

The first church publicly built by the Christians,
some authors maintain to be that of St Saviour at
Rome, founded by Constantine; others contend,
that several churches abroad, called by the name of
St Peter Virgin, were built in honour of that apostle
during his lifetime.

Church, with regard to architecture, Daviler de-
fines a large oblong edifice, in form of a ship, with
nave, choir, isle, chapel, belfry, &c. See each part
under its proper head.

Church, simple, is that which has only a nave and
a choir.

Church with Ises, that which has a row of porti-
cos, in form of vaulted galleries, with chapels in its
circumference.

Church in a Greek cross, that where the length of
the transept part is equal to that of the nave; so called
because most of the Greek churches are built in this
form.

Church in a Latin cross, that whose nave is longer
than the cross part, as in most of the Gothic churches.

Church in Rotunda, that whose plan is a perfect
circle, in imitation of the Pantheon.

For
For the form of the ancient Greek churches, when they had all their parts, it was as follows: first was a porch, or porico, called the *Naos-Hypostyle*, this was adorned with columns on the outside, and on the inside surrounded with a wall; in the middle whereof, was a door, through which they passed into a second portico. The first of these porticos was defined for the *Energumeni*, and penitents in the first stage of their repentance; the second was much longer, defined for penitents of the second class, and the catechumens, and hence called *stoa poricu*, because those placed in it began to be subject to the discipline of the church. These two porticoes took up about one-third of the space of the church. From the second portico, they passed into the nave, and, which took up near another third of the church. In the middle, or at one side of the nave, was the ambo, where the deacons and priests read the gospel, and preached. The nave was defined for the reception of the people, who here asisted at prayers.

Near the entrance of this was the baptistry or font. Beyond the nave was the choir, called, with seats, and round the bema, the altar, crowned with a baldachin, supported by four columns. Under each of the small apsidies, was a kind of table or cupboard, in manner of a beautil.

Though of the Greek churches now remaining, few have all the parts above described, most of them having been reduced to ruins or converted into mosques.

**High-Church** was a denomination originally given to those otherwise called Non-jurors, who refused to acknowledge the title of William III. to the crown of Great Britain, under a notion that James II. though exacled, was still their rightful sovereign. This appellation was given them, because they entertained high notions of the dignity and power of the church, and the extent of its prerogative and jurisdiction. And those who, contrary, were called low-church men, who disapproved of the secession and obitnity of the non-jurors, distingufhing themselves by their moderation toward dissenters, and were left ardent in extending the limits of church authority. The denomination of *high-church men* is now more generally applied to all who form pommous and ambitious conceptions of the authority and jurisdiction of the church, and who would raise it to an absolute independence on all human power.

**Church-Ale.** See Whitsun-Ale.

**Church-Reves.** the same with Church-Wardens.

**Church-Scot,** or Churchchet, a payment or contribution, by the Latin writers frequently called *primitia feminina*; being, at first, a certain measure of whealt, paid to the priest on St. Martin's day, as the first fruits of harvest. This was enjoined by the laws of king Malcom IV. and Canute, c. 10. But after this, Church-scot came to signify a revere of corn paid to the secular priests, or to the religious; and sometimes was taken in so general a sense as to include poultry, or any other provision that was paid in kind to the religious. See Tithes.
in twelve years of age. In 1666, he was made an ensign of the guards during the first Dutch war; and afterwards improved himself greatly in the military art at Tangier. In 1672, Mr. Churchill attended the duke of Monmouth who commanded a body of auxiliaries in the French service, and was soon after made a captain in the duke's own regiment. At the siege of Namur, which happened in that campaign, he distinguished himself so much that he was taken notice of by the celebrated marshal Turenne, who bestowed on him the name of handsome Englishman. In 1673 he was at the siege of Maastricht, where he gained such applause, that the king of France made him a public acknowledgment of his service; and the duke of Monmouth, who had the direction of the attack, told king Charles II. that he owed his life to Mr. Churchill's bravery. In 1681, he married Sarah daughter and co-heir of (with her sister the countess of Tyrconnel) of Richard Jennings, Esq. of Sandrich, in Hertfordshire. The duke of York recommended him in a very particular manner to the king; who, in 1682, created him baron Churchill, in the county of Berwick in Scotland, and made him colonel of the third troop of guards. A little after king James's accession, he was created baron Churchill of Sandrich in the county of Hertford, and made brigadier-general of his majesty's army in the west; where, when the duke of Monmouth came to surprize the king's army, while the earl of Ferriby and the majority of the officers were in their beds, he kept the enemy in play till the king's forces had formed themselves, and thereby saved the whole army. When James showed an intention of establishing the catholic religion in Britain, lord Churchill, notwithstanding the great obligations he owed him, thought it his duty to abandon the royal cause; but even then did not leave him without acquitting him by letter with the reason of his doing. Lord Churchill was graciously received by the prince of Orange; and was by him employed first to re-assemble the troop of guards at London, and afterwards to reduce some lately raised regiments, and to new-model the army; for which purpose he was invested with the rank and title of lieutenant-general. In 1689, he was sworn one of the privy council, and one of the gentlemen of the king's bed-chamber; and on the 9th of April following, was raised to the dignity of earl of Marlborough in the county of Wilts. He assisted at the coronation of their majesties; and was soon after made commander in chief of the English forces sent over to Holland; and here he first laid the foundation of that fame which was afterwards spread over all Europe. In 1690, he was made general of the forces sent to Ireland: where he made the strong garrisons of Cork and Kinsale prisoners of war. The year following, king William showed the good opinion he had of his conduct, by sending him to Flanders to put all things in readines, and to draw the army together against his arrival. In 1692, he was dismissed from all his employments: and, not long after, was with some other peers committed to the tower on an accusation of high treason; which, however, was afterwards found to be a false and malicious report, the authors of which were punished. Marlborough was soon restored to favour, and in 1698 was appointed governor to the earl of Gloucester; with this extraordinary compliment from king William, Churchill.

"My lord, make him but what you are, and my nephew will be all I wish to see him." The same day he was again sworn one of the privy council; and in July following was declared one of the lord justices of England for the admistration of the government, in which great trust he was three times successively in the king's absence. In 1701 he was appointed general of the foot, commander in chief of the English forces, and ambassador extraordinary and plenipotentiary to Holland. After several conferences about a war, he put himself at the head of the army, where all the other generals had orders to obey him. His exploits in the field have been taken notice of under the article BRITAIN, ii. 349-370: we shall therefore only take notice in this place, of the rewards and honours conferred upon him for these exploits. After this first campaign he was created marquis of Blandford and duke of Marlborough, with a pension of £5,000 per annum of the post-office, to devolve for ever upon those enjoying the title of Duke of Marlborough. In 1703, he met Charles III. late emperor, going to Spain, who presented him with a sword set with diamonds. In 1704, having forced the enemy's lines at Schellenberg, he received a letter of thanks from the emperor Leopold, written with his own hand; an honour seldom done to any but sovereign princes. After the battle of Blenheim, he received congratulatory letters from most of the potentates in Europe, particularly from the States General, and from the emperor, who desired him to accept of the dignity of a prince of the empire, which with the queen's leave was conferred upon him by the title of Prince of Mildenhain in the province of Swabia. After the campaign was ended, he visited the court of Prussia, where he laid such schemes as suspended the disputes with the Dutch about king William's estate; which wise conduct caused the whole confederacy to acknowledge that he had done the greatest service possible to the common cause. Upon his return to England, the queen, to perpetuate his memory, granted the interest of the crown in the honour and manor of Woodstock and hundred of Wotton to him and his heirs for ever. In 1705 he made a tour to Vienna, upon an invitation of the emperor Joseph; who highly carreified him, and made him a grant of the lordship of Mildenhain. After the campaign of 1708, theSpeaker of the house of commons was sent to Brabant on purpose to compliment him; and on his return to England he was again complimented in the house of lords by lord chancellor Cowper. All his services, however, and all the honours conferred upon him, were not sufficient to preserve him from being disgraced. After the change of the ministry in 1710, his interest daily declined; and in 1712, on the first day of the new year, he was removed from all his places. Finding all arts used to render him obnoxious in his native country, he visited his principality of Mildenhain, and several towns in Germany; after which he returned to England, and arrived there on the day of the queen's death. After being welcomed by the nobility and foreign ministers,
Churchill, he attended on king George I. in his public entry through London, who appointed him captain-general, colonel of the first regiment of foot-guards, one of the commissioners for the government of Chelsea hospital, and master-general of the ordnance. Some years before his death, he retired from public business. He died at Windsor-lodge in 1722, aged 73, leaving behind him a very numerous posterity, allied to the noblest and greatest families in the three kingdoms. Upon his demise all parties united in doing honour or rather justice to his merit, and his corpse was interred the 9th of August following, with all the solemnity due to a person who had deserved so highly of his country, in Westminster-abbey. The noble pile near Woodstock, which bears the name of Blenheim-houe, may be justly ascribed to his monument; but without pretending to the gift of prophecy, one may venture to foretell, that his glory will long survive that structure; and that so long as British histories remain, or indeed the histories of Europe, his memory will live and be the boast of Britain, which by his labours was raised to be the first of nations, as during the age in which he lived he was deservedly esteemed the first of men. If he had foible, as these are inseparable from human nature, they were so hidden by the glare of his virtues as to be scarcely perceived or were willingly forgotten. A certain parasite, who thought to please Lord Bolingbroke by ridiculing the avarice of the Duke, was flipt short by his Lordship; who said, "He was so very great a man, that I forget he had that vice."

Out of a variety of anecdotes and testimonies concerning this illustrious personage, collected in the new edition of the *Biographia Britannica*, the following selection may serve to illustrate more particularly his disposition and manners.

One of the first things which he did, when very young, was to purchase a box to put his money in; an indication thus of the economical, not to say avaricious, temper that accompanied him through life. Dr Joseph Warton relates, that, on the evening of an important battle, the Duke was heard to chide his servant for having been so extravagant as to light four candles in his tent when Prince Eugene came to confer with him. Mr Tyers, on the other hand, mentioned a circumstance which, if well founded, redounds to his grace's generosity, though in a different respect it is much to his discredit: It is, that during the rebellion 1715 he lent L 10,000 to the earl of Mar. We consider the story as only a traditional report, which has not in itself any great degree of probability; and therefore we are by no means convinced of its truth. The late Mr Richardson junior, the painter, hath recorded a pleasing instance of the Duke's calmness of disposition; for which, indeed, he was always remarkable. "The Duke of Marlborough (says the writer), riding out once with Commissary Marriot, near the commissary's house in the country, it began to rain, and the Duke called for his cloak; Marriot having his put on by his servant immediately. The Duke's servant not bringing the cloak, he called for it again; but the man was still puzzling about the straps and buckles. At last, it raining now very hard, the Duke called again, and asked him, 'What he was about that he did not bring his cloak?' You must fly (grumbles the fellow), if it rains cats and dogs, till I can get at it.' The Duke only turned to Marriot, and said, 'I would not be of that fellow's temper.'"

The Duke of Marlborough (adds Mr Richardson) did by nature and constitution, what Seneca judged by philosophy ought to be done. *Quid ef quare ego servus biarii, nisi profugius, et contempla eum in turbis, fugitivus et cepitque caput?*

Dr Swift, in one of his letters to Stella, relates the following particulars concerning the Duke of Marlborough. "I was early this morning with secretary St John, and gave him a memorial to get the queen's letter for the first-fruits, who has promised to do it in a very few days. He told me 'he had been with the Duke of Marlborough, who was lamenting his former wrong steps in joining with the Whigs, and said he was worn out with age, fatigue, and misfortunes.' I fear it pitted me; and I really think they will not do well in too much mortifying that man, although indeed it is his own fault. He is covetous as hell, and ambitious as the prince of it: he would have been the general for life, and has broken all endeavours for peace; to keep his debts, and get money. He told the Queen 'he was neither covetous nor ambitious.' She said, 'if the could have conveniently turned about, she should have laughed, and could hardly bear it in his face.' He fell in with all the abominable measures of the late ministry, because they gratified him for their own designs. Yet he has been a successful general, and I hope he will continue his command."

Various characters have been drawn of the Duke of Marlborough; most of which we shall omit, as either already sufficiently known, or as not meriting particular notice. That which is given of him by Dr Swift, in his "History of the four last years of the queen," has all the malignity and meanness of a party pamphlet. It is even so foolish as to intimate, that the Duke's military accomplishments were problematical, and that he was destitute of personal courage. Mr Macpherson's character of his grace is very elaborately composed, and displays no small degree of ability and penetration; though it is not, perhaps, entirely free from prejudice. The historian considers it as a taunt, that lord Churchill, at the time of the Revolution, had a design of placing his unfortunate master king James II. a prisoner in the hands of his rival the prince of Orange. But this story must be regarded as wholly unworthy of credit. It is founded upon suggestions and informations to groundless, and even ridiculous, that it cannot deliver a formal refutation. On the other hand, Mr Macpherson has done justice to the Duke of Marlborough's prosecution of the war in Flanders, and hath shown that he conducted it upon the principles of sound wisdom and good policy.

There are two testimonies to the honour of the Duke's memory, by two celebrated noble writers, which cannot be passed over. One is by lord Bolingbroke, in his letters on the Study and Use of History, speaking of the confirmation roused among the allies of the grand confederacy by the death of King William, and of the joy which that event gave to the French, his lordship observes, that 'a short time showed how vain the fears of some and the hopes of others were. By his death, the Duke of Marlborough was raised to the head of the army, and indeed of the
Churchill. confederacy: where he, as a new, a private man, a subject, acquired, by merit and by management, a more decided influence than high birth, confirmed authority, and even the crown of Great Britain, had, won to King William. Not only all the parts of that vast machine, the grand alliance, were kept more in repair, and even the crown of his lordship, in his zeal to extol the duke of Marlborough's external accomplishments, either forgets or deprecates the far greater talents of which he was possessed. There is an observation upon the subject in the British Biography, with which we entirely concur. "That the duke of Marlborough (says the writer) was eminently distinguished by the gracefulness of his manners, cannot be questioned: but the earl of Chesterfield appears to have attributed too much to their influence, when he ascribes—the better half of the duke of Marlborough's greatness and riches to those graces. That the uncommon gracefulness of his manner facilitated his advancement, and contributed to the success of his negotiations, may readily be admitted; but rarely it must have been to much higher qualities that he owed the esteem of King William and of Prince Eugene. He was the most agreeable, and his many victories and conquests. It was not by a polite exterior that he obtained his laurels at Schei- lenberg, at Oudenarde, at Ramillies, and at Blenheim.

How much the duke of Marlborough has been celebrated by our poets, is well known by Addison's "Campaign," and Philips "Blenheim." Mr Addison, in his Rosamond, has properly assumed another and voluntary occasion of paying a fine compliment to his grace's military exploits, and the glory by which they would be followed. Upon the duke's removal from his places, an ode was inscribed to him by Mr Somerville, animated with all the zeal of whiggish enthusiasm, and containing some passages that are truly poetical. Another ode, not much inferior in spirit, was addressed to his grace, on occasion of his embarking for Ostend in the year 1712.

The duke of Marlborough's Scots title of Baron Eynouth, being to heirs-male, died with himself; but his English title going to his daughters and their heirs-male went into the Spencer family, who retain their own surname of Spencer.

Churchill (Charles), a celebrated faultie, the son of Mr Charles Churchill curate and lecturer of St John's, Westminster, was educated at Westminster school, and received some applause for his abilities from his tutors in that famous seminary. His capacity, however, was greater than his application, so that he acquired the character of a boy that could do good if he would. As the slightest accounts of persons so noted are agreeable, it may not be amiss to observe, that having one day got an exercize to make, and from idleness or inattention having failed to bring it to the time appointed, his master thought proper to chastise him with some severity; and even reproached his stupidity; what the fear of stripes could not effect, the fear of shame soon produced, and he brought his exercize the next day, finished in such a manner, that he received the public thanks of all the masters. Still, however, his progress in the learned languages was a slow; nor is it to be wondered at, if we consider how difficult it was for a strong imagination, such as he was possessed of, to conform and walk tamely forward in the trammels of a school education: minds like...
His next performance was his Apology to the Critical Reviewers. This work is not without its peculiar merit; and as it was written against a set of critics whom the world was willing enough to blame, the public read it with their usual indulgence. In this performance he showed a particular happiness of throwing his thoughts, if we may so express it, into poetical paragraphs; so that the sentence swells to the break or conclusion, as we find in prose.

But while his writings amused the town, his actions disgusted it. He now quitted his wife, with whom he had cohabited many years; and resigning his gown and all clerical functions, commenced a complete man of the town, got drunk, frequented stews; and, giddy with false praise, thought his talents a sufficient atonement for all his follies. In some measure to palliate the absurdities of his conduct, he now undertook a poem called Night, written upon a general subject indeed, but upon false principles; namely, that whatever our follies are, we should never attempt to conceal them. This, and Mr Churchill's other poems, being shown to Mr Johnfon, and his opinion being asked, he allowed them but little merit; which being told to the author, he resolved to requite this private opinion with a public one. In his next poem, therefore, of the Ghost, he has drawn this gentleman under the character of Pomposo; and those who disliked Mr Johnfon allowed it to have merit. Mr Johnfon's only reply to Churchill's abuse was, "that he thought him a shallow fellow in the beginning; and could say nothing worse of him still."

The poems of Night and the Ghost had not the rapid sale the author expected; but his Prophecy of Famine soon made ample amends for the late paroxysm in his fame. In this piece, written in the spirit of the famous North Briton, he exerted his virulent pen against the whole Scotch nation; adopting the prejudices of the mob, and dignifying scurrility by the aid of a poetic imagination. It had a rapid and extensive sale, as the character of Mr Wilkes, who had been impeached by Mr Wilkes; who said, before his modification, that he was sure it must take, as it was at once personal, poetical, and political. After its appearance, it was even ascribed by his admirers, that Mr Churchill was a better Poet than Pope. This exaggerated adulation, as it had before corrupted his morals, began now to impair his mind; several succeeding pieces were published, which, being written without effort, are read without pleasure. His Gotham, Independence, The Times seem merely to have been written by a man who desired to avail himself of the avidity of the public curiosity in his favour, and are rather aimed at the pockets than the hearts of his readers. Mr Churchill died in 1764, of a military fever, which he had gone on a visit to Mr Wilkes. After his death his poems were collected and printed together in two volumes 8vo.

CHURCHING OF WOMEN AFTER CHILD-BIRTH, took its rise from the Jewish rise of purification. In the Greek church it was limited to the fortieth day after delivery; but in the western parts of Europe no certain time is observed. There is an office in the liturgy for this purpose.
CHURCHYARD, a piece of ground adjoining to a church, set apart for interment or burial of the dead. — In the church of Rome they are blessed or consecrated with great solemnity. If a churchyard, which has been thus consecrated, shall afterwards be polluted by any indecent action, or profaned by the burial of an infidel, an heretic, an excommunicated person, it must be re consecrated, and the ceremony of the reconciliation is performed with the same solemnity as that of the blessing or consecration.

CHURCHYARD (Thomas), a poet who flourished in the reigns of Henry VIII. Edward VI. Queen Mary and Queen Elizabeth, was born at Shrewsbury; and inherited a fortune, which he soon exhausted in a frivolous attendance on the court, by which he only gained the favour of being retained a domestick, in the family of Lord Surrey; when, by his lordship's encouragement, he commenced poet. Upon his patron's death, he bestowed himself to arms; was in many engagements; was frequently wounded, and was twice made prisoner. He published 12 pieces, which he afterwards printed together in one volume, under the title of Churchyard's Chips; and also the tragedy of Thomas Monbray duke of Norfolk. He died in 1570.

CHURLE, CEBRE, or Carter, in the Saxons times, signified a tenant at will, who held the thanes on condition of rent and service. They were of two sorts: one rented the estate like our farmers; the other tilled and maintained the demesnes, and were called ploughmen. See CEBRE.

CHURNING, in country affairs, the operation of making butter by agitating milk in a well-known vessel called a churn. For accelerating this operation, a correspondent in the Bath Society Papers recommends a little distilled vinegar to be poured into the churn; and the butter will be produced in an hour afterwards. He acknowledges, however, that his experiments have not as yet ascertained the exact quantity of the acid which is necessary to the proper effect, nor the precise time of its being mixed with the cream. But he apprehends a tablespoonful or two to a gallon of cream will be sufficient; nor would he recommend it to be applied till the cream has undergone some considerable agitation. His first trial was after the churning had been going forward half a day: whether he observed the same rule afterwards, he does not say; but all his trials proved successful, the butter being uniformly obtained in about an hour after the mixture.

CHUS, or Chief (Bible). It is a tradition of an ancient standing, that the Chus of the Scriptures denotes Ethiopia, and Chief an Ethiopian: the Septuagint and Vulgate constantly translate it so; and in this they are followed by most interpreters, and by Josephus and Jerome. And yet what Bochart urges to the contrary is of no considerable weight, from Ezekiel xxix. 10, in which the two opposite extremities of Egypt are designated: and therefore Chus, which is opposite to Syene, must be Arabia: but this is more strongly pointed out by Xenophon, by whom Ethiopia is said to be the fourth boundary of Cyrus's empire; and Herodotus distinctly gives the Ethiopians of Asia and Africa, conjoining the former with the Arabs.

CHYLE, in the animal economy, a milky fluid secreted from the aliment by means of digestion. See Anatomy, p. 734, 735.

CHYLIFICATION, the formation of the chyle, or the act whereby the food is changed into chyle. The chyle has by some authors been thought to have a great resemblance in its nature and chemical analysis to milk. The subject, however, hath not yet been but little inquired into. See the article MILK.

CHYME, or CHYMUS, in the common signification of the word, denotes every kind of humour which is intragated by concoccion; under which notion it comprehends all the humours fit or unfit for preserving and nourishing the body, whether good or bad. It frequently imports the finest part of the chyle, when separated from the faeces, and contained in the largest and thoracic duct.

CHYMISTRY. See CHEMISTRY.

CHYMIOLOGI, an appellation given to such naturalists as have employed their time in investigating the properties of plants from their taste and smell.

CHYMOSIS, in medicine, the act of making or preparing chyme. The word comes from Gr. χυμός; from χυμος, fume; χυμη, "I melt." Chymos, according to HOCART, is the foundation of the concoctions made in the body; being a repeated preparation of the most impure and gross parts of the chyle, which being rejected by the ladeals, is imbied by the mederas, and thence carried to the liver, to be there elaborated, purified, and foemolized aferile. It is of this, according to Rogers, that the animal spirits are formed.

CHYMOSIS is also a distillation of the eye-lids, arising from an inflammation; also an inflammation of the tunica cornea in the eye.

CHYTLE, in antiquity, a liquor made of wine and oil, and sometimes used in divination.

CHYTRI, among the Athenians, a festival in honour of Bacchus and Mercury, kept on the 13th of the month Anthesterion.

CHYTRIUM (anc. geog.) a place in Jonia, in which formerly stood Clazomenae; the Clazomenians through fear of the Persians, removing from the continent to an adjacent island (Paunias). Alexander reduced the island, by a mole or causeway, to a peninsula.

CHYTRUS (anc. geog.), an inland town of Cyprus, to the north of Cition: famous for its excellent honey.

CIBALAE, or CIBALIS, (anc. geog.), a town of Pannonia Inferior, on an eminence, near the lake Hulka, to the north-west of Sirmium; the country of the emperor Gratian, where he was brought up to ropemaking; a place rendered famous for the surprisal and defeat of Licinius by Confantine.

CIBBER (Colley), a celebrated comedian, dramatic writer, and poet laureat to the king, was born at London in 1671. His father Cains Gabriel Cibber, was a native of Holstein, and a skilful statury, who executed the baso relieve on the pedestal of the monument, and the two admired figures of lunatices over the piers of the gate to Bethlehem Hospital in Moorfields. Colley, who derived his Christian name from the surname of his mother's family, was intended for the
the church, but betook himself to the flags, for which he conceived an early inclination; and he was some time before he acquired any degree of notice, or even a competent falery. His first essay in writing, was the comedy of Love's Left Shift, acted in 1695, which met with success; as did his own performance of the character of the fop in it. From that time, as he says himself, "My muse and my spouse were so equally prolific, that the one was seldom the mother of a child, but in the same year the other made the father of a play. I think we had a dozen of each fort between us; of both which kinds some died in their infancy, and near an equal number of each were alive when we quitted the theatre." The Careless Husband, acted in 1704, met with great applause, and is reckoned his best play; but none was of more importance to him than the New-venur, acted in 1718, and leveled against the Jacobites. This laid the foundation of the misunderstanding between him and Mr Pope, raised him to be the hero of the Dunciad, and made him poet laureat in 1730. He then quitted the stage, except a few occasional performances; and died in 1757. Cibber neither succeeded in acting nor in writing tragedy; and his odes were not thought to partake of the genius or spirit he showed in his comedies.

His son Theophilus, also a comic actor after him, was born during a great storm in 1703; and after passing a life of extravagance, diætes, and perplexity, perished in another storm in 1756, in the passage between Dublin and England. Theophilus married the sister of Thomas Angustine Arne, the famous musical composer, who became a celebrated tragic actor, and whose honour was sacrificed to her husband's extravagance.

CIBDELOPLACIA, in natural history; a genus of saps debased by a very large admixture of earth; they are opaque, formed of thin crusts, covering vegetables and other bodies, by way of inclusions.

Of this genus we have the following species: 1. A greyish-white one, with a rough surface. 2. A whitish brown one; both these are friable. 3. A hard, pale-brown kind, which is the oëcoca of the heaps. 4. The whitish grey kind, with a smooth surface; this is the unicorn's foot, and the ceratites of authors.

CIBDELOSTRACIA, in natural history, terræ saps, duplicate of all brightness and transparency, formed into thin plates, and usually found coating over the sides of fissures, and other cavities of foses, with congersies of them of great extent, and of plain or botryoidy surfaces.

Of these there are usually reckoned seven kinds: the first is the hard, brownish-white cibdelostracium, found in Germany; the second is the hard, whitish cibdelostracium, with thin crusts, and a smoother surface, found also in the Harts-forests in Germany; the third is the hard, pale-brown cibdelostracium, with numerous very thin crusts, found in helleboran caverns in many parts of England as well as Germany; the fourth is the white, light, and friable cibdelostracium, found also in Germany, but very rarely in any part of England; the fifth is the light, hard, pale-brown cibdelostracium, with a smooth surface, found in almost all parts of the world; the sixth is the whitish, friable crustaceous cibdelostracium, with a rough surface, frequent in Germany and England; and the seventh is the brownish-white friable cibdelostracium, with a dusty surface, found in several parts of Ireland, as well as Germany.

CIBORIA, in antiquity, the large hulse of Egyptian beans, which are said to have been so large as to serve for drinking cups; whence they had their name ciborium, signifying a cup, in the Egyptian language.

CIBORIUM, in ecclesiastical writers, the covering for the altar. This covering is supported by four high columns, and forms a kind of tent for the eucharist, in the Romish churches. Some authors call it turris gellatoria and others pyxis; but the pyxis is properly the box in which the eucharist is preserved.

CIBUS FERIALIS, in antiquity, an entertainment peculiar to a funeral; for which purpose, beans, parly, lettuce, bread, eggs, lentils, and salts were in use.

CICADA, the Frog-hopper or Flea-locust; Plate in zoology, a genus of insects belonging to the order CXLIX. of hemiptera. The beak is injected; the antennæ are fetteous; the four wings are membranaceous and deflected; and the feet, in most of the species, are of the jumping kind. The species are fifty-one. The larvae of several of this genus evacuate great quantities of a frothy matter upon the branches and leaves of plants, in the midst of which they constantly refuse, probably for shelter against the search of other animals, to which it would become a prey. Nature has afforded this kind of defence to insects whose naked and soft bodies might otherwise very easily be injured; perhaps also the musculature of this foam may serve to screen it from the fultry beams of the sun. On removing the foam, you discover the larva concealed underneath; but it does not long remain uncovered. It soon emits fresh foam, that hides it from the eye of observation. It is in the midst of this foamy substance the larva goes through its metamorphosis into a chrysalis and perfect insect. Other larvæ, whose bodies are not so soft, run over plants without any manner of defence, and escape from insects that might hurt them, by the nimbleness of their running, but especially of their leaping.

The chrysalids, and all the larvae that produce them, differ little from each other, only that the former have the middiments of wings, a kind of knob at the place where the wings will afterwards be in the perfect insect. As to other respects, the chrysalids walk, leap, and run over plants and trees; as do the larva and the frog hopper, which they are to produce. At length they throw off their teguments of chrysalids, slip their last skin, and then the insect appears in its utmost state of perfection. The male alone is then endowed with the faculty of singing, which it exercises not with its throat, but with an organ situated under the abdomen. Behind the legs of the male are observed two valves, which, raised up, divulge several cavities, separated by various membranes. The middle contains a feally triangle. Two vigorous muscles give motion to another membrane, which alternately becomes conical and convex. The air agitated by this membrane, is modified within the other cavities; and by the help of this sonorous instrument, he amorously solicits his female. By pulling the muscles of a frog-hopper lately dead, it may be made to sing. This insect begins its song early in the morning, and continues it during the heat of the noon tide sun. Its lively and animated music is to the country
**Cicada**

Cicada. *Cicada pectinicornis*, or Locust of North America, ranks with the cricket and grass-hopper, as one genus of insects belonging to the order of hemiptera, and has most of the distinguishing characteristics of the grass-hopper, though its legs do not appear formed for leaping, as it is observed the insect seldom removes without raising its wings. The characters of the Cicada, or American locust, are these: The beak is inflected; the antennae are fuscous; the four wings are membranaceous, and delicately, and have much the appearance of the wings of some of the fly kind; the thorax is compressed and angulated, and the feet, in most of the species, are of the jumping kind. A gentleman who observed it in Pennsylvania in 1782, gives the following account.

"This remarkable insect, though but trivial attention has been given to its history, appears as an extraordinary phenomenon in the works of creation. Its periodical visits—its long absences—its number being from the earth, where they have, perhaps, undergone various transformations, whilst they have lain, entombed, for the space of 15, 16, or even 17 years, (for they are not always regular in their visits) certainly deserve some enquiry.

"We know not the progress of the American locust, through its several changes during its long confinement in the earth. I have no doubt but it often alters its appearance, and though these changes remain, as yet, amongst the arena of nature, yet some interesting observations may result from the pursuit of the enquiry, as far as their last appearance, which was in the year 1782, will admit of.

"Towards the latter end of May, under such trees as had been planted, previous to their former visit, the ground was perforated; so as, in some degree to resemble a honey-comb; and from these perforations, issued an army of these insects, which, if they had been ended with the voracionsness of the locusts of the east, must have spread devastation and terror throughout the country they fixed upon for a visit. But happily the cicada or locust, in this state, is not more injurious than the spurious summer grass-hopper.

"The appearance of the locust, when first escaping from its earthly manse, is a large amber-coloured grub-worm, about one inch and a half in length, and about an inch and half in circumference. The feet are somewhat flattened, as those of the grasshopper, and considerably shorter;—the insect seldom leaping, as has been observed,—in the outer covering, or grub-case, if the term may be admitted, near the back of the neck, begins an opening, which continues down the body, nearly half the length of the insect; through this opening the locust protrudes itself, and appears, at first, a white coloured moth, nearly resembling a filk-worm, in its moth state, though much larger. The wings in this tender state of the insect are wonderfully folded in close rolls near their base, so exquisitely compact, that it required several careful observations, to comprehend the possibility of the wings being formed with the insect, as it really appeared an almost instantaneous creation, when they were expanded, which was performed by the locust shaking itself with a considerable force.

"When the insect relieves itself from the outer covering or grub-worm case, the wings are of the hue of rich milk. In this state, the filaments, which add strength to them, are of the same white colour, and instead of the transparency which they afterwards obtain, they are now remarkably opaque; but as soon as the moisture dries from off the wings of the insect, these filaments become more firm, and have a dark brown colour which approaches a black, as the locust becomes stronger.

"The time when they issue from the ground, is about an hour or two after fun-set; soon after which they begin their exertions to free themselves from the grub-case, which the stronger ones effect in an hour or two. They remain on the branches of the trees, which they have attained, before this last metamorphosis until morning, when they are of an high amber colour; have acquired their strength, and are able to contend with some of their enemies. The weaker ones, and those who do not leave the earth till morning, do not so easily effect their transformation, and often prove a delicious prey to the larger and even the smaller birds.

"White in the grub-worm state, there is a film in the back of the skin, sufficiently large to admit the locust to pass therefrom, which, notwithstanding, is not done without great exertions. At the time of their leaving the grub-case, for it cannot be, with propriety, termed a chrysalis, life and motion is strong in the insect, even when it is about affuming its new form. And when we consider that every particular limb, every part of the body however delicately and tenderly formed,—and really some of them, at this time, are almost incomprehensibly thin and tender—is included in a separate case, and that these tender parts must be necessarily extricated from their sheaths, before the insect can enjoy uninterrupted freedom, we certainly feel our astonishment increase, in observing, that those so elegantly formed members escape uninjured from even the extremities of their covering. When this escape is effected, the insect leaves the place where its covering is, and rests at a very short distance from it, where it remains until the moisture is evaporated from its body. The wings, as well as the insects, when first protruded from the grub-case, are very moist and tender; though by degrees they dry, and become more firm and rigid. But should any accident prevent the cicada from a free expansion of its wings, for a considerable time after the grub-case is forsaken, the poor insect is doomed to remain either in a state of total or partial debility—all that should it be too weak as to be unable to expand its wings thoroughly, while the moisture and pliancy remain, as soon as they become dry and rigid, they are fixed in that particular or total want of expansion; and in this helpless state, the cicada is a certain prey even to the long-appalled indolent emmer.
 Cicada.

"The locust-grub, rising from the ground, is nearly the colour of the locust when it has attained its full perfection, though not altogether as dark; its strength is very great, nearly equaling that of the scarabaeous car
defly, without a leader, as is usual with the eastern locusts) were they to feed on plants the damage must certainly be observable: and as they live in the moth state twelve or thirteen days, it is probable they have a portion of the dew of heaven for their sustenance. Then they dry up as the silkworm moth,—the male becoming superannuated two or three days before the female.

"Having pursued the locust thro' its several moth states, the numerous offspring it has deposited in the slender twigs of trees, have filled some claim to an investigation.—The eggs are of a cylindrical form, rounded at the ends, and are of such a consistence, that they require a hard pressure between the fingers to crush them. The substance within, as in most other small eggs, is a white, transparent, and viscous fluid. In about the space of fourteen days, from the time of their first being left by the parent, the egg produces a whitish insect, somewhat larger than the silk-worm, when fresh hatched, which leaves the branch where the nest was, and, dropping on the ground, either enters into the hole through which the old locust filled, or turns the earth aside afresh, and entombs itself there, to undergo the metamorphosis of its ancestors.

"In digging wells, cellars, &c, in America, insects of very different appearances have been discovered: some twenty feet deep, which have been supposed to be of this species—others have been discovered nearer the surface, of which no doubt remains but that they are the grub of the locust—and early in the spring, previous to their assuming the moth state, the plough
thare often furnishes the blackbird, which follows the ploughman, with a rich repast of them; for which, by his clamours and flutterings, he endeavours to express his obligations. Varieties of this genus appear annually, they are in general much larger than the cicada septendecim, and of a greyish colour: the dark brown or amber colour which the others have, appearing in these mottled with a dirty white."

CICATRICULA, among natural historians, denotes a small whitish speck in the yolk of an egg, supposed to be the first rudiments of the future chick.

CICATRIX, in surgery, a little seam or elevation of callous flesh rising on the skin, and remaining there after the healing of a wound or ulcer. It is commonly called a fear.

CICATRIZANTS, in pharmacy, medicines which assist nature to form a cicatrix: Such are Armenian be, powder of turfy, &c.

Cicatrizants are otherwise called scabretries, sputules, incurvatarum, agglutinans, &c.

CICCA, in botany, a genus of the terrandria order, belonging to the monoeia class of plants. The male calyx is teraphyllous; there is no corolla: the female calyx tripphyllous; no corolla; four stiles; the capsule quadrilocules, or four berried.

CICELY,
CICELY, in botany, the English name of a species of chlorophyllum. See CHLOREPHYLLUM.

Cicer, or Chick- pea, in botany: A genus of the dervandria order, belonging to the diadelphia class of plants; and in the natural method ranking under the Papilionaceae, or 32d order. The calyx is quinqupartite, as long as the corolla, with its four uppermost segments incumbent on the vexillum: the legumen is rhomboidal, turgid, and dispermous. There is but one species, which produces pea-shaped like the common ones, but much smaller. They are much cultivated in Spain, where they are natives, being one of the ingredients in their oils; as also in France; but are rarely known in Britain.
